NLM Citation: Kolb H, Fernandez E, Nelson R, editors. Webvision: The Organization of the Retina and Visual System [Internet]. Salt Lake City (UT): University of Utah Health Sciences Center; 1995-.

Understanding the organization of the vertebrate retina has been the goal of many talented visual scientists during the past 100 years. With Cajal's (1892) anatomic descriptions of the cell types that constitute the retina in a number of vertebrate species, and with an early understanding of the role of visual purple in photochemistry in combination with psychophysical studies of adaptation and color vision, we had in the sixties the rudiments of an understanding of how the retina might be organized and functioning.

To go further, though, we were beginning to need detailed information of neural circuits that underlie these functions. It was the advent of electron microscopy, microelectrode recording techniques, and pharmacology that then allowed us an era of very rapid advancement. The purpose of this Electronic Tutorial is to summarize these recent advances and to describe our present understanding, based primarily on anatomic investigations, of the Neural Organization of the Mammalian Retina. As time goes on we have been inviting other authors to write chapters on their speciality concerning the retina or other visual pathways. A great addition has been a section on Psychophysics of Vision which we hope will be of general information to all interested in learning the basics of visual perception.

About the Editors

Dr. Helga Kolb

Dr. Helga Kolb was born and educated in England receiving B.Sc., M.Sc. and Ph.D. degrees from the University of Bristol. Her first position in eye research was at the Institute of Ophthalmology, Judd Street, London. In 1966, Dr. Kolb emigrated to the USA. She took up positions in eye research in the Wilmer Institute, Johns Hopkins University, The National Eye Institute, Bethesda and the National Institute of Neurological Diseases and Stroke, Bethesda. Eventually Helga settled with her husband Richard Normann in the beautiful mountain west at the University of Utah, Salt Lake City, Utah. She is presently Professor Emeritus of Ophthalmology and Visual Science at the John Moran Eye Center, University of Utah. Her research interests include light and electron microscopy and immunostaining of the retina with emphasis on retinal neurocircuitry. Many of her important contributions to retinal research have been with her long time collaborators, Dr. Ralph Nelson and Dr. Nicolas Cuenca. In 1993 she was honored with the Proctor Medal award by the Association for Research in Vision and Ophthalmology (ARVO), in 2000 with the Von Sallmann award and in 2002 with the "Margaret Pittman Lectureship award" from the National Institutes of Health. In recognition of her contribution to vision research over the years, in 2011, she and her husband, Dick Normann, were awarded the Doctor Honoris Causa degrees from Miguel Hernandez Universidad de Elche, Spain.

Dr. Helga Kolb: helga.kolb@hsc.utah.edu

Dr. Eduardo Fernandez

Dr. Eduardo Fernandez was born in Elda (Spain) in 1962. Received the M.D. degree from the University of Alicante (Spain) in 1986 and the Ph. D. degree in Neurosciences with honors from the University of Alicante in 1990. His collaboration with Dr. Helga Kolb, began with a stay from 1990 to 1991 under a postdoctoral fellowship of the Spanish Government (FPI program). During that time he worked on the synaptic organization of the turtle retina and on the neural transmitter modulation of 2nd messenger systems in retinal cells. He is currently Associate Professor at the University Miguel Hernandez (Spain) and Director of the Foundations of Vision and Artificial Vision Division of the Institute of Bioengineering of the University Miguel Hernandez (Alicante, Spain). In the last years he has been using histological as well as electrophysiological techniques to understand how mammalian retinal cells and the circuitry within the retina can manage and code visual information. He is also actively working on the development of a visual neuroprosthesis for the profoundly blind.

Dr. Eduardo Fernandez: e.fernandez@umh.es

Dr. Ralph Nelson

Dr. Ralph Nelson was born in Hartford Connecticut. He received his B.A. in Biophysics from Amherst College in 1967 and his Ph.D. in Biophysics from Johns Hopkins University in 1972. He currently heads the Neural Circuitry Unit at The National Institutes of Neurological Disorders and Stroke, National Institutes of Health, Bethesda Maryland. While at Johns Hopkins, he studied conductance mechanisms responsible for light responses of retinal bipolar cells and in his postdoctoral studies at the National Institutes of Health he pioneered the use of intracellular recording and dye-marking of retinal neurons in the mammalian retina. Together with

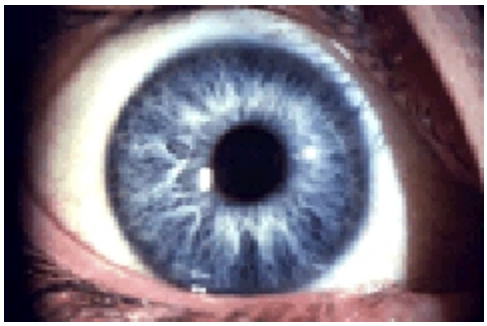
Helga Kolb he has made major contributions towards the understanding of ON and OFF pathways and the neural processing of rod and cone signals in the mammalian retina. Dr. Nelson's laboratory is currently investigating the relationship of receptors on retinal neurons to processing of visual information in retinal neural circuits, and has begun to explore zebrafish as a model system for such studies.

Dr. Ralph Nelson: NelsonR@ninds.nih.gov

Introduction

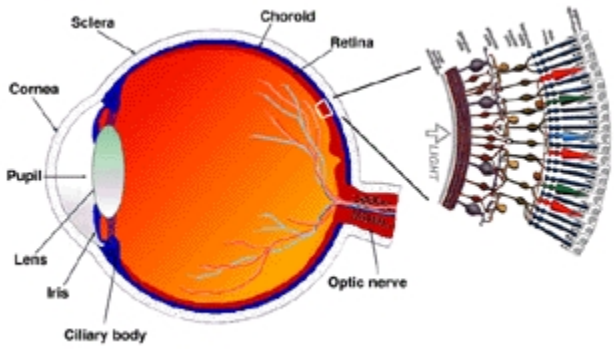
Our eyes are marvelous sense organs that allow us to appreciate all the beauty of the world we live in, to read and gain knowledge, and to communicate our thoughts and desires to each other through visual expression and visual arts.

Vision is the most fundamental of our senses and it is perhaps the greatest tragedy of all when blindness robs us of this modality. Although all parts of the eye are important for perceiving a good image, the most vital layer for vision is the retina. The retina is essentially a piece of brain tissue that gets direct stimulation from the outside world's lights and images.



Understanding the organization of the vertebrate retina has been and is still the goal of many talented visual scientists over the years. Ramon y Cajal in the 19th century already presented the first comprehensive anatomic descriptions of the neural cell types that constitute the retina in a number of vertebrate species. There then followed an understanding of the role of visual purple in photochemistry and important psychophysical studies on image formation, light and dark adaptation and color vision.

To go further, though, we were beginning to need detailed information of neural circuits that underlie these functions. It was the advent of electron microscopy, microelectrode recording techniques, immunostaining and pharmacology in the 20th century that then allowed us a very rapid advancement of knowledge on the organization of the retina and visual system. The purpose of this Electronic Tutorial is to summarize our present understanding of the field, based primarily on anatomical and physiological investigations. As time goes on we have been inviting other authors to write chapters on their speciality concerning the retina and higher visual pathways. We also attempt to add clinical research findings in cell biology and genetics of retinal diseases. A great addition has been a section on **Psychophysics of Vision** which we hope will be of general information to all interested in learning the basics of visual perception.



We have tried to present material at the cutting edge of the present knowledge, but in a simple way that is accessible to both students, professional and non-expert people.

If you have questions, suggestions for improvements, or other useful comments, do not hesitate to contact us at the addresses listed in About the Editors.

Foundations

Gross Anatomy of the Eye

Helga Kolb

Created: May 1, 2005; Updated: May 1, 2007.

Overview

When looking into someone's eyes, we can easily see several structures (Fig. 1):

- A black-looking aperture, the **pupil**, that allows light to enter the eye (it appears dark because of the absorbing pigments in the retina).
- A colored circular muscle, the **iris**, which is beautifully pigmented and gives us our eye color (the central aperture of the iris is the pupil). This circular muscle controls the size of the pupil so that more or less light, depending on conditions, is allowed to enter the eye. Eye color, or more correctly, iris color, is due to variable amounts of eumelanin (brown/black melanins) and pheomelanin (red/yellow melanins) produced by melanocytes. More eumelanin is found in brown-eyed people, and more pheomelanin is found in blue- and green-eyed people. The *melanocortin-1 receptor* (*MC1R*) gene is a regulator of eumelanin production and is located on chromosome 16q24.3. Point mutations in the *MC1R* gene affect melanogenesis. The presence of point mutations in the *MC1R* gene alleles is a common feature in light-skinned and blue- and green-eyed people (1, 2).
- A transparent external surface, the **cornea**, that covers both the pupil and the iris. This is the first and most powerful lens of the optical system of the eye and allows, together with the crystalline lens, the production of a sharp image at the retinal photoreceptor level.
- The "white of the eye", the **sclera**, which forms part of the supporting wall of the eyeball. The sclera is continuous with the cornea. Furthermore, this external covering of the eye is in continuity with the dura of the central nervous system.

The Eyeball

When we remove the eye from the orbit, we can see that the eye is a slightly asymmetrical sphere with an approximate sagittal diameter or length of 24 to 25 mm and a transverse diameter of 24 mm. It has a volume of about 6.5 cc.

A cross-sectional view of the eye shows (Fig. 2):

- Three different layers:
  1. The external layer, formed by the **sclera** and **cornea**.
  2. The intermediate layer, divided into two parts: anterior (**iris** and **ciliary body**) and posterior (**choroid**).
  3. The internal layer, or the sensory part of the eye, the **retina**.
- Three chambers of fluid: **anterior chamber** (between cornea and iris), **posterior chamber** (between iris, zonule fibers and lens), and the **vitreous chamber** (between the lens and the retina). The first two chambers are filled with aqueous humor, whereas the vitreous chamber is filled with a more viscous fluid, the vitreous humor.
- The sagittal section of the eye also reveals the lens, which is a transparent body located behind the iris. The lens is suspended by ligaments (called zonule fibers) attached to the anterior portion of the ciliary body. The contraction or relaxation of these ligaments, as a consequence of ciliary muscle actions, changes the shape of the lens, a process called **accommodation** that allows us to form a sharp image on the retina.

Light rays are focused through the transparent cornea and lens upon the retina. The central point for image focus (the visual axis) in the human retina is the **fovea**. Here a maximally focused image initiates resolution of the finest detail and direct transmission of that detail to the brain for the higher operations needed for

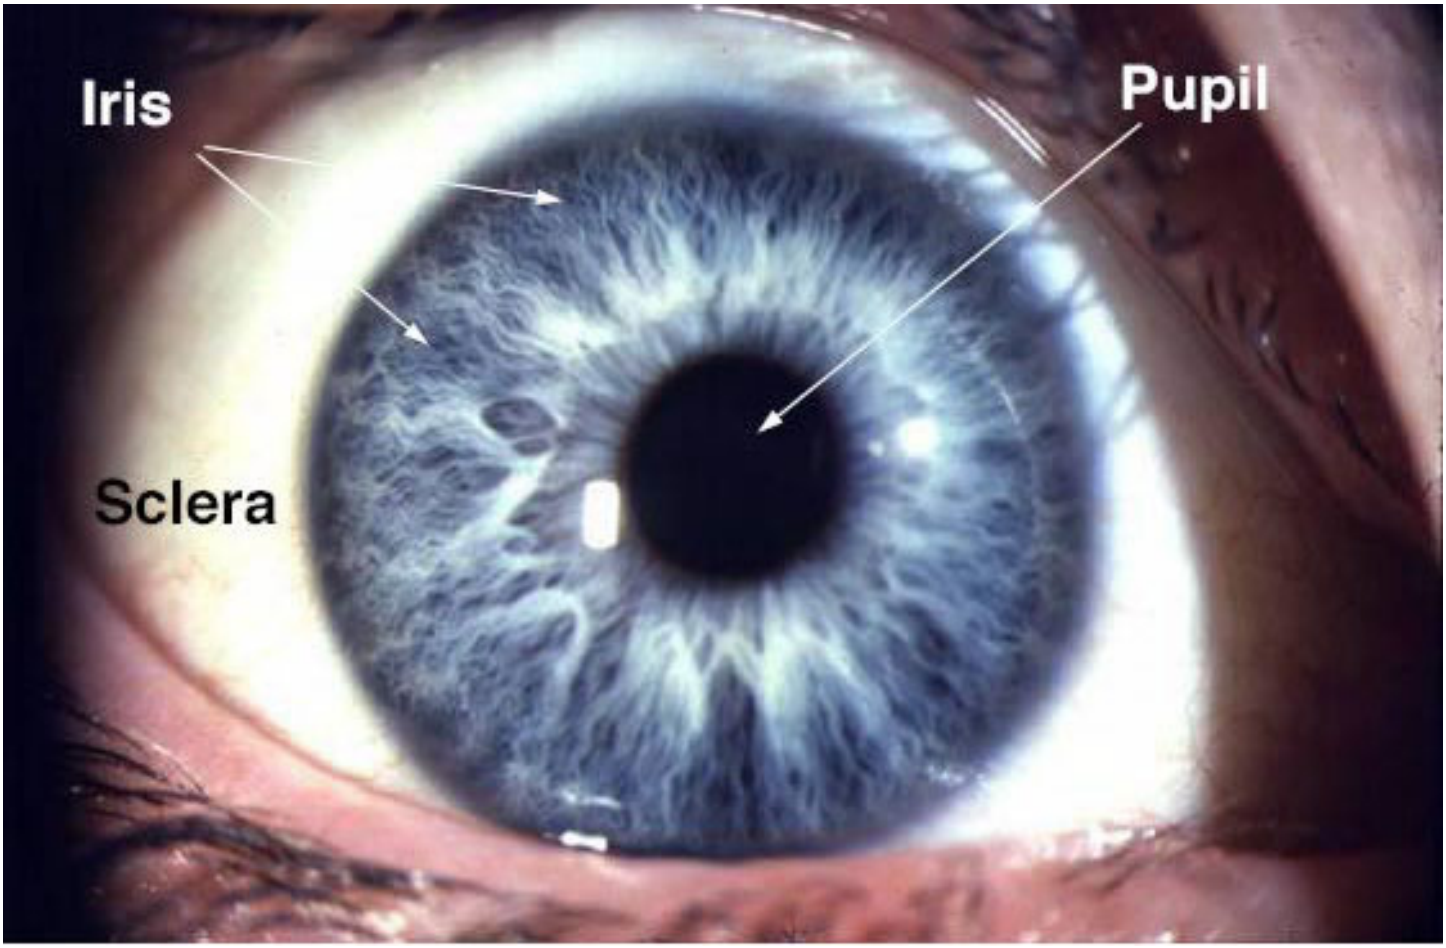


Figure 1. View of the human eye.

perception. The optic axis is slightly closer to the nasal area and projects closer to the optic nerve head. The optic axis is the longest sagittal distance between the front or vertex of the cornea and the furthest posterior part of the eyeball. The eye is rotated around the optic axis by the eye muscles. Instead of a fovea, some vertebrate retinas have another specialization of the central retina, known as an **area centralis** or a visual streak.

Extraocular Muscles

Each eyeball is held in position in the orbital cavity by various ligaments, muscles, and fascial expansions that surround it (Fig. 3). Inserted into the sclera are three pairs of muscles (six muscles altogether). Two pairs are rectus muscles that run straight to the bony orbit of the skull, orthogonal to each other (the superior rectus, the inferior rectus, the lateral rectus, and the medial rectus muscles). Another pair of muscles, the oblique muscles (superior oblique and inferior oblique), are angled, as the name implies, obliquely. These muscles, named **extraocular muscles**, rotate the eyeball in the orbits and allow the image to be focused, at all times, on the fovea of the central retina.

Development of the Eye

The retina is a part of the central nervous system and an ideal region of the vertebrate brain to study, because similar to other regions of the central nervous system, it **derives from the neural tube** (Fig. 4). The retina is formed during development of the embryo from **optic vesicles** outpouching from two sides of the developing neural tube. The primordial optic vesicles fold back in upon themselves to form the **optic cup**, with the inside of

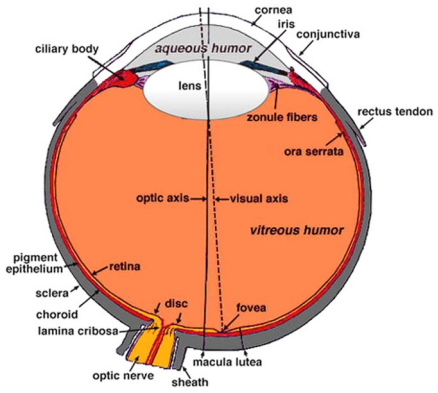

Figure 2. Sagittal section of the adult human eye.

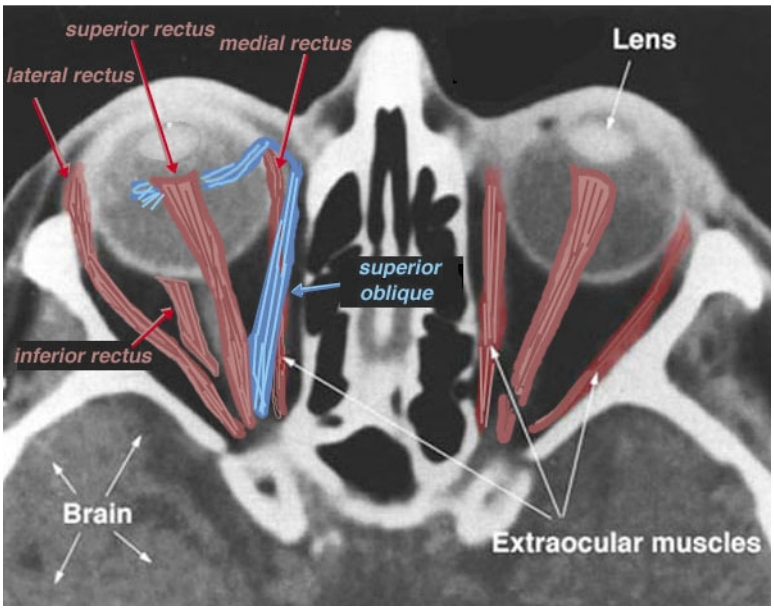

Figure 3. CT horizontal transverse scan.

the cup becoming the retina and the outside remaining a single monolayer of epithelium, known as the retinal pigment epithelium. Initially, both walls of the optic cup are one-cell thick, but the cells of the inner wall divide to form a neuroepithelial layer many cells thick—the retina (see the movie of the morphogenesis).

Sensory retinal development begins as early as the optic vesicle stage, with the migration of cell nuclei to the inner surface of the sensory retina. Additional retinal development is characterized by the formation of more layers, arising from cell division and subsequent cell migration. The retina develops in an inside-to-outside manner: ganglion cells are formed first, and photoreceptors cells become fully mature last.

Additional changes in retinal morphology are accomplished by simultaneous formation of multiple, complex intercellular connections. Thus, by 5 months of gestation, most of the basic neural connections of the retina have been established (Fig. 5) (4).

The functional synapses are made almost exclusively in the two plexiform layers, and the perikarya of the nerve cells are distributed in the three nuclear layers.

Photoreceptor cell maturation begins with the formation of outer segments (OS) containing visual pigment from multiple infoldings of the plasma membrane of each cell. Outer segment formation proceeds, and the eye becomes sensitive to light at about 7 months of gestation.

The final portion of the sensory retina to mature is the fovea, where the ganglion cell layer thickening begins during midgestation. The outer nuclear layer is also wider here than elsewhere in the retina and consists almost entirely of developing cone cells. The ganglion cell nuclei migrate radially outward in a circle, leaving the fovea free of ganglion cell nuclei. Cell-cell attachments persist, however, and foveal cone cells alter their shape to accomodate the movement of ganglion cells. Foveal development continues with cell rearrangements and alteration in cone shape until about 4 years after birth (5, 6).

Surface membranes cover the eye cup and develop into lens, iris, and cornea, with the three chambers of fluid filled with aqueous and vitreous humors (Fig. 6).

Preview

In the following chapters, we will describe in greater detail the individual nerve cells that make up the retina and the functional pathways into which these neurons are organized. Eventually, we will progress to a stage where we can understand the summary diagrams (Fig. 7 and Fig. 8) that show the function and wiring of the two best understood mammalian retinas—the cat and primate retinas.

Simple Anatomy of the Retina

Helga Kolb, PhD[1]

Created: May 1, 2005; Updated: January 31, 2012.

1. Overview

When an ophthalmologist uses an ophthalmoscope to look into your eye he sees the following view of the retina (Fig. 1).

In the center of the retina is the optic nerve, a circular to oval white area measuring about 2 x 1.5 mm across. From the center of the optic nerve radiate the major blood vessels of the retina. Approximately 17 degrees (4.5-5 mm), or two and half disc diameters to the left of the disc, can be seen the slightly oval-shaped, blood vessel-free reddish spot, the fovea, which is at the center of the area known as the macula by ophthalmologists (Fig. 1). An animation of the view from iris to retina can be seen in movie 1.

A circular field of approximately 6 mm around the fovea is considered the central retina while beyond this is peripheral retina stretching to the ora serrata, 21 mm from the center of the retina (fovea). The total retina is a circular disc of between 30 and 40 mm diameter (1-3).

The retina is approximately 0.5 mm thick and lines the back of the eye. The optic nerve contains the ganglion cell axons running to the brain and, additionally, incoming blood vessels that open into the retina to vascularize the retinal layers and neurons (Fig. 2). A radial section of a portion of the retina reveals that the ganglion cells (the output neurons of the retina) lie innermost in the retina closest to the lens and front of the eye, and the photosensors (the rods and cones) lie outermost in the retina against the pigment epithelium and choroid. Light must, therefore, travel through the thickness of the retina before striking and activating the rods and cones (Fig. 2). Subsequently the absorbtion of photons by the visual pigment of the photoreceptors is translated into first a biochemical message and then an electrical message that can stimulate all the succeeding neurons of the retina. The retinal message concerning the photic input and some preliminary organization of the visual image into several forms of sensation are transmitted to the brain from the spiking discharge pattern of the ganglion cells.

A simplistic wiring diagram of the retina emphasizes only the sensory photoreceptors and the ganglion cells with a few interneurons connecting the two cell types such as seen in figure 3.

When an anatomist takes a vertical section of the retina and processes it for microscopic examination it becomes obvious that the retina is much more complex and contains many more nerve cell types than the simplistic scheme (above) had indicated. It is immediately obvious that there are many interneurons packed into the central part of the section of retina intervening between the photoreceptors and the ganglion cells (Fig. 4).

All vertebrate retinas are composed of three layers of nerve cell bodies and two layers of synapses (Fig. 5). The outer nuclear layer contains cell bodies of the rods and cones, the inner nuclear layer contains cell bodies of the bipolar, horizontal and amacrine cells and the ganglion cell layer contains cell bodies of ganglion cells and displaced amacrine cells. Dividing these nerve cell layers are two neuropils where synaptic contacts occur (Fig. 5).

The first area of neuropil is the outer plexiform layer (OPL) where connections between rod and cones, and vertically running bipolar cells and horizontally oriented horizontal cells occur (Figs. 6 and 7).

Author Affiliation: 1 Moran Eye Institute, University of Utah School of Medicine, Salt Lake City; Email: Helga.kolb@hsc.utah.edu.

Corresponding author.

The second neuropil of the retina, is the inner plexiform layer (IPL), and it functions as a relay station for the vertical-information-carrying nerve cells, the bipolar cells, to connect to ganglion cells (Figs. 8 and 9). In addition, different varieties of horizontally- and vertically-directed amacrine cells, interact in further networks to influence and integrate the ganglion cell signals. It is at the culmination of all this neural processing in the IPL that the message concerning the visual image is transmitted through ganglion cells to the brain along the optic nerve.

2. Central and peripheral retina compared

Central retina close to the fovea is considerably thicker than peripheral retina (compare Figs. 10A with 10B). This is due to the increased packing density of photoreceptors, particularly the cones, and their associated bipolar and ganglion cells in central retina compared with peripheral retina.

Central retina is cone-dominated retina whereas peripheral retina is rod-dominated. Thus in central retina the cones are closely spaced and the rods fewer in number between the cones (Figs. 10A and 10B).

The outer nuclear layer (ONL), composed of the cell bodies of the rods and cones, is about the same thickness in central and peripheral retina. However in the peripheral retina the rod cell bodies outnumber the cone cell bodies while the reverse is true for central retina. In central retina, the cones have oblique axons displacing their cell bodies from their synaptic pedicles in the outer plexiform layer (OPL). These oblique axons, with accompanying Müller cell processes, form a pale-staining fibrous-looking area known as the Henle fibre layer. The latter layer is absent in peripheral retina.

The inner nuclear layer (INL) is thicker in the central area of the retina compared with peripheral retina, due to a greater density of cone-connecting second-order neurons (cone bipolar cells), smaller-field and more closely-spaced horizontal cells, and amacrine cells concerned with the cone pathways (Fig. 10). As we shall see later, cone-connected circuits of neurons are less convergent in that fewer cones impinge on second order neurons, than rods do in rod-connected pathways.

A remarkable difference between central and peripheral retina can be seen in the relative thicknesses of the inner plexiform layers (IPL), ganglion cell layers (GCL) and nerve fibre layers (NFL) (Figs. 10A and 10B). This is again due to the greater numbers and increased packing-density of ganglion cells needed for the cone pathways in the cone-dominant foveal retina as compared the rod-dominant peripheral retina. The greater number of ganglion cells means more synaptic interaction in a thicker IPL and greater numbers of ganglion cell axons coursing to the optic nerve in the nerve fibre layer (Fig. 10A).

3. Müller glial cells

Müller cells are the radial glial cells of the retina (Fig. 11). The outer limiting membrane (OLM) of the retina is formed from adherens junctions between Müller cells and photoreceptor cell inner segments. The inner limiting membrane (ILM) of the retina is likewise composed of laterally contacting Müller cell end feet and associated basement membrane constituents.

The OLM forms a barrier between the subretinal space, into which the inner and outer segments of the photoreceptors project to be in close association with the pigment epithelial layer behind the retina, and the neural retina proper. The ILM is the inner surface of the retina bordering the vitreous humor and thereby forming a diffusion barrier between neural retina and vitreous humor (Fig. 11).

Throughout the retina the major blood vessels of the retinal vasculature supply the capillaries that run into the neural tissue. Capillaries are found running through all parts of the retina from the nerve fibre layer to the outer plexiform layer and even occasionally as high as in the outer nuclear layer. Nutrients from the vasculature of the choriocapillaris behind the pigment epithelium layer supply the delicate photoreceptor layer.

Movie 1. An animation from the iris to the retina.
Download video

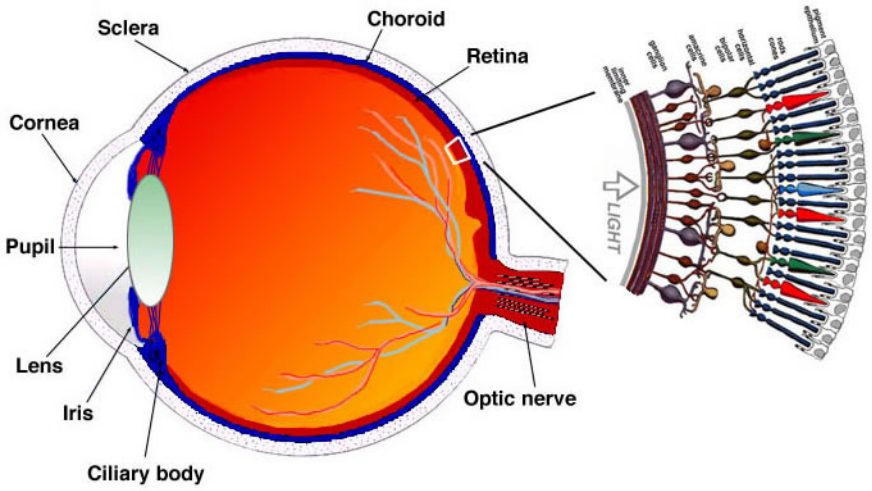

Figure 2. A drawing of a section through the human eye with a schematic enlargement of the retina.

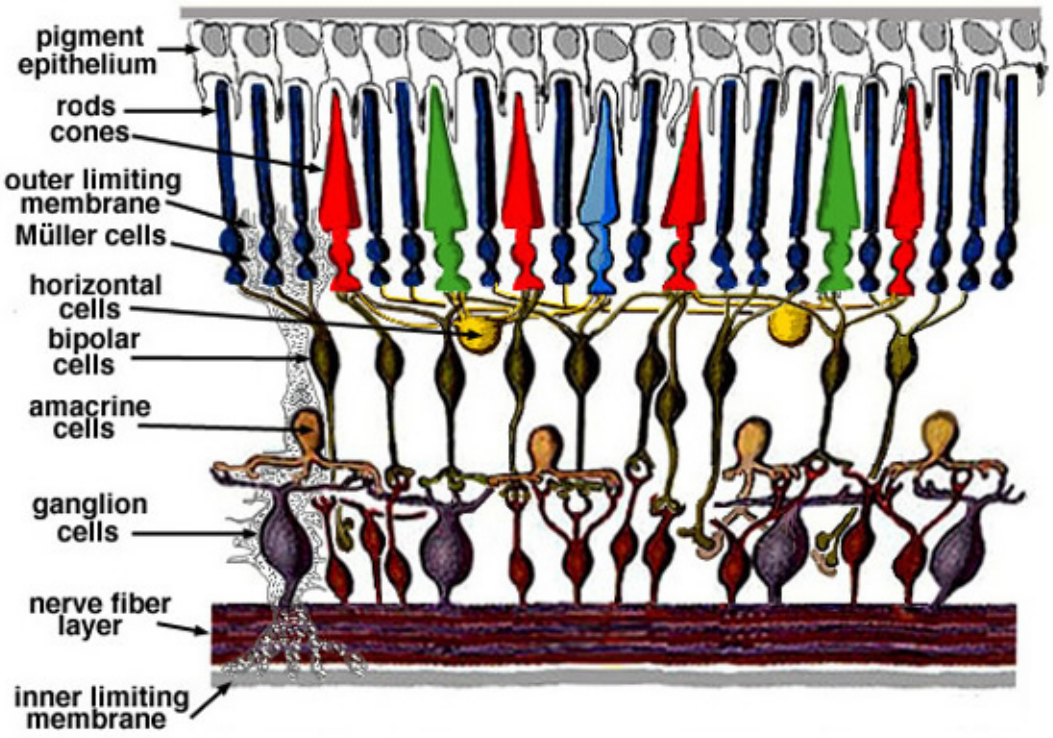

Figure 3. Simple diagram of the organization of the retina.

4. Foveal structure

The center of the fovea is known as the foveal pit (1) and is a highly specialized region of the retina different again from central and peripheral retina we have considered so far. Radial sections of this small circular region of retina measuring less than a quarter of a millimeter (200 μm) across are shown below for human (Fig. 12A) and for monkey (Fig. 12B).

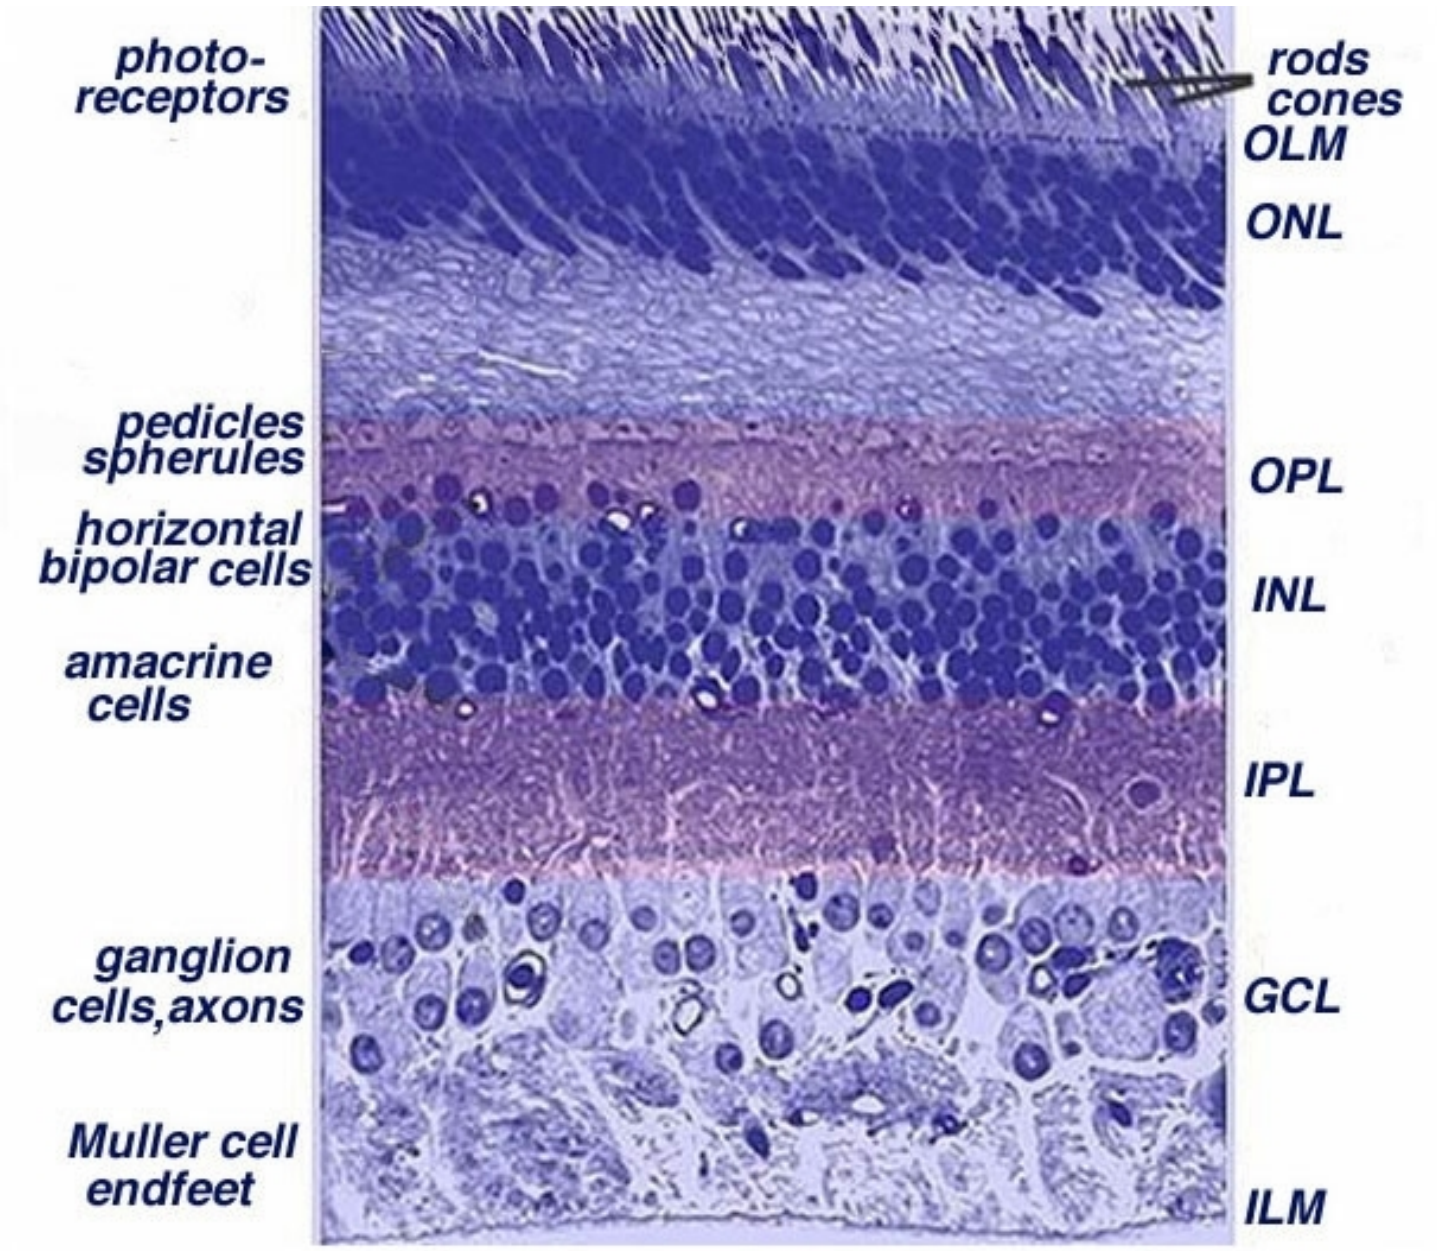

Figure 4. Light micrograph of a vertical section through central human retina.

The foveal pit is an area where cone photoreceptors are concentrated at maximum density with exclusion of the rods, and arranged at their most efficient packing density which is in a hexagonal mosaic. This is more clearly seen in a tangential section through the foveal cone inner segments (Fig. 13).

Below this central 200 μm diameter central foveal pit, the other layers of the retina are displaced concentrically leaving only the thinnest sheet of retina consisting of the cone cells and some of their cell bodies. Radially distorted but complete layering of the retina then appears gradually along the foveal slope (right and left sides of Figs. 12a and 12b) until the rim of the fovea is made up of the displaced second- and third-order neurons related to the central cones. Here the ganglion cells are piled into six layers so making this area, called the foveal rim or parafovea (1), the thickest portion of the entire retina.

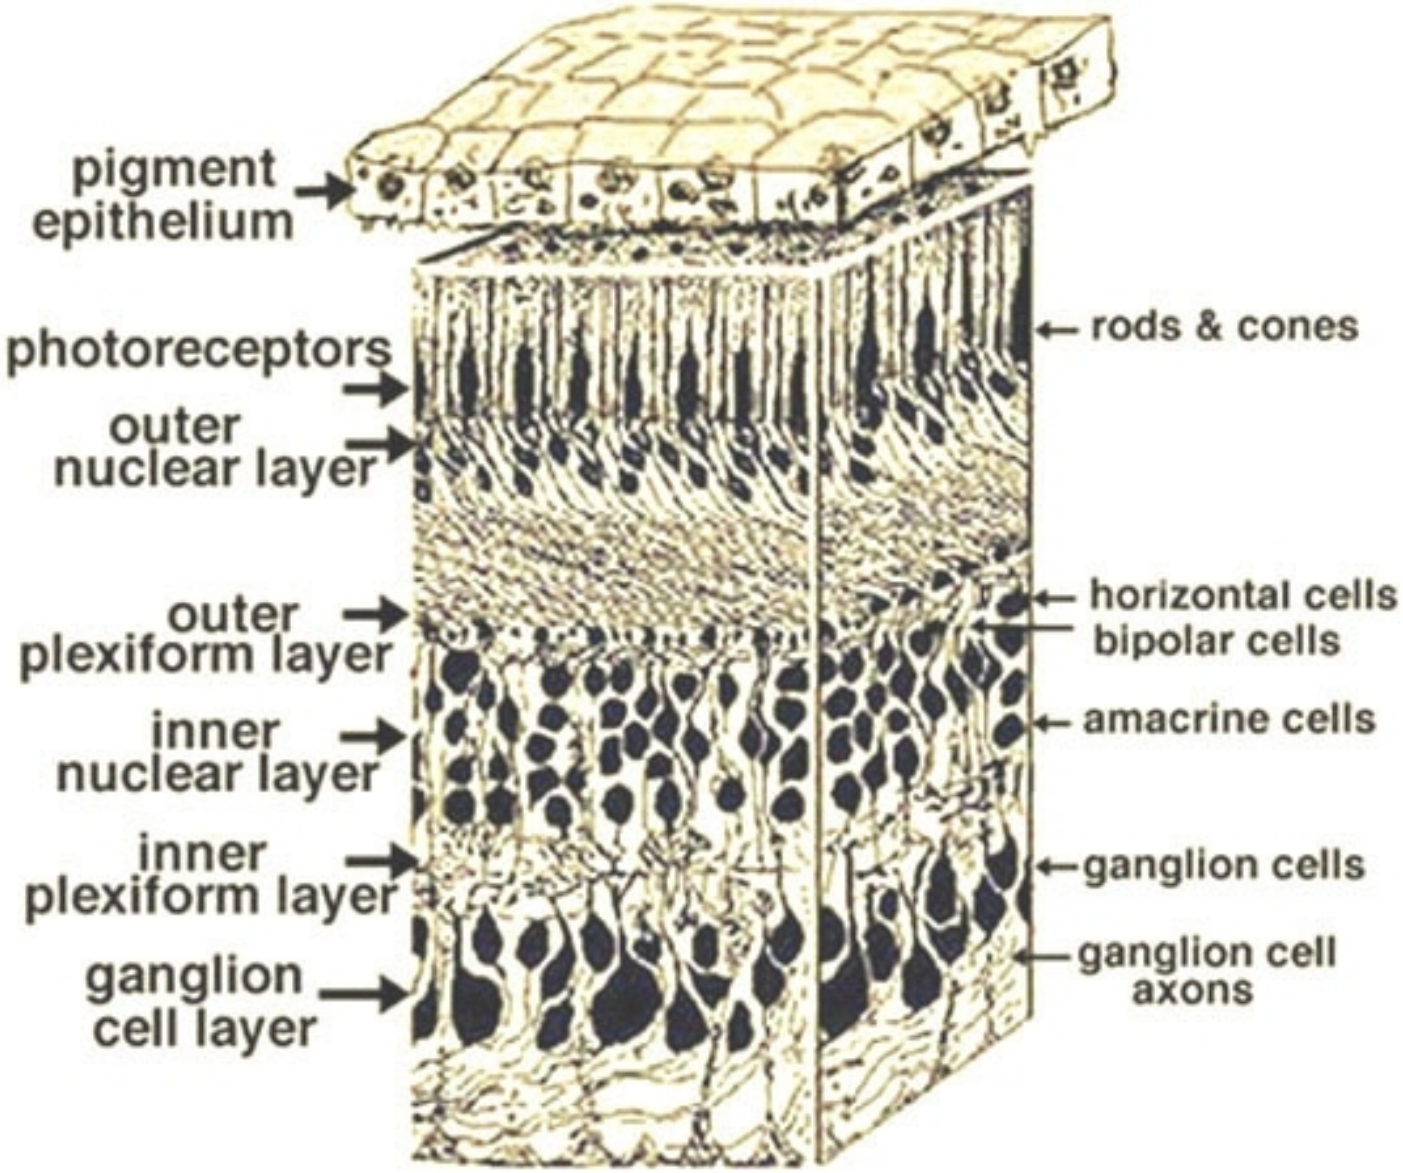

Figure 5. 3-D block of a portion of human retina.

5. Macula lutea

The whole foveal area including foveal pit, foveal slope, parafovea and perifovea is considered the macula of the human eye. Familiar to ophthalmologists is a yellow pigmentation to the macular area known as the macula lutea (Fig. 14).

This pigmentation is the reflection from yellow screening pigments, the xanthophyll carotenoids zeaxanthin and lutein (4), present in the cone axons of the Henle fibre layer. The macula lutea is thought to act as a short wavelength filter, additional to that provided by the lens (5). As the fovea is the most essential part of the retina for human vision, protective mechanisms for avoiding bright light and especially ultraviolet irradiation damage are essential. For if the delicate cones of our fovea are destroyed, we become blind.

The yellow pigment that forms the macula lutea in the fovea can be clearly demonstrated by viewing a section of the fovea in the microscope with blue light (Fig. 15). The dark pattern in the foveal pit extending out to the edge of the foveal slope is caused by the macular pigment distribution (6).

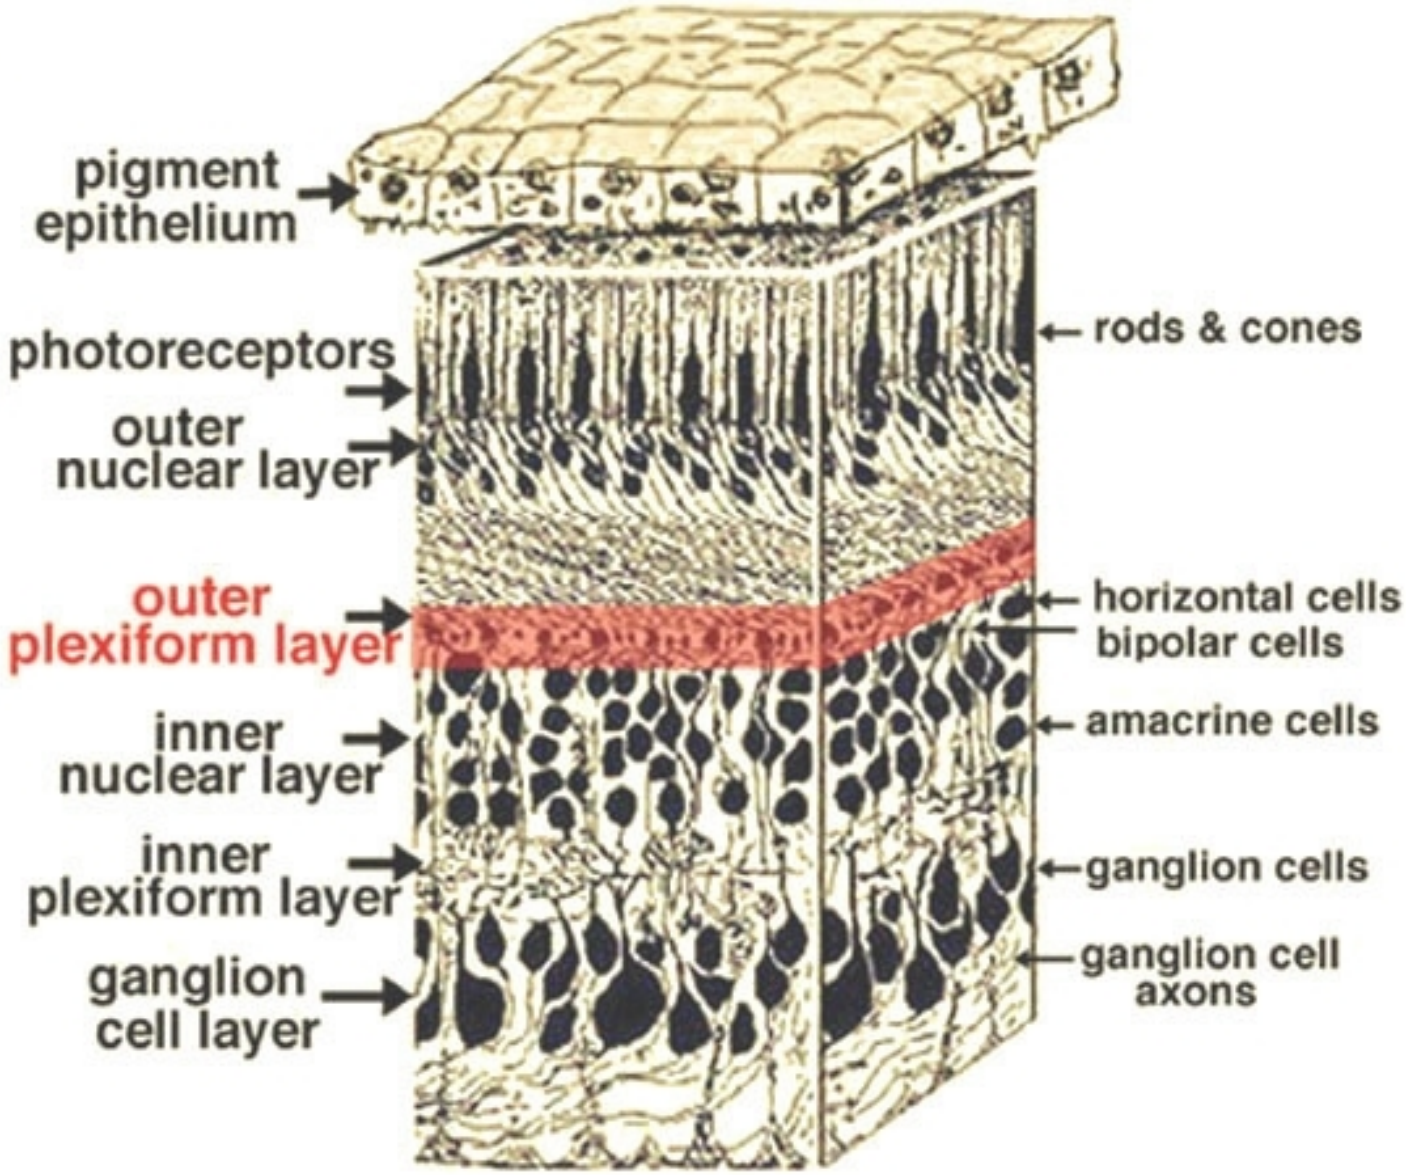

Figure 6. 3-D block of retina with the outer plexiform layer (OPL) highlighted in red. .

If one were to visualize the foveal photoreceptor mosaic as though the visual pigments in the individual cones were not bleached, one would see the picture shown in Figure 16 (lower frame) (picture from Lall and Cone, 1996). The short-wavelength sensitive cones on the foveal slope look pale yellow green, the middle wavelength cones, pink and the long wavelength sensitive cones, purple. If we now add the effect of the yellow screening pigment of the macula lutea we see the appearance of the cone mosaic in Figure 16 (upper frame). The macula lutea helps enhance achromatic resolution of the foveal cones and blocks out harmful UV light irradiation (Fig. 16 from Abner Lall and Richard Cone, unpublished data).

6. Blood supply to the retina

There are two sources of blood supply to the mammalian retina: the central retinal artery and the choroidal blood vessels. The choroid receives the greatest blood flow (65-85%) (7) and is vital for the maintainance of the outer retina (particularly the photoreceptors) and the remaining 20-30% flows to the retina through the central

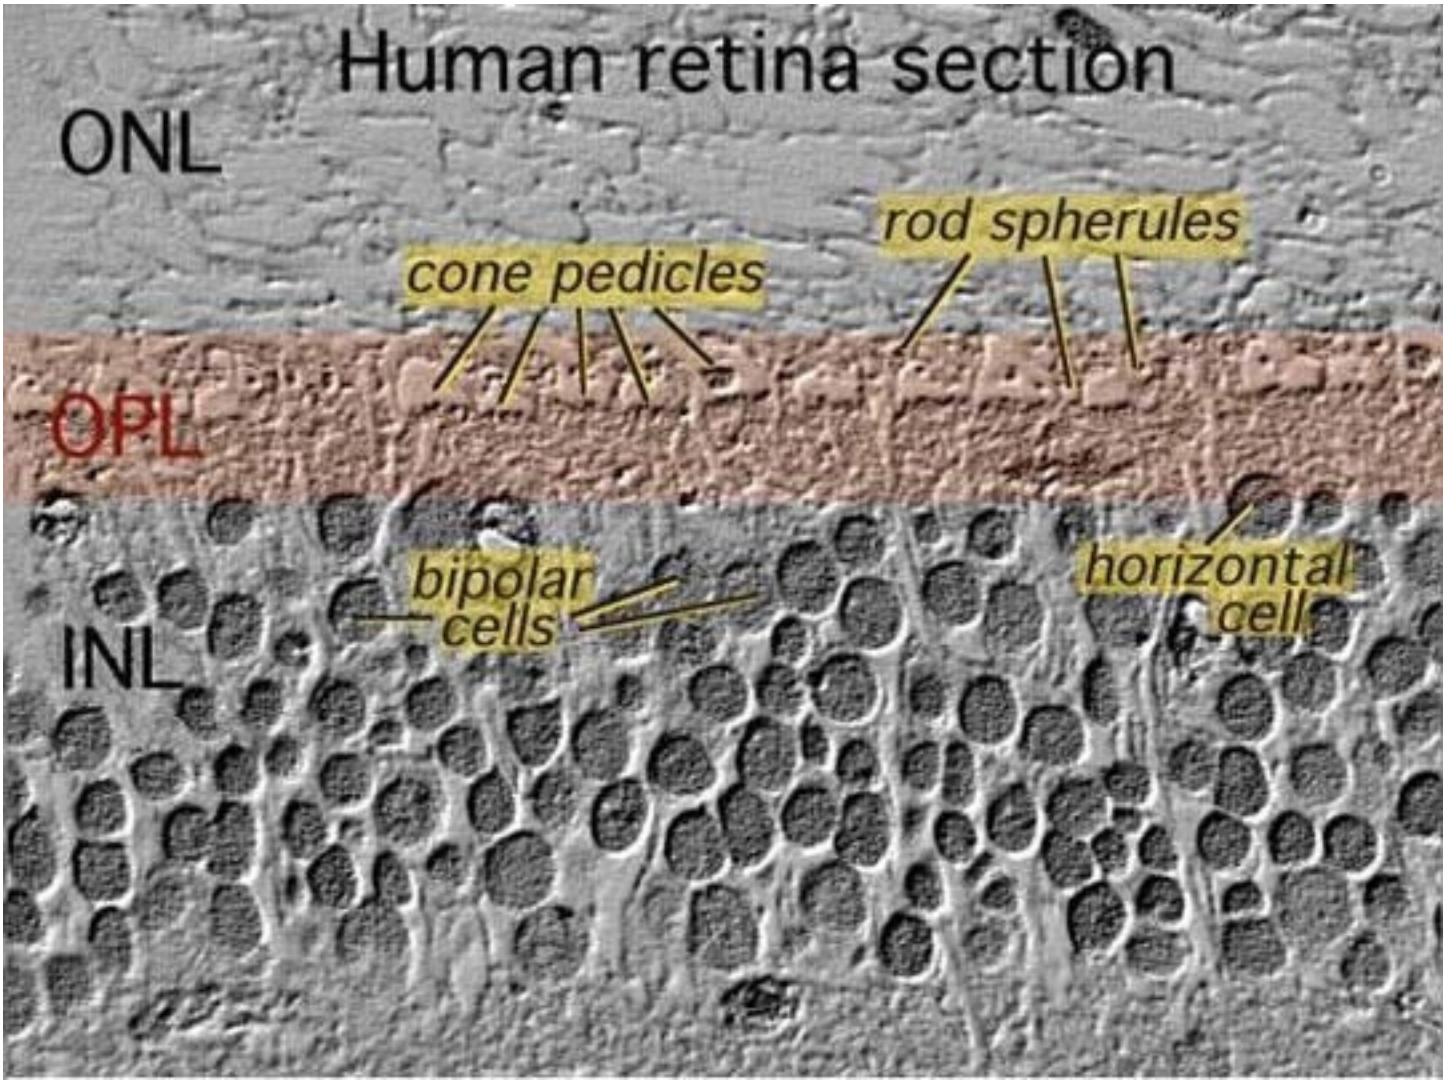

Figure 7. Light micrograph of a vertical section through the outer plexiform layer (OPL). Cone pedicles and rod spherules are the synaptic terminals of cones and rods. The outer nuclear layer (ONL) contains the cell bodies of rods and cones. The inner nuclear layer (INL) contains the cell bodies of horizontal cells, bipolar cells, and amacrine cells.

retinal artery from the optic nerve head to nourish the inner retinal layers. The central retinal artery has 4 main branches in the human retina (Fig. 17).

The arterial intraretinal branches then supply three layers of capillary networks i.e. 1) the radial peripapillary capillaries (RPCs) and 2) an inner and 3) an outer layer of capillaries (Fig. 18A). The precapillary venules drain into venules and through the corresponding venous system to the central retinal vein (Fig. 18B).

The radial peripapillary capillaries (RPCs) are the most superfical layer of capillaries lying in the inner part of the nerve fiber layer, and run along the paths of the major superotemporal and inferotemporal vessels 4-5 mm from the optic disk (8). The RPCs anastomose with each other and the deeper capillaries. The inner capillaries lie in the ganglion cell layers under and parallel to the RPCs. The outer capillary network runs from the inner plexiform layer to the outer plexiform layer thought the inner nuclear layer (8).

As will be noticed from the flourescein angiography of Figure 17, there is a ring of blood vessels in the macular area around a blood vessel- and capillary-free zone 450-600 μm in diameter, surrounding the fovea. The macular vessels arise from branches of the superior temporal and inferotemporal arteries. At the border of the avascular zone the capillaries become two-layered and finally join as a single layered ring. The collecting venules are

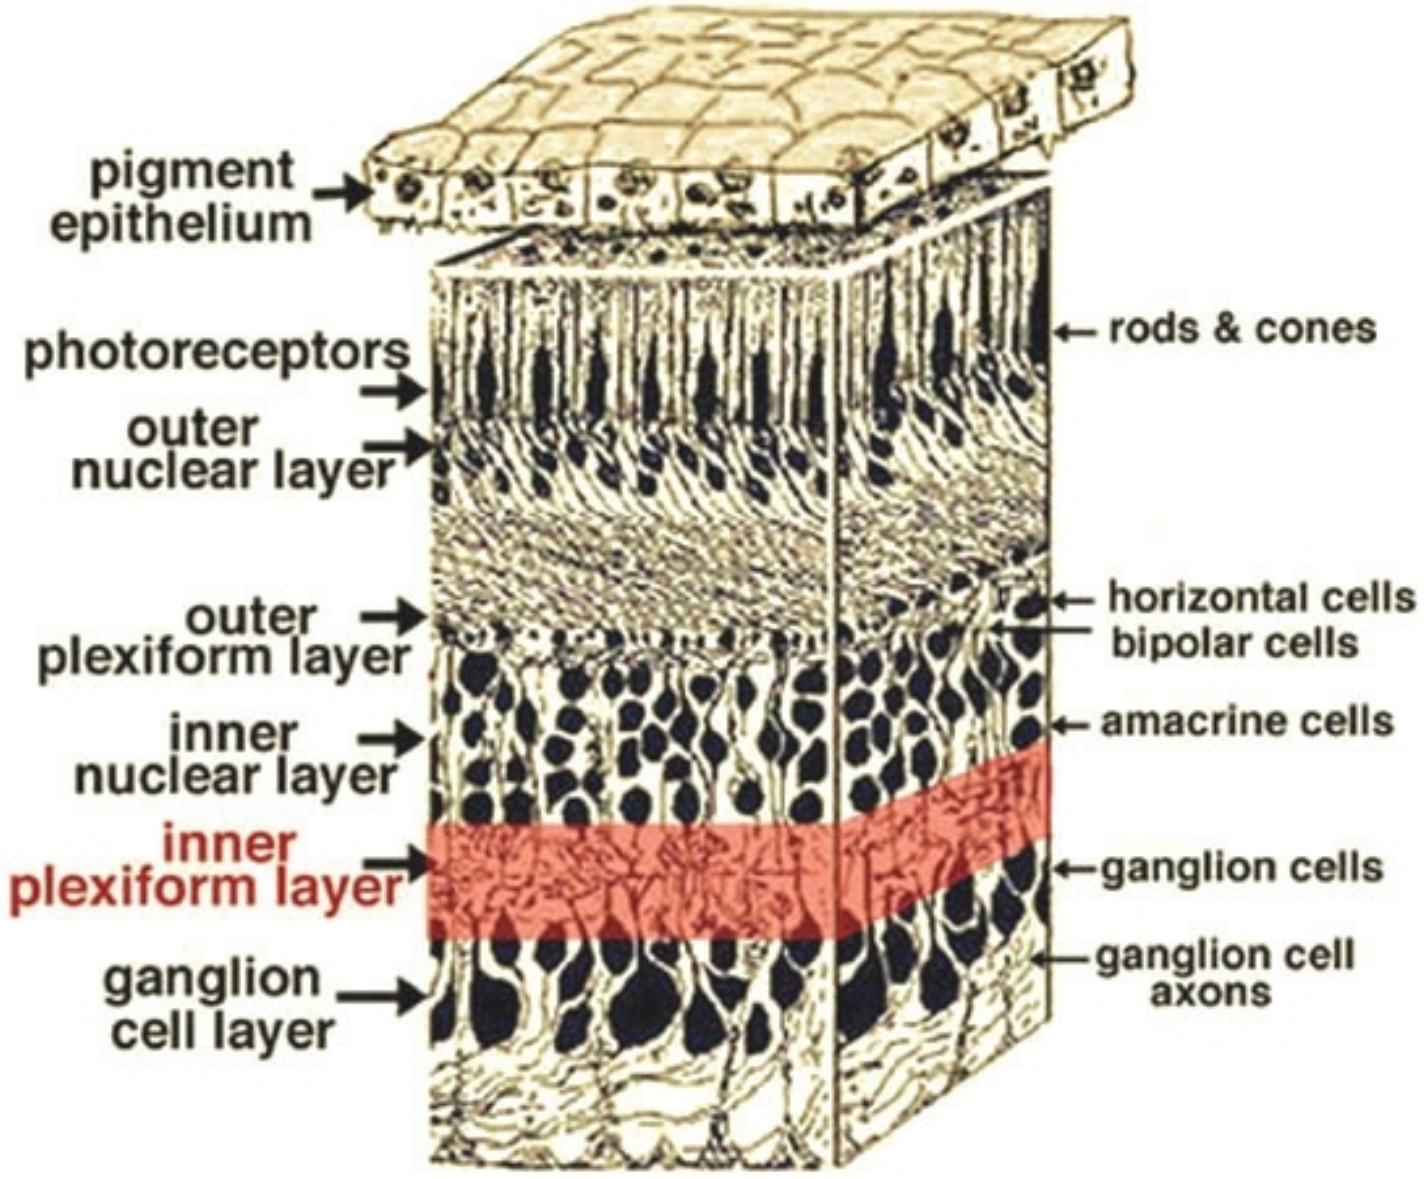

Figure 8. 3-D block of retina with the inner plexiform layer (IPL) highlighted in red.

deeper (posterior) to the arterioles and drain blood flow back into the main veins (Fig. 19). In the rhesus monkey this perimacular ring and blood vessel free fovea is clearly seen in the beautiful drawings made by Max Snodderly's group (9) (Fig. 20).

The choroidal arteries arise from long and short posterior ciliary arteries and branches of Zinn's circle (around the optic disc). Each of the posterior ciliary arteries break up into fan-shaped lobules of capillaries that supply localized regions of the choroid (10). The macular area of the choroidal vessels is not specialized like the retinal blood supply is (8). The arteries pierce the sclera around the optic nerve and fan out to form the three vascular layers in the choroid: outer (most scleral), medial and inner (nearest Bruch's membrane of the pigment epithelium) layers of blood vessels. This is clearly shown in the corrosion cast of a cut face of the human choroid in figure 21A (8). The corresponding venous lobules drain into the venules and veins that run anterior towards the equator of the eyeball to enter the vortex veins (Fig. 21b). One or two vortex veins drain each of the 4 quadrants of the eyeball. The vortex veins penetrate the sclera and merge into the ophthalmic vein as shown in the corrosion cast of figure 21B (8).

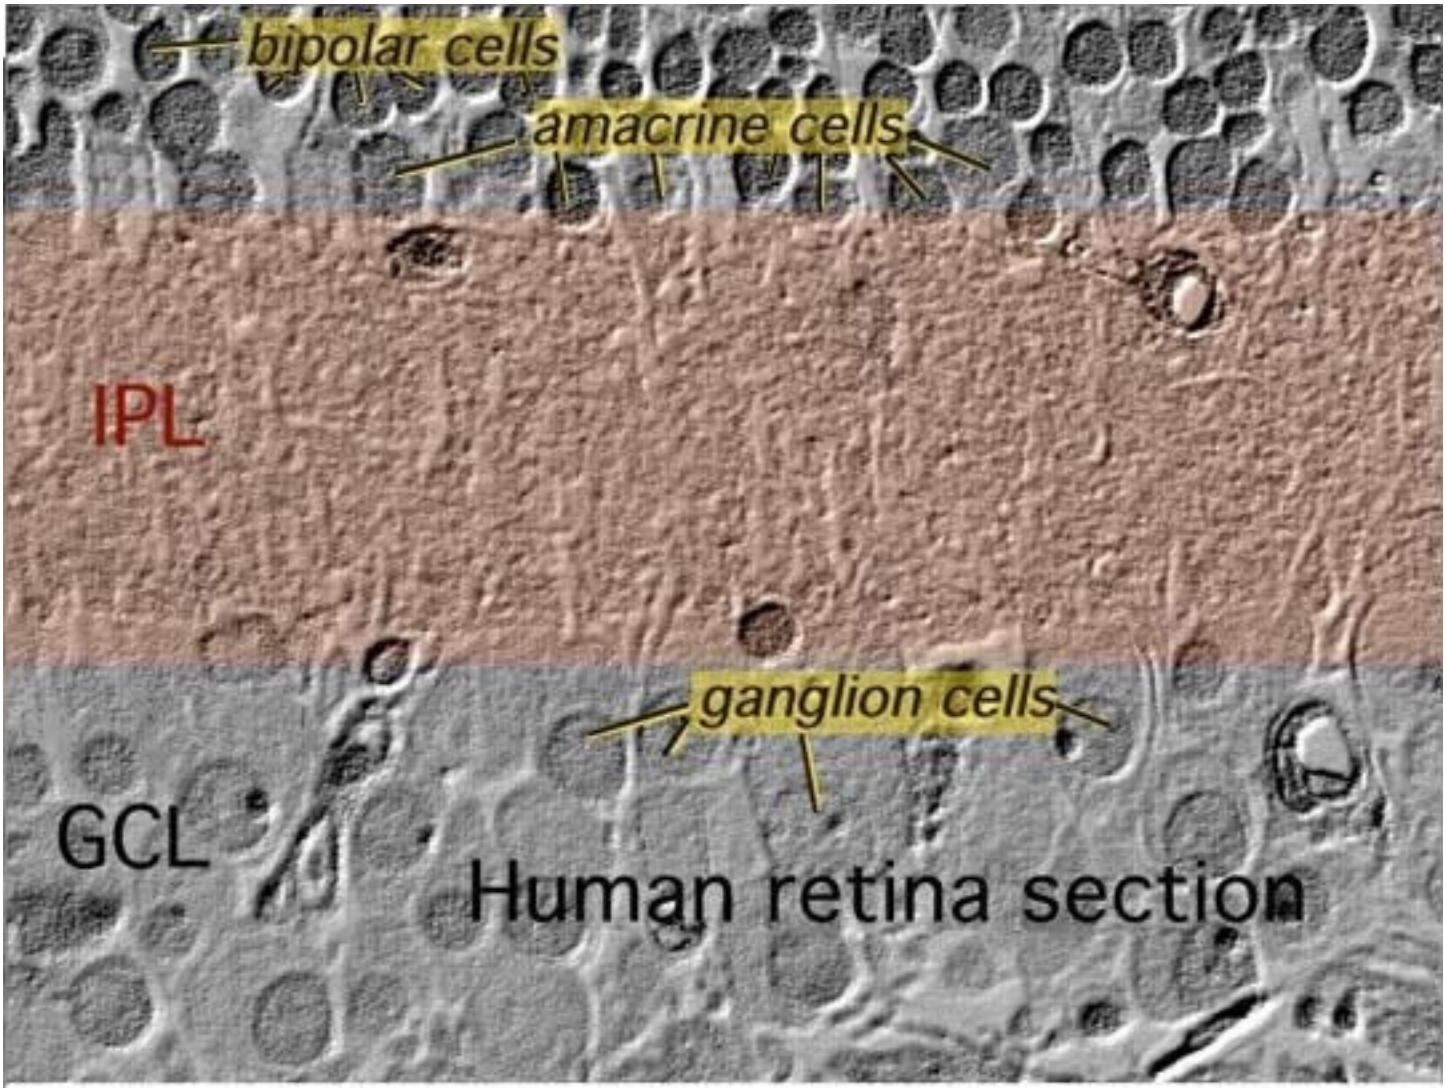

Figure. 9. Light micrograph of a vertical section through the inner plexiform layer (IPL), highlighted in red. Amacrine cells and bipolar cells lie above the IPL. Ganglion cells form the ganglion cell layer (GCL) which lies just below the IPL. Processes from all 3 cell types interconnect within IPL circuitry.

7. Degenerative diseases of the human retina

The human retina is a delicate organization of neurons, glia and nourishing blood vessels. In some eye diseases, the retina becomes damaged or compromised, and degenerative changes set in that eventually lead to serious damage to the nerve cells that carry the vital messages about the visual image to the brain. We indicate four different conditions where the retina is diseased and blindness may be the end result.

Age related macular degeneration is a common retinal problem of the aging eye and a leading cause of blindness in the world. The macular area and fovea become compromised due to the pigment epithelium behind the retina degenerating and forming drusen (white spots, Fig. 22) and allowing leakage of fluid behind the fovea. The cones of the fovea die causing central visual loss so we cannot read or see fine detail.

Glaucoma (Fig. 23) is also a common problem in aging, where the pressure within the eye becomes elevated. The pressure rises because the anterior chamber of the eye cannot exchange fluid properly by the normal aqueous outflow methods. The pressure within the vitreous chamber rises and compromises the blood vessels of the optic

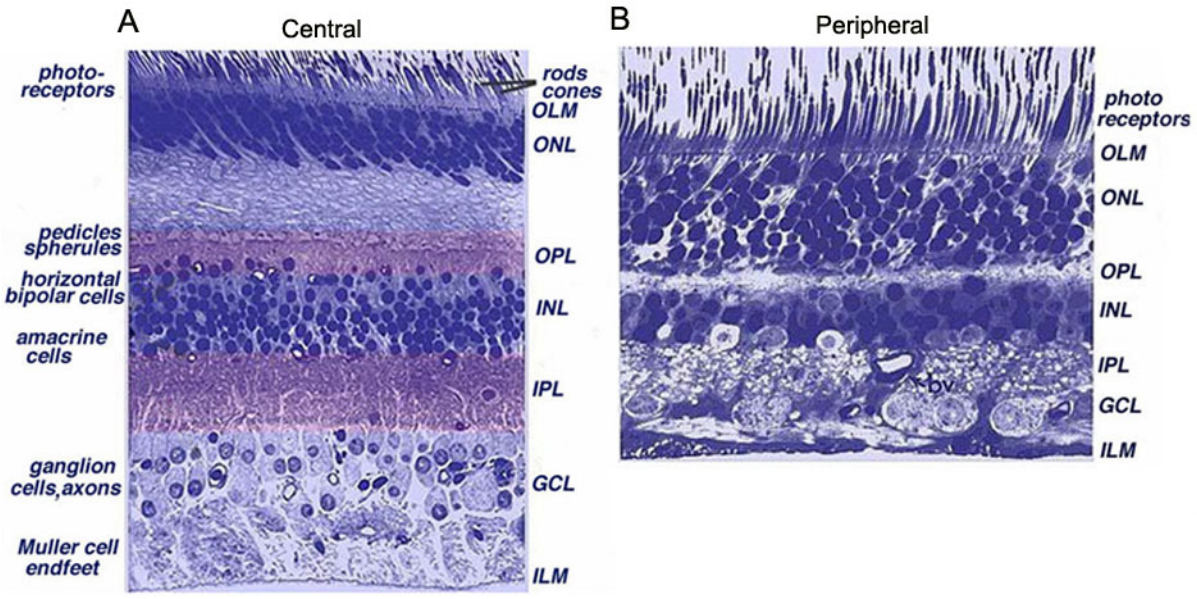

Figure 10. Different structure of central and peripheral human retina. *A*. In central retina the inner and outer plexiform layers (IPL, OPL) are thicker than in peripheral retina. The inner nuclear and ganglion cell layers (INL, GCL) contain more cells, but of smaller diameter. *B*. Peripheral retina is thinner overall than central retina, though cells are larger in diameter, most layers are thin. The outer nuclear layer (ONL) is densely populated with rods. OLM, outer limiting membrane; ILM, inner limiting membrane.

nerve head and eventually the axons of the ganglion cells so that these vital cells die. Treatment to reduce the intraocular pressure is essential in glaucoma.

Retinits pigmentosa (Fig. 24) is a nasty hereditary disease of the retina for which there is no cure at present. It comes in many forms and consists of large numbers of genetic mutations presently being analyzed. Most of the faulty genes that have been discovered concern the rod photoreceptors. The rods of the peripheral retina begin to degenerate in early stages of the disease. Patients become night blind gradually as more and more of the peripheral retina (where the rods reside) becomes damaged. Eventually patients are reduced to tunnel vision with only the fovea spared the disease process. Characteristic pathology is the occurrence of black pigment in the peripheral retina and thinned blood vessels at the optic nerve head (Fig. 24).

Diabetic retinopathy is a side effect of diabetes that affects the retina and can cause blindness (Fig. 25). The vital nourishing blood vessels of the eye become compromised, distorted and multiply in uncontrollable ways. Laser treatment for stopping blood vessel proliferation and leakage of fluid into the retina, is the commonest treatment at present.

Anatomy and Physiology of the Retina

The Retinal Pigment Epithelium

Olaf Strauss, PhD[1]

Created: January 26, 2011.

1. Introduction

The simplest light detecting organs are composed of two cell types: the light sensitive photoreceptor and the pigmented cell. Both cell types appear in conjunction in every eye of the animal kingdom from insects, mollusca to higher vertebrates (1). Functional interaction of both the pigmented cell and the photoreceptor cells is essential for visual function (2-5). Already beginning with the embryonic development the functional differentiation of the photoreceptor layer and the retinal pigment epithelium (RPE) depend on each other (6, 7). When the communication between the developing RPE and the developing neuronal retina is interrupted the RPE is able to form a multilayered retina-like structure by itself (8).

The RPE and the neural retina co-differentiate during development of the eye. Parts of the RPE/photoreceptor interaction such as importing the vitamin A derivitive, retinal, its metabolism and recycling are initiated before vision starts, and serve as differentiation signals for both tissues (9, 10). Furthermore, analyses of hereditary types of retinal degeneration reveal a strong dependence of the RPE on the photoreceptors and vice versa. For example, mutations in genes which are expressed in the photoreceptor cells can lead to a primary RPE disease with loss of photoreceptors occurring secondarily. Or, on the other hand, mutations in genes which are expressed in the RPE can lead to primary photoreceptor degeneration. Thus the ability of the photoreceptor cell to detect light depends on its interaction with the pigmented cell.

In the vertebrate eye the RPE is located between the light-sensitive outer segments of the photoreceptors and blood supply of the choroid. It is a hexagonally packed, tight-junction, connected, single sheet of cells containing pigment granules (Figures 1 and 2, PG) and organelles for digestion of photoreceptor outer segment membranes into phagosomes (Figure 2, Phagosomes, Ph). With its apical membrane and processes (Figure 1, ap), it faces the subretinal space which is occupied by an extracellular matrix specialized to enable interaction between the RPE and the light sensitive outer segments of the photoreceptors (Figures 1 and 2, os, ROS) (11-14). With its basolateral membrane, the RPE is in contact with the highly specialized multilayered Bruch's membrane (Figures 1 and 2, BM) which also represents an interaction matrix for the RPE with blood flow in the fenestrated vessels of the choroid (the choriocapillaris, CC; Figures 1 and 2) (15).

Figure 3 shows a summary drawing of the pigment epithelium and its functional attributes that will be discussed in the following chapter. Pigment epithelial functions are: light absorption, epithelial transport, spatial ion buffering, visual cycle, phagocytosis, secretion and immune modulation.

2. Absorption of light

At a first glance, light absorption is the most obvious function of the RPE. The cells are heavily pigmented and cover the inner surface of the bulbus. As in a camera, this improves the quality of the optical system of the eye by absorbing scattered light. For a long time this function was believed to be the only one by the RPE. Now we know of a great many other functions of the RPE (see above, Figure 3).

In the human eye, light is focused by a lens onto the cells of the macula resulting in a strong concentration of photo-oxidative energy in the retina (16-18). Furthermore, the choroid is a tissue which shows a higher specific blood perfusion than the kidney (19-22). But, the oxygen extraction by the retina during the passage through the

choroid is relatively low. The venous blood from the choroid still shows an oxygen saturation of more than 90%. Thus the RPE is exposed from the retinal side to a strong photo-oxidative energy and from the blood side by an overflow of oxygen. Photo-oxidation leads to damage of the photoreceptor outer segment tips so they need a constant renewal process from their base (see Photoreceptors, Webvision) (described below in section 6). The renewal process however involves the phagocytosis of destroyed and shed photoreceptor outer segments by the RPE. This adds a strong load of free radicals in addition to the high photo-oxidative environment. Thus the RPE has to be capable of maintaining the structural integrity of the retina by an efficient defense against free radicals, photo-oxidative exposure and light energy (16-18).

For this purpose the RPE has several lines of defense and the first line is the melanosomes or pigment granules (17). Depending on the light-dark cycle, they move inside the cytoplasm to the apical processes under light conditions. The light absorption by the melanosomes heats up of the RPE/choroid complex to temperatures above 40^{o} C (23, 24). It is possible that the high perfusion of the choroid serves to transport away the heat from the retina. Further lines of defense are high concentrations of non-enzymatic and enzymatic anti-oxidants and the ability of the cells to repair damaged lipids, proteins and DNA. In man, these mechanisms provide protection of the photoreceptor/RPE/choroid complex and maintenance of the structural integrity of this complex for decades. However, it is known that the human retina accumulates lipofuscin (an end product of phagosome breakdown) during its life-time, beginning at a young age. This accumulation debilitates the RPE cells and their lines of defense become weaker over time (17, 25-29). It is believed that a reduced capability to absorb light and to compensate for oxidative damage are important factors initiating the chain of events leading to the onset of age-related macular degeneration in the older population (see Age-Related Macular Degeneration, Webvision).

3. Epithelial transport

The RPE forms a tight-junction epithelium located between the blood flow of the choroid and the outer segments of the photoreceptors. There are tight junction between the lateral surfaces of the hexagonal epithelial sheet (Fig. 2, TJ) (4, 30, 31). In this way the RPE forms a part of the blood/retina barrier. The barrier function of a tight epithelium implies an efficient isolation of the inner retina from systemic influences at the choroidal side.

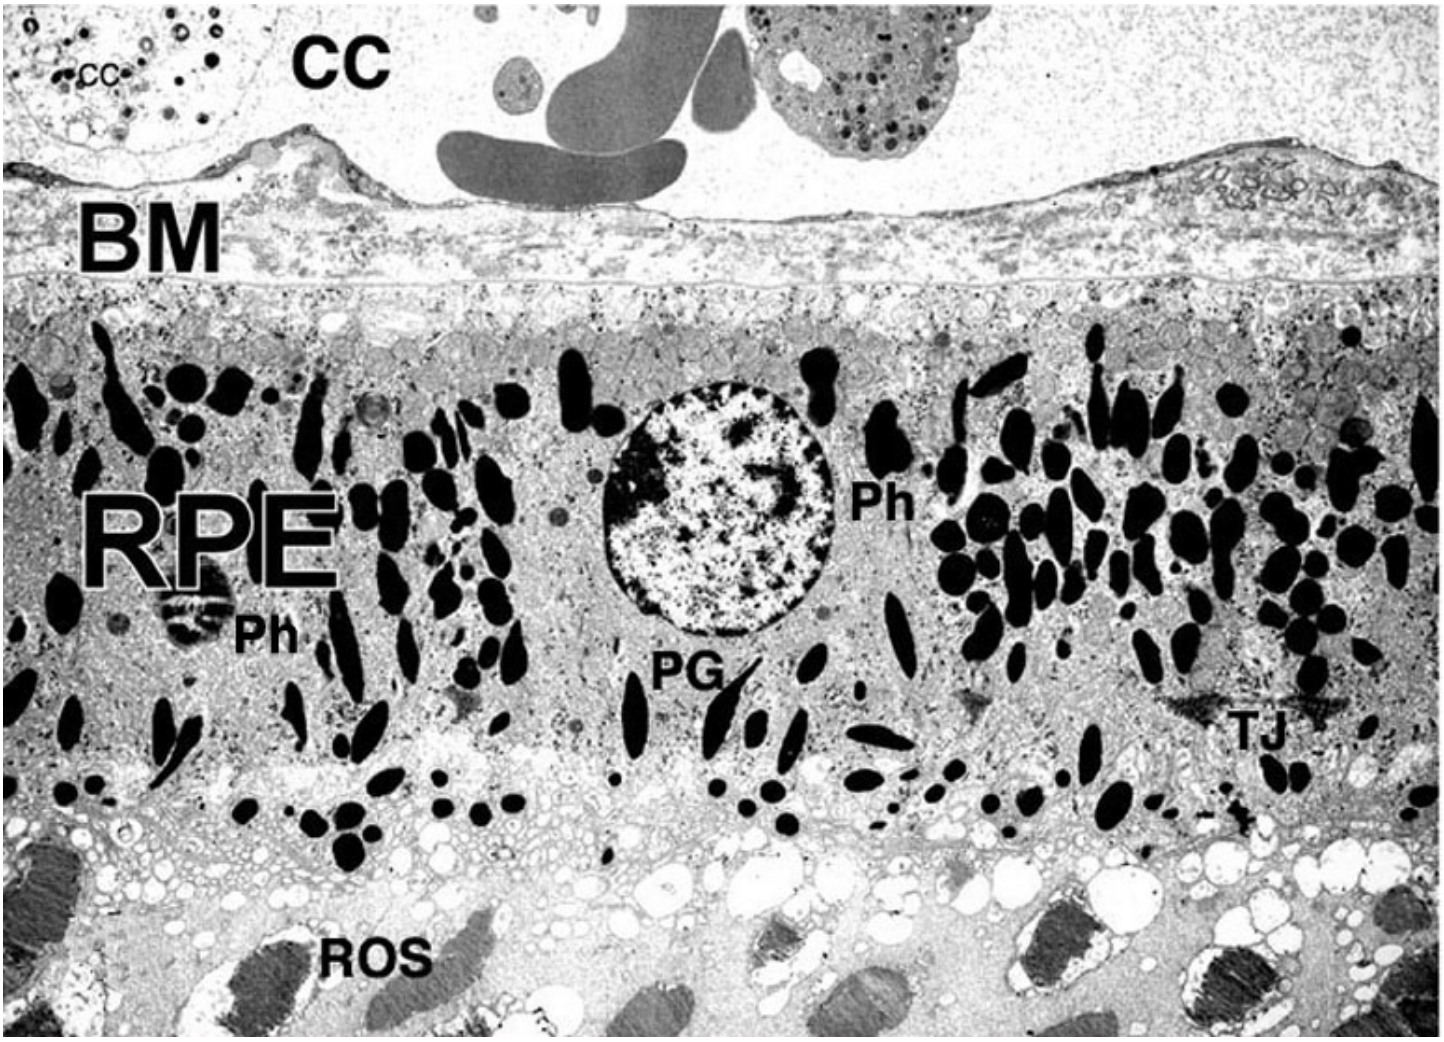

Figure 2. Transmission electron micrograph of the RPE cells and the RPE-choroid interface in a normal human donor eye. cc, choriocapillaris; BM, Bruchs membrane; RPE, retinal pigment epithelium; ROS, rod photoreceptor outer segments; Ph, phagosomes; PG, pigment granules; TJ, tight junctions.

This is of importance for the immune privilege of the eye (see section 8) and for a highly selective transport between the blood and the subretinal space. This epithelial transport serves to supply nutrients to the photoreceptors (transport from the blood to the retinal side), control the ion homeostasis in the subretinal space and to eliminate water and metabolites from retinal tissue (transport from the retinal to the blood side).

Transport from the blood side to the retina

The photoreceptors are highly specialized cells which need the supply of essential metabolites. These are glucose for energy metabolism, retinal for the visual cycle of the opsins, and ω-3 fatty acids for specialized phospholipids to compose the membranes of photoreceptors which are highly enriched by ω-3 fatty acids. All these nutrients are taken up by the RPE and are transported to the photoreceptors. To transport glucose the RPE expresses the glucose transporters GLUT1 and GLUT3 in both the apical and basolateral membrane (32, 33). GLUT3 serves for the basic transport whereas GLUT1 is responsible for an inducible transport system to meet metabolic needs. The transport of retinal starts with uptake of retinol from the blood and is then transferred into the visual cycle of retinal which is described below (Section 5). To transport ω-3 fatty acids, the RPE preferentially takes up 22:6ω3 fatty acid in a concentration dependent manner (34, 35). Inside the RPE the compound is incorporated

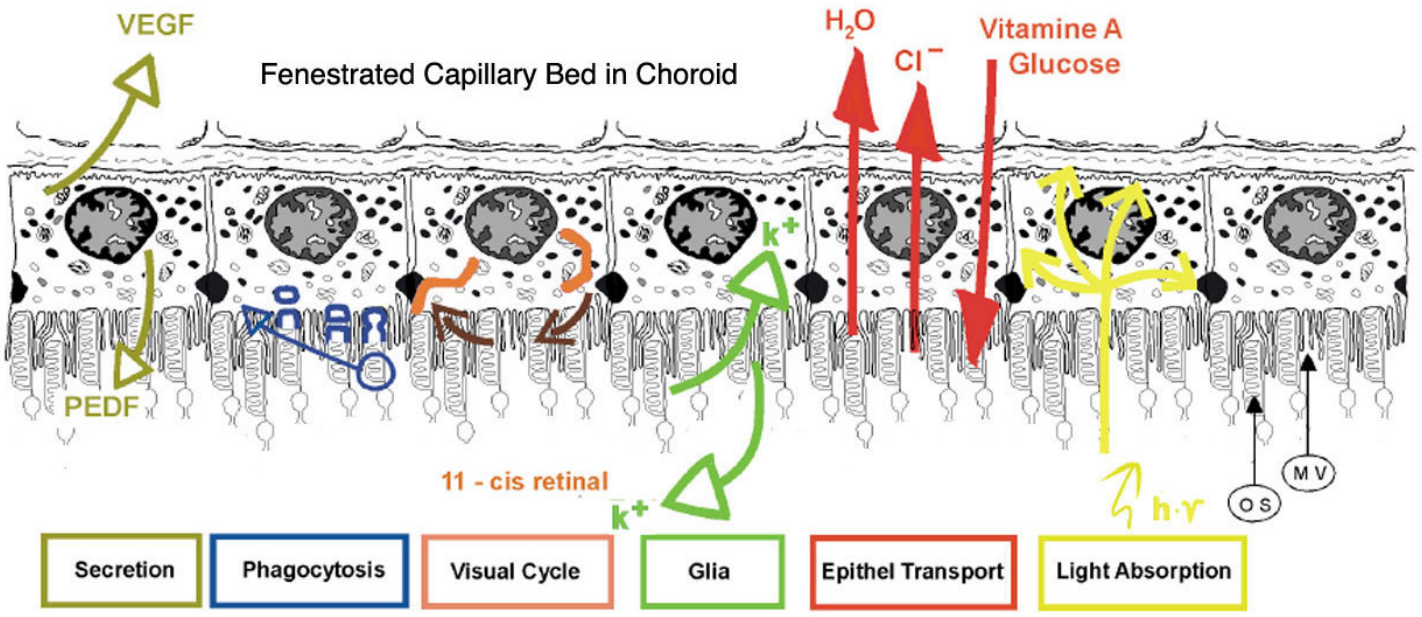

Figure 3. Summary diagram of the major functions of the RPE from Strauss, 2005 (2).

into glycerolipids for synthesis, storage and subsequent delivery in a recycling process involving the phagocytotic process (see Section 6).

Transport from the subretinal space to the blood side

Mainly water, ions and metabolic end products are transported from the retinal side to the blood side (4, 30, 31, 36, 37). The retina is the tissue with the highest cell density in the human body. The photoreceptors, neurons and glial cells, have a high metabolic turn-over rate leading to production of metabolic water which accumulates in the retina. In addition, intraocular pressure drives a movement of water from the anterior eye towards the retina where it accumulates. Furthermore, a large part of the metabolic activity of retinal cells results in the production of lactic acid. Up to 19 mM lactic acid concentration has been reported in the subretinal space (38).

Water is eliminated from subretinal space by active transport by the RPE. The transportation rate was estimated to range from 1.4 to 11 µl x cm^{-2} x h^{-1} (39-41). This transport of water is driven by a transepithelial transport of Cl^- from subretinal space to the blood side through the RPE (Figure 4A). The Cl^- transport is an active transport driven by the activity of the apically localized Na^+/K^+-ATPase which uses the energy of ATP to transport 3 Na^+ in exchange for 2 K^+ against concentration gradients out of RPE cells. The K^+ ions which are transported into the cytoplasm recycle through apically localized Kir7.1 inward rectifier K^+ channels into the subretinal space (42). This results in a gradient for Na^+ into the RPE cell which has a low intracellular Na^+ concentration. The recycling of K^+ back into the subretinal space through inward rectifier K^+ channels enhances the transport efficiency by the Na^+/K^+-ATPase because it decreases the gradient for K^+ across the apical membrane of the RPE (43). The reason why the Na^+/K^+-ATPase is apically located is not clear. As will be explained below in Section 4, it probably serves to maintain the ion homeostasis in the subretinal space by spatial buffering of ions. The Cl^-driven transport of water establishes an adhesion force between the RPE and the neuronal retina which is removed by blocking the Na^+/K^+-ATPase with Ouabain (44).

The transportation pathway begins with an uptake of Cl^- from subretinal space, across the apical membrane of the RPE cells. Driven by the gradient for Na^+ which is established by the Na^+/K^+-ATPase, Cl^- is taken into the cell across the apical membrane by the activity of the $Na^+/K^+/2Cl^-$ co-transporter (4, 30, 36, 45). Since K^+ recycles back through apical inward rectifier channels into the subretinal space and Na^+ is transported out of the

cell by the Na^+/K^+-ATPase, the transport activity of the $Na^+/K^+/2Cl^-$ co-transporter results mainly in an accumulation of Cl^- inside RPE cells. Depending on the species, the intracellular Cl^- activity ranges from 20 – 60 mM (46-48). Since the basolateral membrane has a large Cl^- conductance the Cl^- which accumulates in the intracellular space of the RPE leaves the cell across the basolateral membrane to the blood side. This results in a basolateral negative transepithelial potential ranging between 5 -15 mV (30, 31).

A crucial step in this transport pathway is the basolateral membrane conductance for Cl^-. Thus mechanisms which regulate the efflux pathway across the basolateral membrane regulate the overall epithelial transport of Cl^- across the RPE. For this purpose, different types of Cl^- channels, which differ in their activation mechanisms to link Cl^- conductance to different second-messenger pathways of RPE cells, are localize in the basolateral membrane. A basic transportation rate seems to be provided by the ClC-2 Cl^- channel (49).

In a knock-out mouse model for ClC-2 Cl^- channels, an absence of a transepithelial potential is observed and the mice become blind, showing a phenotype comparable to that of Retinitis pigmentosa (49). Another basolateral Cl^- channel might be CFTR (cystic fibrosis transmembrane regulator) which enables a cAMP-dependent modulation of the Cl^- transport across the basolateral membrane (50, 51) and a Ca^{2+}-dependent Cl^- channel which enables a regulation of the transport by changes in intracellular Ca^{2+}. The molecular identity of this Cl^- channel is possibly bestrophin-1 (52).

As mentioned above the metabolic activity results in large concentrations of lactic acid in the subretinal space. Lactic acid is eliminated from subretinal space by the RPE (37, 53) (Figure 4B). Uptake of lactic acid occurs across the apical membrane of the RPE by the mono-carboxylate transporter-1 MCT1 and the release of lactic acid to the blood side across the basolateral membrane occurs via the activity of the mono-carboxylate transporter-3 (MCT3). The transport of lactic acid requires an efficient pH regulation and an adaptation of the volume transport because a large amount of transported water is metabolic water. The pH regulation of the RPE cells involves the activity of Na^+ coupled, secondary active transport mechanisms of the apical membrane of the RPE (54, 55). H^+ ions are removed from the cytoplasm by the Na^+/H^+-exchanger and HCO_3^- is accumulated in the cytosol by the transport activity of the $Na^+/2HCO_3^-$ co-transporter (56). At the basolateral membrane of the RPE, a HCO_3^-/Cl^- exchanger interferes with control of intracellular HCO_3^- by the apical $Na^+/2HCO_3^-$ co-transporter. At high pH the RPE transports HCO_3^- from subretinal space to the blood side. At low pH the basolateral HCO_3^-/Cl^- exchanger is stimulated, which increases the intracellular HCO_3^- concentration and HCO_3^- released to the subretinal space across the apical membrane by the activity of the Na^+/HCO_3^- co-transporter, which runs then in the reverse mode.

The involvement of the HCO_3^-/Cl^- exchanger at the basolateral membrane links the water transport to the pH regulation and therefore to the transport of lactic acid (46, 47, 56-62). At resting conditions, the HCO_3^-/Cl^- exchanger in the basolateral membrane reduces the transportation rate of Cl^- across the basolateral membrane, and therefore, the transepithelial transport of volume, because a small amount of Cl^-, which leaves the cell through basolateral Cl^- channels, is transported back into the intracellular space by the activity of the HCO_3^-/Cl^- exchanger. At low pH the HCO_3^-/Cl^- exchanger transports Cl^- out of the cell to take up HCO_3^- for pH regulation, which in turn leads to increase of Cl^- and volume transport. This is supported by the pH sensitivity of basolateral ClC-2 Cl channel which increases its activity by a decrease of extracellular pH. The fact that the transport of volume is linked to the HCO_3^- transport is used in the treatment of macular edema. Application of inhibitors of carbonic anhydrase increases the speed of volume resorption by the RPE (62, 63). The transport of osmolytes across the RPE from subretinal space to the blood side establishes an osmotic driving force for water across the RPE.

The RPE is a tight epithelium which means that the transport of water cannot occur through any paracellular transportation route. All transported volume has to take the transcellular route. For this purpose the RPE expresses aquaporine-1 water channels which are localized in both the basolateral and the apical membrane of

the RPE (64, 65). However it has also been suggested that the mono-carboxylate transporters are able to transport water.

4. Spatial buffering of ions

As described above, the RPE maintains the ion homeostasis of the subretinal space by epithelial transport of ions. However, the light-dependent changes of the photoreceptor activity and the activity of the second order neurons lead to very fast changes in the subretinal space, which requires a fast and capacitative compensation by the RPE (66). If these changes were not compensated for, the overall excitability of the photoreceptors and the neurons would quickly change and proper signal transduction of visual information would not be possible. The normal transepithelial transport of ions would be too slow to compensate quickly enough for these changes.

Other mechanisms based on the activity of voltage-dependent ion channels add to the basic transepithelial transport of ions. In this process the compensation for changes in the subretinal K^+ concentration and retinal volume are most important. In the dark cGMP-gated cation channels are open in the outer segments of photoreceptors. The influx of Na^+ and Ca^{2+} through these channels is counterbalanced by an outflow of K^+ at the inner segment. These ionic currents represent the so called dark current (67). When light falls onto photoreceptor outer segments, the cGMP-dependent cation channels are closed and the K^+ outflow at the inner segment becomes smaller. At the same time Na^+/K^+-ATPase at the inner segment takes up K^+ into the photoreceptor. This results in a reduction of the K^+ concentration in the subretinal space from 5 mM to 2 mM (4, 66). This decrease is compensated for by the RPE. The mechanism is based on the fact that the ion conductance of the apical membrane of the RPE is dominated by a K^+ conductance (36). The light-induced decrease in the subretinal K^+ concentration leads to hyperpolarization of the apical RPE membrane. This in turn leads to activation of inward rectifier K^+ channels generating an efflux of K^+ into the subretinal space, and to an increase of the subretinal K^+ concentration back to normal values (68). For this purpose the RPE expresses Kir7.1 channels located in the apical membrane of the RPE (69). Kir7.1 channels were found to display a rather mild rectification but show increased conductance when extracellular K^+ is decreased. This makes these K^+ channels the ideal candidates for this function (42, 70). This compensatory pathway enables fast reactions of the RPE to either decreases or increase in the subretinal K^+ concentration.

A model, which has been developed by LaCour, explains the compensation of K^+ concentration changes by epithelial transport with a rather small transepithelial K^+ transport from subretinal space to the blood side under control conditions (68, 71). The major part of K^+ which is taken up across the apical membrane, via the activity of the $Na^+/K^+/2Cl^-$ co-transporter, recycles back into subretinal space through apical K^+ channels. A smaller part leaves the cell across the basolateral membrane to the blood side. In the case of a decrease of the subretinal K^+ concentration, apical membrane conductance for K^+ increases. This leads to an increases in the proportion of K^+ which recycles back to the subretinal space and, subsequently, to further decrease in the transepithelial transport of K^+ by the RPE. In the situation where the subretinal K^+ concentration increases, the apical membrane conductance decreases due to inactivation of Kir7.1 channels and due to depolarization of the apical membrane. Now a smaller proportion of K^+ which is taken up across the apical membrane can recycle back to the subretinal space. This increases the amount of K^+ which is transported across the RPE to the blood side. Due to the fast coupling of K^+ concentration with apical transmembrane potential, and ion conductance, the RPE is able to respond to changes in the subretinal K^+ concentration as fast as they occur.

When the retina is stimulated by light, a small and transient change in the extracellular volume in the retina is observed (36, 72). These changes are compensated for by Müller glia cells in the inner retina and by the RPE at the outer retina. Again the compensation mechanism is a fast reaction which adds to the sustained transepithelial transport by the RPE, in this case the transport of water. The fast coupling is again enabled by voltage-dependent modulation of ion transport. As described above the transport of water into the RPE is driven by a transepithelial transport of Cl^- which is linked to the transport of HCO_3^- and lactate. The light-dependent

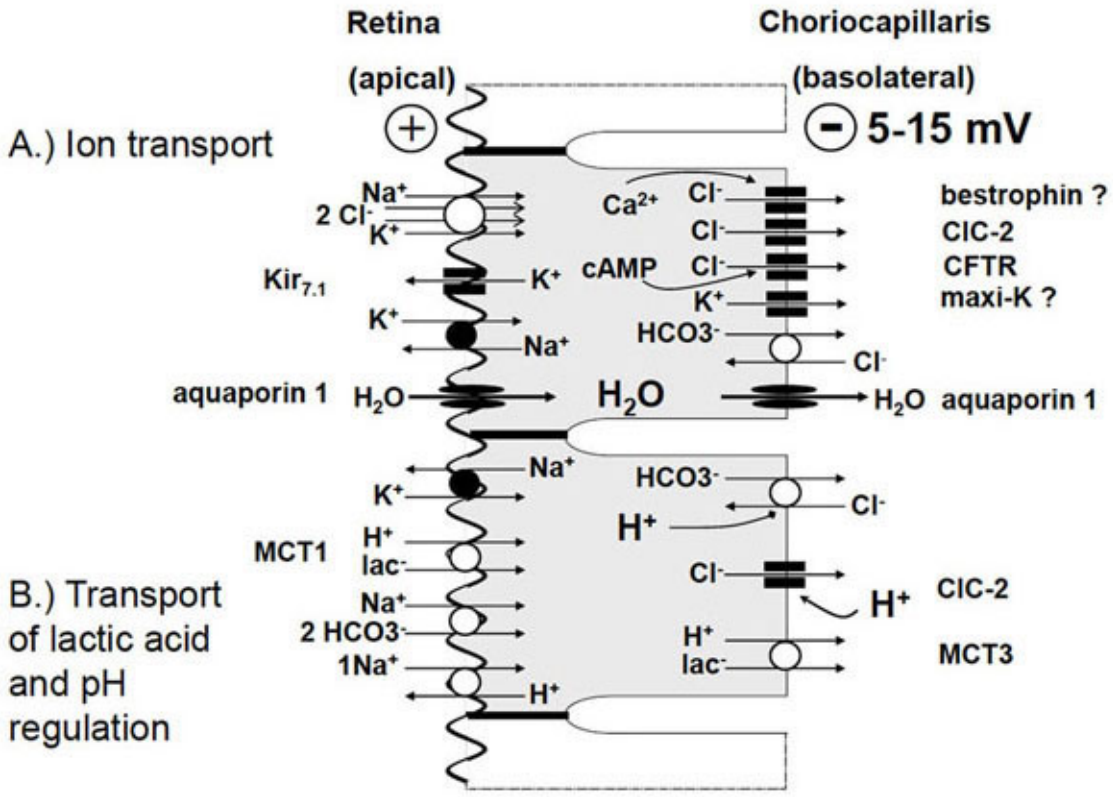

Figure 4. Epithelial transport and pH regulation in RPE cells. A. Transepithelial transport of ions across the RPE: Cl^- is predominantly transported from the subretinal space to the choriocapillaris. This transport drives water through aquaporins from the subretinal space to the choriocapillaris. The driving force for epithelial transport is provided by the apically located Na^+/K^+-ATPase. K^+ transported by the ATPase recycles through the apical membrane and facilitates establishment of a Na^+ gradient into the cell. The Na^+ gradient serves to drive uptake K^+ and Cl^- on the apical side resulting in a high intracellular Cl^- activity. Cl^- is extruded from the cell on the basolateral side through Cl^- channels. The efficiency Cl^- extrusion from the cell is reduced by activity of a Cl^-/HCO_3^- exchanger which transports Cl^- back into the cell. B) Transport of lactic acid and pH regulation: Lactic acid is removed from the subretinal space by the lac-/H^+ cotransporter. Through the basolateral membrane lactic acid leaves the cell using a different subtype of lac-/H^+ cotransporter. The necessary pH regulation occurs using a Na^+/H^+ exchanger and a Na^+/HCO_3^- exchanger in the apical membrane and a Cl^-/HCO_3^- exchanger at the basolateral membrane. The activity of Cl^-/HCO_3^- exchanger is supported by basolateral Cl^- channels which result in a cycling of Cl^- across the basolateral membrane. In the case of intracellular acidification the Cl^-/HCO_3^- exchanger is inhibited whereas Cl^- channels are activated. This increases the net water transport. Abbreviations: ClC-2, voltage-dependent Cl channels of the ClC family; CFTR, cystic fibrosis transmembrane conductance regulator; Kir7.1, inwardly rectifying K^+ channel 7.1; maxi-K, large conductance Ca^{2+}-dependent K^+ channel; MCT1, monocarboxylate transporter 1; MCT3, monocarboxylate transporter 3. From Strauss, 2005 (2).

modulation of water transport is based on the fact that the apical Na^+/HCO_3^- co-transporter is electrogenic. This means that this transportation activity is not electroneutral because it does not transport an equivalent amount of positive and negative charges (56, 73-75). The light-dependent hyperpolarisation of the apical membrane reduces the transport rate of Na^+/HCO_3^- co-transporter which in turn leads to intracellular acidification. As described above the water transport can be enhanced by intracellular acidification which leads to an increased efflux of Cl^- across the basolateral membrane of the RPE.

5. Visual Cycle

Vision starts with the absorption of a photon by the chromophore of rhodopsin, 11-cis retinal (67, 76-78). After absorption of a photon 11-cis retinal has changed its conformation into all-trans retinal and rhodopsin becomes meta-rhodopsin in a defined time before its activity is terminated by phosphorylation. After additional reaction

steps, rhodopsin is able to exchange all-trans retinal for 11-cis retinal and it can be activated again by a photon. Thus all-trans retinal needs to be re-isomerized to ensure a sufficient delivery of 11-cis retinal for all visual needs and proper visual function (1, 79). Since photoreceptors do no express a re-isomerase for all-trans retinal, the re-isomerization takes place in the RPE. For this purpose all-trans retinal is delivered to the RPE, re-isomerised to 11-cis retinal and delivered back to photoreceptors. This process is called the visual cycle of retinal (80-82, see Phototransduction, Webvision]. The visual cycle for rods occurs via the RPE (Figure 5). The visual cycle for cones is less clear. It can be that part of the cone all-trans retinal is recycled by the RPE and part is recycled by Müller glia cells.

The visual cycle of rods starts in the discs in the outer segments where all-trans retinal is transferred from the intradiscal space to the cytosolic space of the rod outer segment by an ATP-driven flippase ABCR or ABCA4 (ATP-binding cassette protein). This step involves the reaction of all-trans-retinal with phosphatidylethanolamine to N-retinylidine-phosphatidylethanolamine. In the next step all-trans retinal is reduced to all-trans retinol by a membrane bound retinol-dehydrogenase and is delivered to the subretinal space where it is loaded to IRBP (interstitial retinal binding protein), a carrier protein, and transported to the RPE. After uptake into the RPE all-trans retinol is transferred to CRBP (cellular retinol binding protein) which delivers all-trans retinol to a protein complex of several enzymes. This complex consists of LRAT (lecithin:retinol transferase), RPE65 (RPE protein with 65 kDa) and RDH5 (11-cis-retinol dehydrogenase). The three enzymes catalyze the three step reaction from all-trans retinol to 11-cis retinal: esterification of retinol by adding an aycl-group (LRAT), re-isomerisation to 11-cis using the energy from ester-hydrolysis (RPE65) and oxidation to 11-cis retinal (RDH5). The reaction is accelerated by CRALBP (cellular retinylaldehyde-binding protein) which is also part of the enzyme complex and to which 11-cis retinal is immediately transferred. From CRALBP 11-cis retinal is released to IRBP and transported back to photoreceptors. The exact mechanisms by which all-trans retinol enters the RPE and by which 11-cis retinal leaves the RPE are not clear.

The visual cycle fulfills an essential task of maintaining visual function and needs therefore to be adapted to different visual needs such as vision in darkness or lightness (1, 79). For this, functional aspects come into play: the storage of retinal and the adaption of the reaction speed. Basically vision at low light intensities requires a lower turn-over rate of the visual cycle whereas during light the turn-over rate is much higher. In the transition from darkness to light suddenly, large amount of 11-cis retinal is required. This comes not directly from the visual cycle but from several retinal pools of retinal binding proteins which are connected to each other by the transportation and reaction steps of the visual cycle. The first pool is the amount of 11-cis retinal which is in the rod outer segments. When the level of this pool is reduced, then the refilling of this pool is started by uptake of retinal from the next pool: the IRBP in the subretinal space. A drop in the retinal level of this pool is refilled from CRALBP which can be refilled from RPE65. With the connected pools for 11-cis retinal the changes in illumination can quickly be adapted. Thus, the RPE plays a crucial role in visual function, in the light adaptation. RPE65 plays a double crucial role in the visual cycle (83, 84). On one hand it catalyses the re-isomerization reaction at light conditions. In the dark it functions as a retinol binding protein and represents an important retinol pool for the visual cycle. RPE65 combines both essential functions for adaptation of the visual cycle: storage and enzyme reaction.

6. Phagocytosis of photoreceptor outer membranes

As mentioned above the light-sensitive photoreceptor outer segments (POS) goes through a constant destruction due to photo-oxidative damage. To maintain vision, the POS are constantly renewed by shedding the destroyed tips of the POS and by phagocytosis of the POS by the retinal pigment epithelium (3, 4, 85-89). This is a diurnally regulated process which takes place in the morning and is triggered by light (86-88, 90-93). It takes approximately eleven days to renew the whole length of the photoreceptor outer segment. Night active or day active animals show the same diurnal rhythm of phagocytosis (94). In this process the proper length of the photoreceptor outer segments is maintained by a coordinated activity of phagocytosis and POS shedding. The

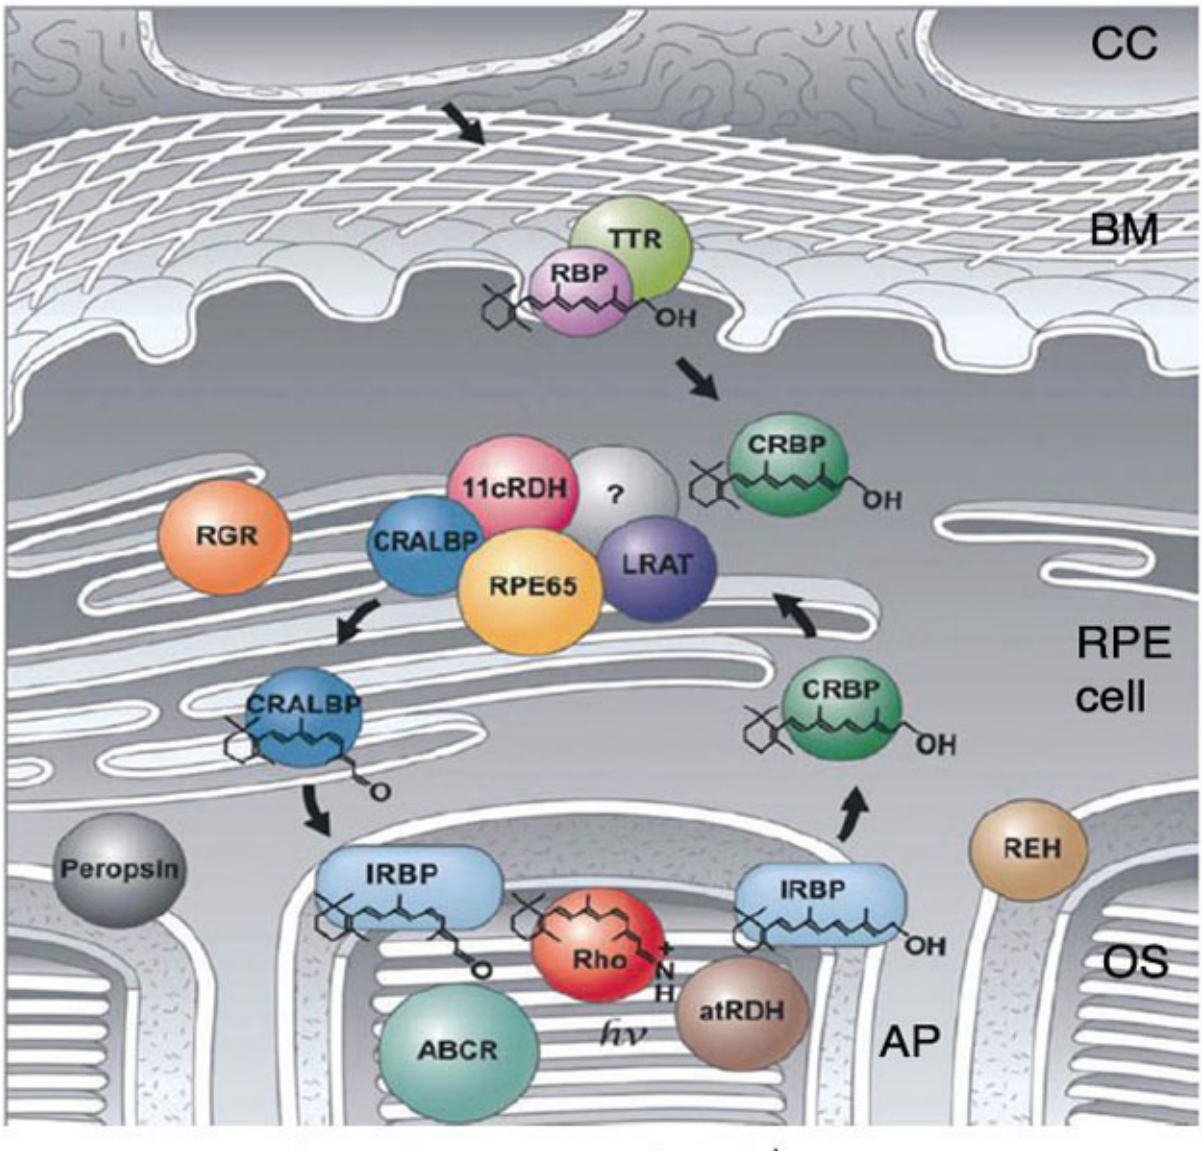

Figure 5. The visual cycle as adapted from Thompson and Gal (81). Light transduction starts with photon absorption by rhodopsin. The process of light absorption underlies the stereochemical change of 11-cis retinal into all-trans retinal. All-trans retinal is metabolized into all-trans retinol and transported to the RPE. In the RPE retinol is re-isomerized to 11-cis retinal and then redelivered to the photoreceptors. The regeneration seems to follow two pathways. One occurs through an as yet unidentified enzyme thought to function as an isomerohydrolase. The second pathway involves a light-dependent pathway using the RPE-retinal G-protein coupled receptor which isomerises all-trans retinal to 11-cis retinal, following light absorption. Abbreviations: CC, choidocapillaris; BM, Bruchs membrane; OS, outer segments; AP, apical processes; IRBP, interstitial retinal binding protein; CRBP, cellular retinol binding protein; CRALBP, cellular retinaldehyde binding protein; atRDH, all-trans retinol dehydrogenase; 11cRDH, 11cis retinol dehydrogenase; LRAT, lecithin retinol acyltransferase; RPE65, RPE specific protein with MD 65 kD; RGR, RPE-retinal G-protein coupled receptor; RBP/TTR, retinol-binding protein/transthyretin complex.

process is not only regulated by the circadian rhythm but also by coordination between the RPE and the photoreceptors.

Primarily three receptors have been identified to be involved in the regulation of phagocytosis of POS by the RPE (Fig. 6, above): CD36, receptor-tyrosinekinase c-mer (MerTK) and $\alpha_V\beta_5$ integrin (95-102). Basically CD36 is required for the process of POS internalization, MerTK is required to activate the phagocytosis and $\alpha_V\beta_5$ integrin is required for binding of POS, and for the initiation of the phagocytosis in the diurnal state. The interplay between these receptors ensures regulated and coordinated POS phagocytosis. The relevance of these

receptor molecules in the cell membrane was unraveled in the phenotypes of different knock-out animals. A loss of MerTk leads to human Retinitis pigmentosa and to a comparable type of retinal degeneration in the Royal College of Surgeons (RCS) rat which represents the oldest animal model for inherited retinal degeneration [100-102]. The loss of β5-integrin leads to a loss of circadian regulation of phagocytosis with a subsequent late onset of lipofuscin accumulation in the RPE (97-99).

It is not known what signaling molecule enables the communication between the RPE and the photoreceptors at the start of phagocytosis. It may be that the presence of the shed POS is sufficient to initiate the phagocytosis (103). The first step in this process is the binding of POS to the RPE through the αVβ5 integrin. The secreted glycoprotein milk fat globule-EGF8 (MFG-8), which is expressed by the RPE and can activate αVβ5 integrin, seems to be an important activator of diurnal stimulation of phagocytosis (104-106). Activation of the integrin produces an intracellular signaling cascade which involves focal adhesion kinase (FAK) (98). FAK is able to phosphorylate MerTK which can now be activated. The activation mechanism for MerTK is not clear. The natural ligand for MerTK is a protein called Gas6 (growth-arrest-specific protein 6). Gas6 is found in the retina and is strongly expressed by the RPE (107). Thus it can be that the Gas6 is an autocrine stimulator of phagocytosis by the RPE.

However a recent publication suggested that probably another ligand for MerTk is playing a role. In this publication it was shown that the tubby and tubby-like proteins, which are found in photoreceptors, can bind to MerTK and represent "eat-me" signals for the process of phagocytosis by RPE cells (and also for macrophages) (108). Activation of MerTK results in an intracellular signaling cascade which involves the generation of inositol-1,4,5-trisphosphate (InsP3) and a subsequent increase in intracellular free Ca^{2+}. The phagocytosis by itself is enabled by the phagocytosis receptor CD36.

7. Secretion

The RPE is an epithelium which closely interacts with photoreceptors on one side but must also be able to interact with cells on the blood side of the epithelium, such as endothelial cells or cells of the immune system. In order to communicate with the neighboring tissues the RPE is able to secrete a large variety of factors and signaling molecules. It secretes ATP, fas-ligand (fas-L), fibroblast growth factors (FGF-1, FGF-2, and FGF-5), transforming growth factor-β (TGF-β), insulin-like growth factor-1 (IGF-1), ciliary neurotrophic factor (CNTF), platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), lens epithelium-derived growth factor (LEDGF), members of the interleukin family, tissue inhibitor of matrix metalloprotease (TIMP) and pigment epithelium-derived factor (PEDF) (2).

In the healthy eye some of these factors are constantly released and help to maintain the structural integrity of the neighboring tissues. PEDF is for example a neurotrophic factor which is secreted to the apical/retinal side of the RPE to stabilize the neuronal retina by prevention of apoptosis (109-111). VEGF and TIMP are secreted to the basolateral side of the RPE and are required to stabilize the fenestrated structure of the endothelium of the choroid (112). Other factors are activated when the retina or the RPE are exposed to pathological conditions such as hypoxia or metabolic stress. In order to enable a finely regulated secretory activity of the RPE in health and disease the RPE expresses a number of Ca^{2+}-dependent regulatory mechanisms (113) (Figures 7 and 8). If the regulation of secretion fails under certain pathologies then the RPE will promote proliferative diseases such as choroidal neovascularisation.

The main trigger of secretory activity in the RPE is an increase in intracellular free Ca^{2+} second-messengers. In order to regulate secretion specific for the different factors, the RPE expresses a large number of different ion channels or transporters which increase intracellular free Ca^{2+}. As in many other secretory tissues such as the beta-cells of the pancreas or neuroendocrine cells, the RPE expresses voltage-dependent Ca^{2+} channels of the neuroendocrine subtype. The latter are composed of the $Ca_V1.3$ subtype (114-116). In the RPE the L-Type channel is regulated by either cytosolic tyrosine kinases, such as src-type kinase, or by receptor tyrosine kinase,

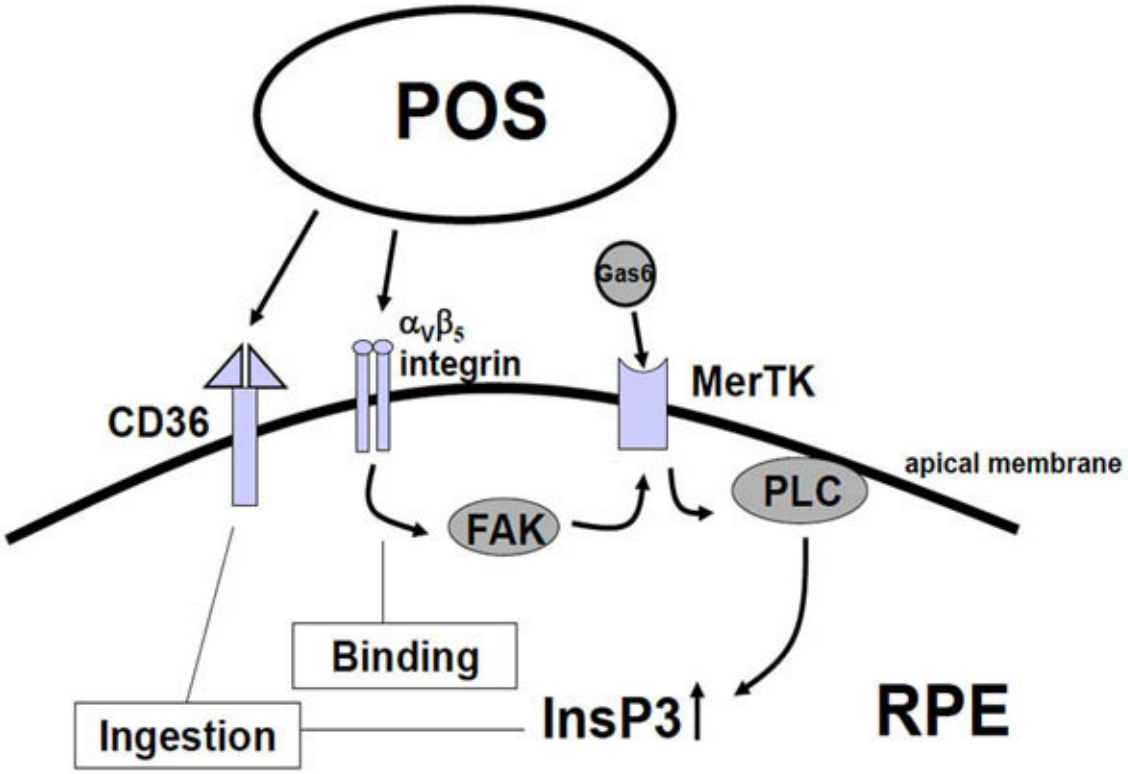

Figure 6. Phagocytosis.The figure shows the molecules involved in the initiation of photoreceptor outer segment phagocytosis. The initiation starts with binding of photoreceptor outer segment membranes. The event of binding is transduced into an intracellular signal, a rise in intracellular InsP3, which in turn leads to ingestion of the bound photoreceptor outer segment membranes. Binding is likely mediated by integrins and signal transduction occurs through the receptor tyrosine kinase MerTK. Ingestion involves the macrophage receptor CD36. Coordinated signal transduction occurs through integrin and MerTK interaction through the focal adhesion kinase. Abbreviations: CD36, macrophage phagocytosis receptor; FAK, focal adhesion kinase; Gas6, Growth-arrest-specific protein 6; InsP3, inositol-1,4,5-trisphosphate; MerTK, receptor tyrosine kinase c-mer; PLC, phospholipase C; POS, photoreceptor outer segment. From Strauss, 2005 (2).

such as the FGF receptor FGFR-2 (117-119). Since a large number of factors are known to increase secretion by the RPE acting via tyrosine kinase, the L-type channel regulates of number of different factors.

Another Ca^{2+} channel, which is thought to be involved in the regulation of growth-factor secretion by the RPE, is the TRPV2 channel (transient-receptor-potential channel, vanilloid subtype) (120). Activation of this channel leads to an increased secretion of VEGF by the RPE. It seems that mainly the IGF-1 stimulated VEGF is increased by a signal cascade involving the activation of TRPV2. This ion channel is an interesting candidate for understanding some clinical observations. TRPV2 channels can be activated by heat. And heat-dependent activation of TRPV2 channels can stimulate the secretion of VEGF. Laser treatment which causes an increase in the temperature of the RPE is often used in the treatment of degenerations such as AMD or diabetic retinopathy. This same laser treatment most probably causes an increase in the secretion of growth-factors from the RPE and it may be that TRPV2 activation is permitting this secretion.

8. Immune privilege of the eye

The inner eye represents an immune privileged space which is disconnected from the immune system of the blood stream (121-123). The immune privilege is supported by the RPE in two ways. First, it represents a mechanical and tight barrier which separates the inner space of the eye from the blood stream. Second, the RPE

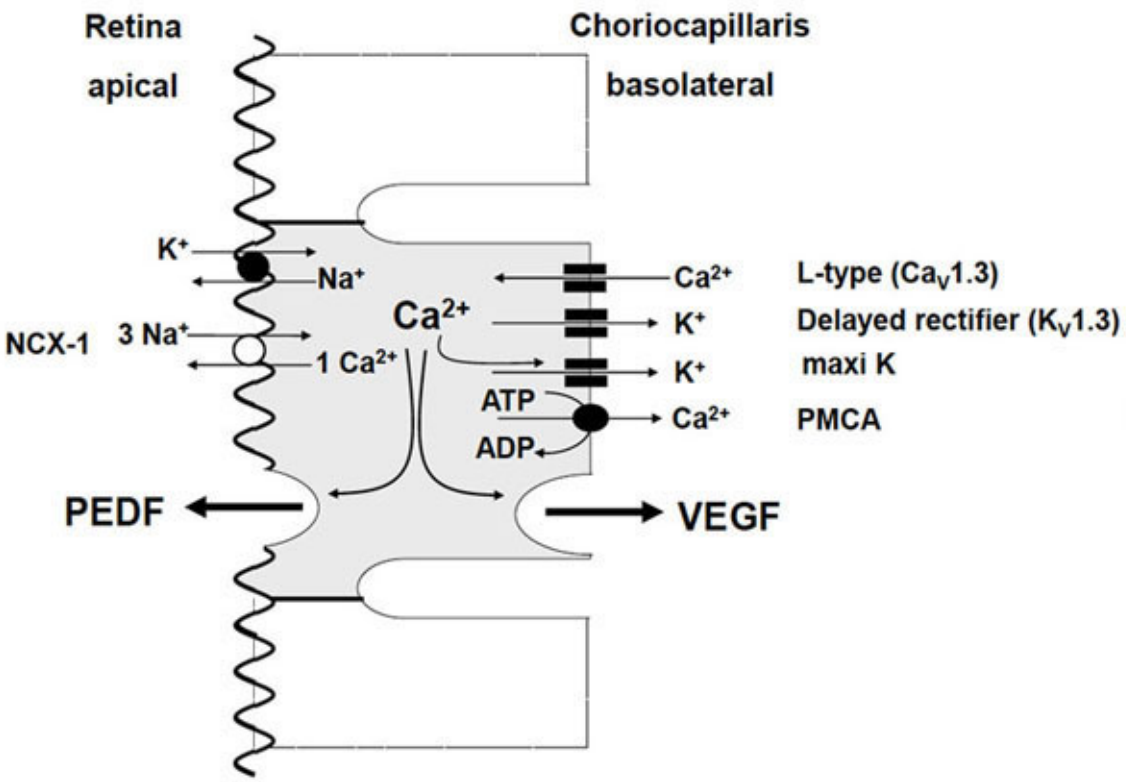

Figure 7. In the healthy eye the RPE secretes the neurotrophic factor PEDF into the subretinal space at the apical side of the RPE. The angiogenic factor, VEGF is secreted from the basolateral side into the extracellular matrix where it stabilizes the endothelium of the choriocapillaris and helps to keep it fenestrated. RPE cells express the neuroendocrine subtype of L-Type Ca2+ channels. Activation of these channels increases intracellular free Ca2+ which triggers the release of growth factors. This is terminated by either deactivation of L-type channels via activation of delayed rectifier K+ channels and hyperpolarization of the cell or by transport mechanism which decrease intracellular free Ca2+ such as Ca2+ ATPase or Na+/Ca2+ exchanger. Abbreviations: Delayed rectifier (KV1.3), outwardly delayed rectifying K+ channel composed of KV1.3 subunits; L-Type (CaV1.3), L-type Ca2+ channel of the neurendocrine subtype defined by the CaV1.3 or α1D subunit; maxi-K, large conductance Ca2+-dependent K+ channel; NCX-1, cardiac sodium calcium exchanger-1; PEDF, pigment epithelium-derived factor; PMCA, plasma membrane calcium-ATPase; VEGF, vascular endothelial growth factor. From Strauss 2005 (2).

is able communicate with the immune system in order to silence immune reaction in the healthy eye or, on the other hand, to activate the immune system in the case of disease (Figure 8). For these purposes the RPE can secrete immune modulatory factors such as interleukin-8 (IL-8) (124), complement factor H (CFH) (125, 126) or monocyte chemotactic protein-1 (MCP1) (127). Also the RPE is able to react to different factors of immune signaling cascades by expressing corresponding receptors. The receptors are MHC receptors (128, 129), toll-like receptors (130) or receptors for signaling molecules such as tumor-necrosis factor- α(TNF-α) (131).

The knowledge that the RPE is able to interact with the immune system has gained an increasing interest lately. Many types of retinal degeneration seem to be associated with an insufficiency to silence the immune reactions, for example, in age-related macular degeneration (See Age-Related Macular Degeneration (AMD), Webvision). On the other hand, an understanding of the immune privilege of the RPE is going to be helpful in the treatment of retinal degenerations by injected peptides, gene-therapy via viruses or in approaches using transplantation.

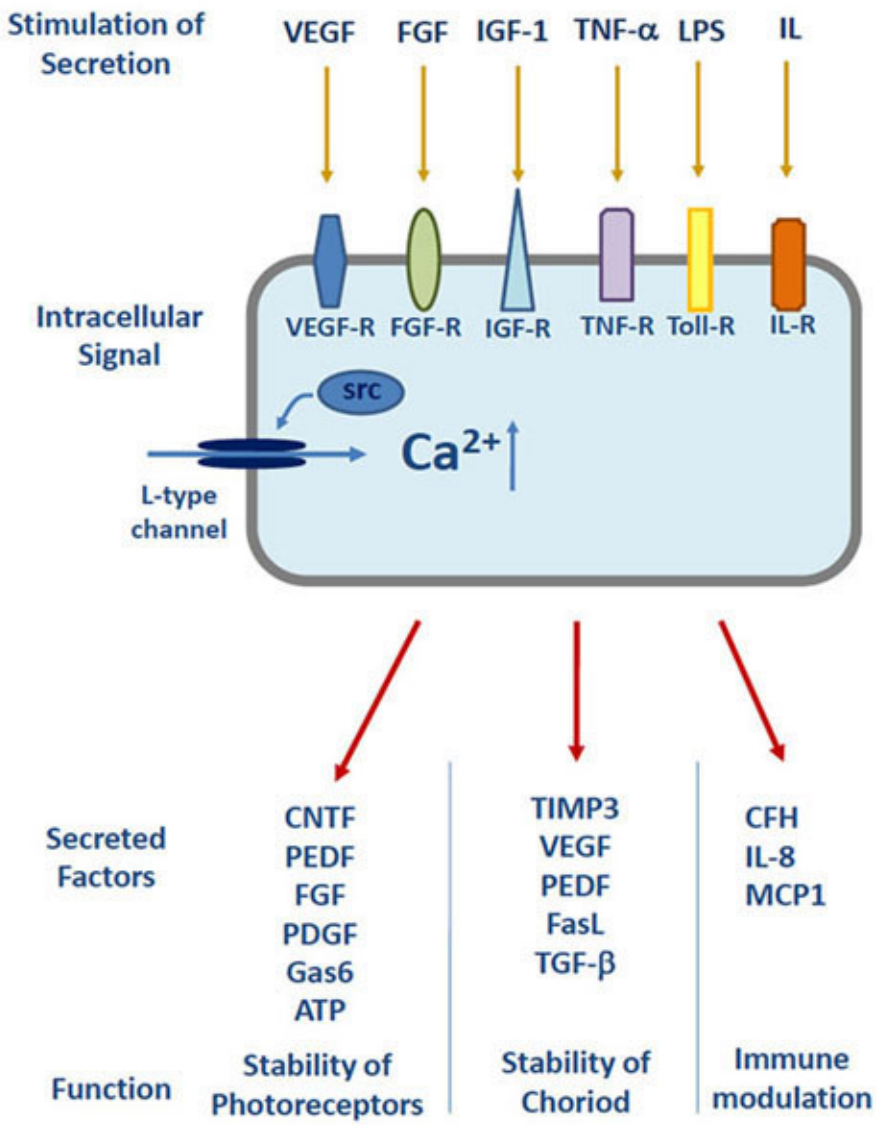

Figure 8. Growth-factor signalling in the RPE. Stimulation of secretion by the RPE and summary of the secreted molecules by their functional role. Trigger for secretion are Ca^{2+}-channels of the RPE. Abbreviations: ATP, Adenosine triphosphate; CFH, complement Factor H; CNTF, ciliary neurotrophic factor; FASL, CD95 apoptosis receptor ligand; FGF, fibroblast growth factor; IL, interleukin; IGF-1, insulin-like growth factor-1; LPS, lipopolysaccharides; PEDF, pigment epithelium-derived factor; PDGF, platelet-derived growth factor; TIMP3, tissue inhibitor of metallo matrix proteases; VEGF, vascular endothelial growth factor; TGF-β, transforming growth factor-β. Receptors: FGF-R, fibroblast growth factor receptor; IGF-R, insulin-like growth factor receptor; IL-R, interleukin receptor; MCP-1, monocyte chemotactic protein 1; TNF-R, tumor necrosis factor receptor; Toll-R, toll-like receptors; VEGF-R, vascular endothelial growrc, src-type intracellular tyrosine kinase. About the Author

Olaf Strauss is a Berliner, educated in Berlin until receiving his doctorate in Zoology and Physiology in 1990 and the habilitation in 1999 from the Berlin Freie University. After five years as a professor in Experimental Ophthalmology, UKE, Hamburg, he took up a position in Experimental Ophthalmology at the University Hospital, Regensburg. He is presently Professor in Experimental Ophthalmology at the University of Regensburg. His research interests have always been on understanding the function of the retinal pigment epithelium. Two major areas of research on the RPE are of interest: secretion and phagocytosis. His work has focused on the Ca^{2+}-dependent regulation by ion channels and cytosolic Ca^{2+} stores. Recent work focuses on the interaction of bestrophin-1 with voltage-dependent Ca^{2+} channels in Best's vitelliforme macular dystrophy and on the systemic influence on retinal function by the renin-angiotensin system.

Photoreceptors

Helga Kolb, PhD[1]

Created: May 1, 2005; Updated: February 28, 2012.

Two or three types of cone photoreceptor and a single type of rod photoreceptor are present in the normal mammalian retina. Some non-mammalian retinas have even more cone types (see later).

1. Light microscopy and ultrastructure of rods and cones

In vertical sections of retina prepared for light microscopy with the rods and cones nicely aligned, the rods and cones can be distinguished rather easily.

Cones are robust conical-shaped structures with cell bodies situated in a single row just below the outer limiting membrane (OLM) and with inner and outer segments protruding into the subretinal space towards the pigment epithelium (Fig. 1, Fig. 2). In foveal retina, where only cones are concentrated, their cell bodies are layered in oblique columns below the outer limiting membrane. Rods, on the other hand, are slim rod-shaped structures with their inner and outer segments filling the area between the larger cones in the subretinal space and stretching to the pigment epithelium cells. Rod cell bodies make up the remainder of the outer nuclear layer below the cone cell bodies. Apical processes from the pigment epithelium envelop the outer segments of both rods and cones (not always clear in histological sections).

The higher magnification afforded by the electron microscope allows better resolution of rod and cone photoreceptors.

Ultrathin sections viewed in an electron microscope (Fig. 2, Fig. 3) show rods and cones from human and squirrel retinas (1). The photoreceptor consists of 1) an outer segment, filled with stacks of membranes (like a stack of poker chips) containing the visual pigment molecules such as rhodopsins, 2) an inner segment containing mitochondria, ribosomes and membranes where opsin molecules are assembled and passed to be part of the outer segment discs, 3) a cell body containing the nucleus of the photoreceptor cell and 4) a synaptic terminal where neurotransmission to second order neurons occurs.

Outer and inner segments of rods (i.s.) are generally thinner than those of cones in mammalian retinas. For example, the rod inner segments are 2 μm and the cone inner segments are about 6 μm in diameter in peripheral human retina. In the fovea, however, where there are only cone photoreceptors, the most central cones are even thinner than the average rod at about 1.5 μm diameter. Inner segment regions of both rods and cones are filled with long thin mitochondria. At the top of the inner segment a thin cilium joins the inner and outer segments of the rods and cones (Fig. 3 and see movie 1).

2. Outer segment generation

It is from the base of the cilium that membrane evaginations and invaginations occur to produce the outer segment (o.s.) or the important visual pigment-bearing portion of the photoreceptor. Outer segments of both the rods and cones arises from outpouching (Fig. 4) of the photoreceptor cell plasma membrane at this point (see below) (2). An animation of outer segment generation appears in movie 2.

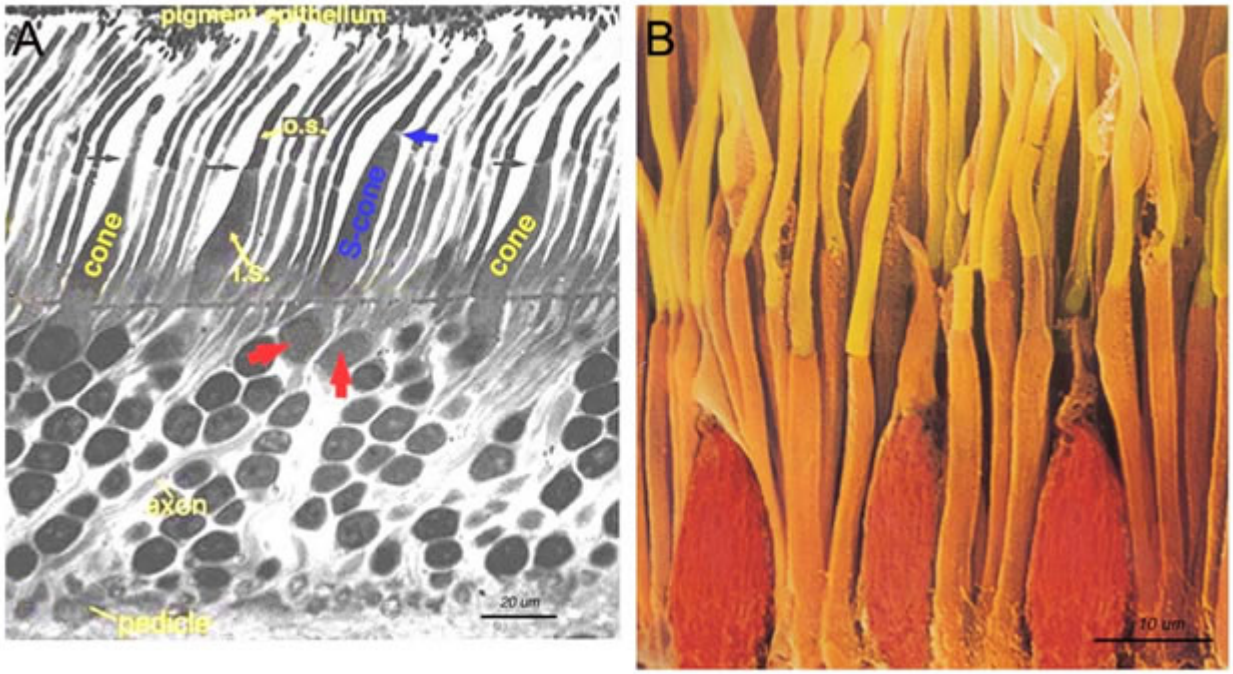

Figure 1. Primate rods and cones. *A*. Semi-thin section of human outer retina to show the rods and cones. Short-wavelength S-cones (blue cones) are commonly found occurring next to a neighboring longer-wavelength cone (red arrows). *B*. Scanning electron micrograph of the rods and cones of the primate retina. The image is adapted from one by Ralph C. Eagle of Photo Researchers, Inc.

These expanding membrane plates (Fig. 5) become detached as free floating discs inside the outer segment membrane in the case of the rods. In the case of the cones though, the outer segment discs remain attached to the outer segment membrane.

So the outer segment is a structure filled entirely with discs of folded double membranes in which are embedded the light sensitive visual pigment molecules (Fig. 6).

The opsin molecule, which binds the chromophore 11-cis retinal to form the visual pigment, is manufactured in the Golgi apparatus of the inner segment and presented to the outer membrane at the cilium, via fusion areas using G-proteins (3, 4).

In contrast, the other part of the visual pigment molecule in the outer segment discs which is retinal (vitamin A product), is provided to the discs from the pigment epithelium via carrier molecules (retinal binding proteins, IRBP) within the interphotoreceptor matrix of the subretinal space (Fig. 7) (5, 6). This is further covered in the chapter The Retinal Pigment Epithelium by Olaf Strauss.

3. Visual pigments and visual transduction

Vertebrate photoreceptors can respond to light by virtue of their containing a visual pigment embedded in the bilipid membranous discs that make up the outer segment. The visual pigment consists of a protein called opsin and a chromophore derived from vitamin A known as retinal. The vitamin A is manufactured from beta-carotene in the food we eat, and the protein is manufactured in the photoreceptor cell (see above). The opsin and the chromophore are bound together and lie buried in the membranes of the outer segment discs (Fig. 8).

About 50% of the opsin is within the bilipid membrane connected by short protein loops outside. Each molecule of rhodopsin consists of seven of these transmembrane portions surrounding the chromophore (11-cis retinal) in the lipid bilayer (Fig. 9). The chromophore apparently lies horizontally in the membrane and is bound at a lysine residue to helix seven (7, 8) (Fig. 9). Each outer segment disc, of course, contains many thousands of visual

Download video

pigment molecules. Upon absorption of a photon of light, the retinal isomerizes from the 11-cis form to the all-trans form which starts conformational changes in the molecule resulting in bleaching. Several intermediaries are formed in bleaching among them metarhodopsin II which activates the G-protein transducin and a further cascade of events summarized below (7, 9) and in the Webvision chapter Phototransduction in Rods and Cones by Yingbin Fu.

Light transduces the visual pigment via the following enzyme cascade: photons - rhodopsin - activated rhodopsin (metarhodopsin II) - a GTP binding protein (transducin) - an enzyme hydrolyzing cGMP (cGMP-phosphodiesterase) - closes a membrane bound cGMP-gated cation channel. The Webvision chapter on Phototransduction explains the details of this process.

In the dark, steady current flows into the open channels, carried mainly by Na^+ ions, constituting a "dark current" that partially depolarizes the photoreceptor cell (Fig. 10). Thus, the depolarized photoreceptor releases neurotransmitter (the amino acid glutamate) from its synaptic terminals onto second-order neurons in the dark. On light stimulation the rhodopsin molecules are isomerized to the active form, the above cascade ensues, leading to closure of the cation channels of the photoreceptor membrane, stopping the dark current and causing the photoreceptor cell membrane to hyperpolarize and cease neurotransmitter release to second-order neurons (Fig. 10) (10-13).

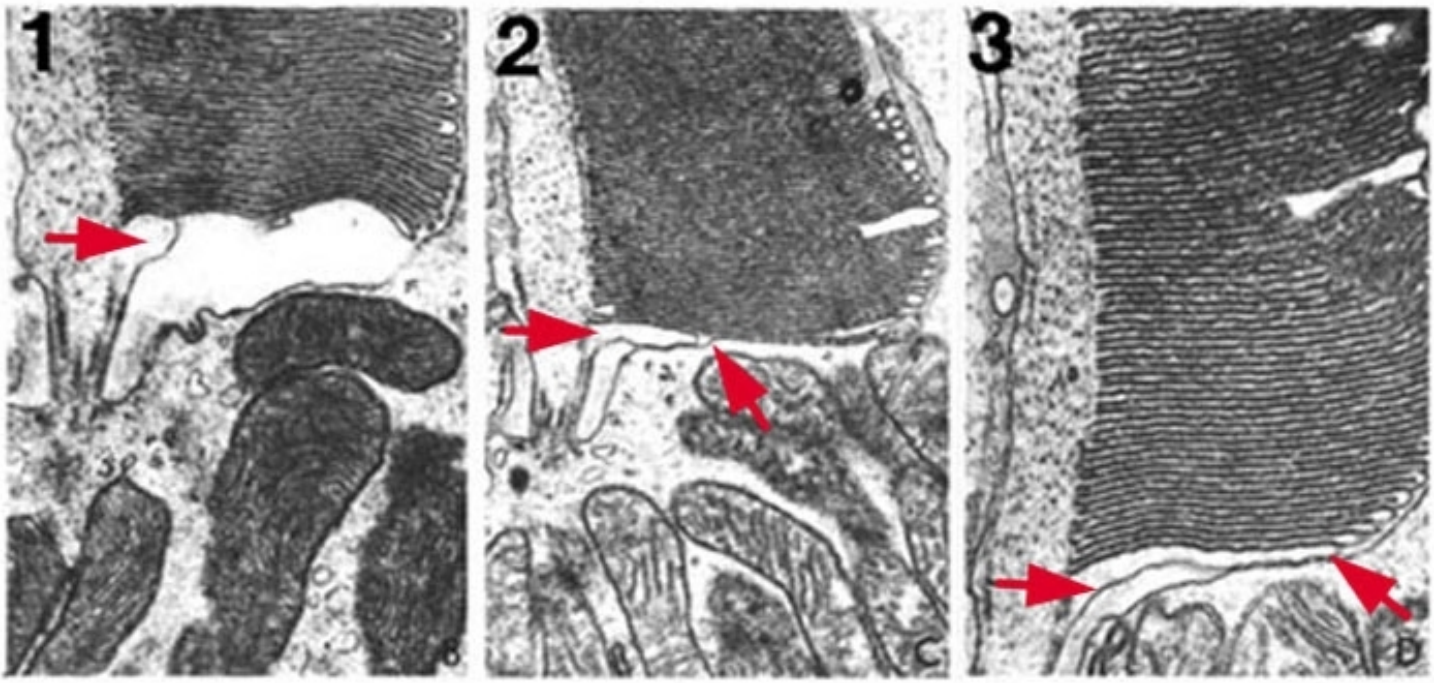

Figure 4. Photoreceptor outer segments are generated at the cilium (red arrows). The illustration is adapted from Steinberg, Fisher and Anderson, 1980 (2).

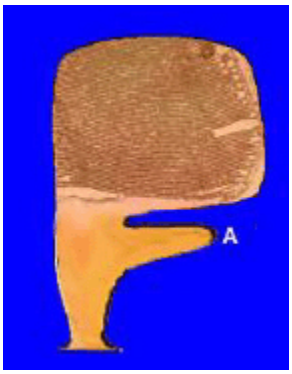

Movie 2. An animation of the outer segment generation.

Download video

The "dark current" is composed mainly of the influx of the Na^+ component (80%) however, a Ca^{2+} component (15%) and a Mg^{2+} component (5%) are also present (13). In darkness there must be a mechanism to remove Ca^{2+} as well as the excess Na^+, and it is thought to be done so through a sodium/calcium exchanger in the membranes of the outer segment of the photoreceptor. Ca^{2+}, once thought to be the second messenger in linking the rhodopsin photoisomerization to the membrane events is now known to have a secondary but important regulatory role in phototransduction. Although it does not directly participate in the transduction cascade it does improve the signaling capability of the rods in speeding the recovery after illumination and down regulating of the rods sensitivity in steady illumination (13). The latter effect is a mechanism for light adaptation. For it must be remembered that a photoreceptor cell does not simply detect light. It can also adapt to environmental light. For example cone photoreceptors can adapt so that our visual system can see from the dim shadows under a tree to objects in bright sunlight snow, a shift of light intensity of 7-9 log units of light intensity (14). Rod photoreceptors, thought at one time not to light adapt, are now known to adapt over a range of 2 log

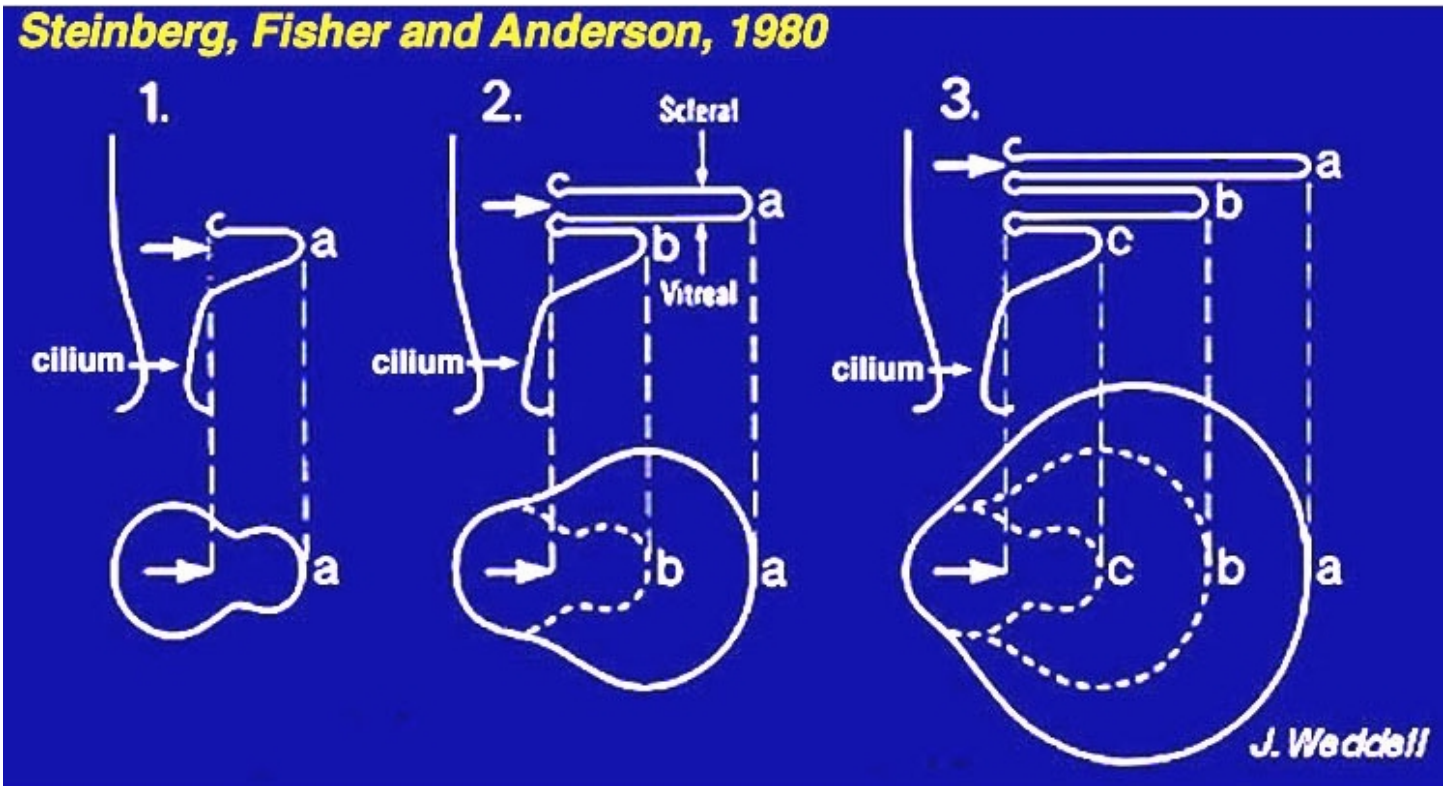

Figure 5. Diagram of outer segment generation. The schema is from Steinberg, Fisher and Anderson, 1980 (2).

units of background intensity and combined with a network adaptation through the whole visual system, allows as much as 5 log units of background intensity adaptation in rod driven vision (13). An animation of phototransduction appears in movie 3.

4. Phagocytosis of outer segments by pigment epithelium

The stacks of discs containing visual pigment molecules in the outer segments of the photoreceptors are constantly renewed. New discs are added at the base of the outer segment at the cilium as discussed above. At the same time old discs are displaced up the outer segment and are pinched off at the tips and engulfed by the apical processes of the pigment epithelium (Fig. 11, Fig. 12). These discarded, spent discs become known as phagosomes in the pigment epithelial cells. They are then broken down by lysis. Photoreceptor outer segment discs are phagocytosed by the pigment epithelium in a diurnal cycle. There is a burst of disc shedding at light on in the morning, judged by increased numbers of phagosomes in the pigment epithelium shortly thereafter (15). An animation of phototransduction appears in movie 4.

Cone outer segments differ from rod outer segments in several respects. Firstly, they are shorter and more conical with a wider base and tapering shape compared with those of rods. Secondly, as mentioned above, their discs are connected to the plasma membrane throughout the extent of the outer segment, and thus they are open to extracellular space. Apical processes of the pigment epithelium phagocytize chunks of cone outer segments, just as they do the rod outer segments, but at a different time in the diurnal cycle compared with rods i.e. at light off-set compared light-onset (15-19).

5. Different types of cone photoreceptor

As we have seen from the morphological appearances described above, two basic types of photoreceptor, rods and cones, exist in the vertebrate retina (Fig. 13). The rods are photoreceptors that contain the visual pigment -

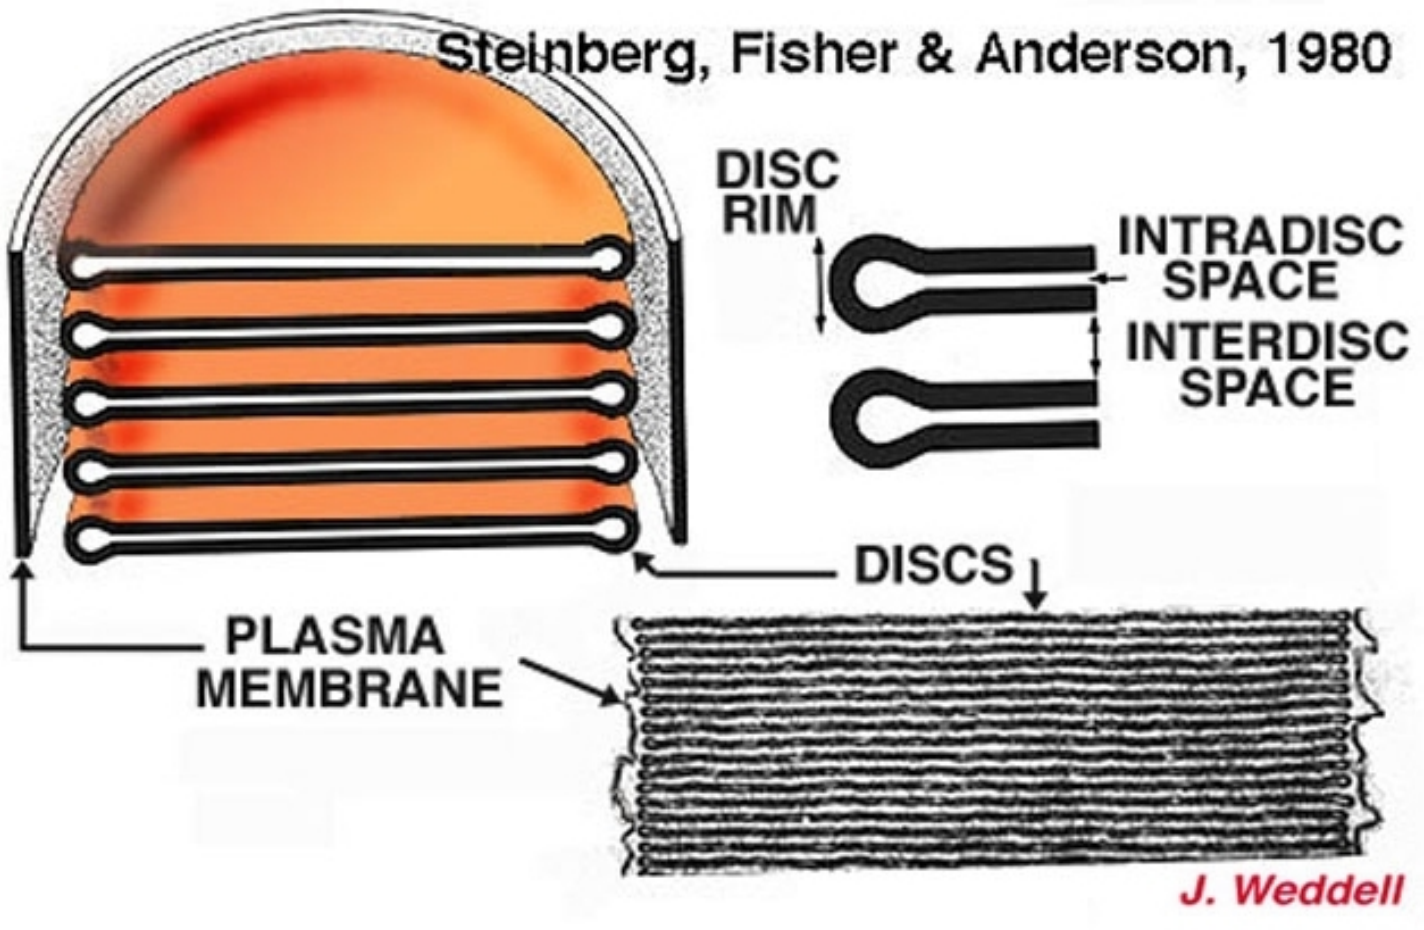

Figure 6. Drawing and micrograph of rod outer segment discs. The illustration is from Steinberg, Fisher, and Anderson, 1980 (2).

rhodopsin and are sensitive to blue-green light with a peak sensitivity around 500 nm wavelength. Rods are highly sensitive photoreceptors and are used for vision under dark-dim conditions at night. Cones contain cone opsins as their visual pigments and, depending on the exact structure of the opsin molecule, are maximally sensitive to either long wavelengths of light (red light), medium wavelengths of light (green light) or short wavelengths of light (blue light). Cones of different wavelength sensitivity and the consequent pathways of connectivity to the brain are, of course, the basis of color perception in our visual image.

Three different cone mechanisms can be detected in behavioral, psychophysical and physiological testing (Fig. 14A). These mechanisms are the basis of so called trichromatic vision which most humans have. Where only one or two visual pigment bearing types of cone are present the vision is said to be monochromatic or dichromatic.

Most mammalian species are dichromatic containing as well as rods only middle and short wavelength sensitive cones in their retinas. Primates and humans, birds, reptiles and fish are trichromatic, tetrachromatic and some even pentachromatic (within the latter three vertebrate phyla).

Thus long, medium and short wavelength cones have been demonstrated to exist in human retina by photometric, psychophysical and molecular biological methods: L-cones (red) are known to be maximally sensitive to wavelengths peaking at 564nm, M-cones (green) at 533nm and S-cones (blue) at 437nm respectively (Fig14A) (20).

Normal human color vision depends on the three cone mechanisms. This adds an additional dimension to color vision over those of dichromatic mammals, creating reds and greens rather than just long wavelength (red) and

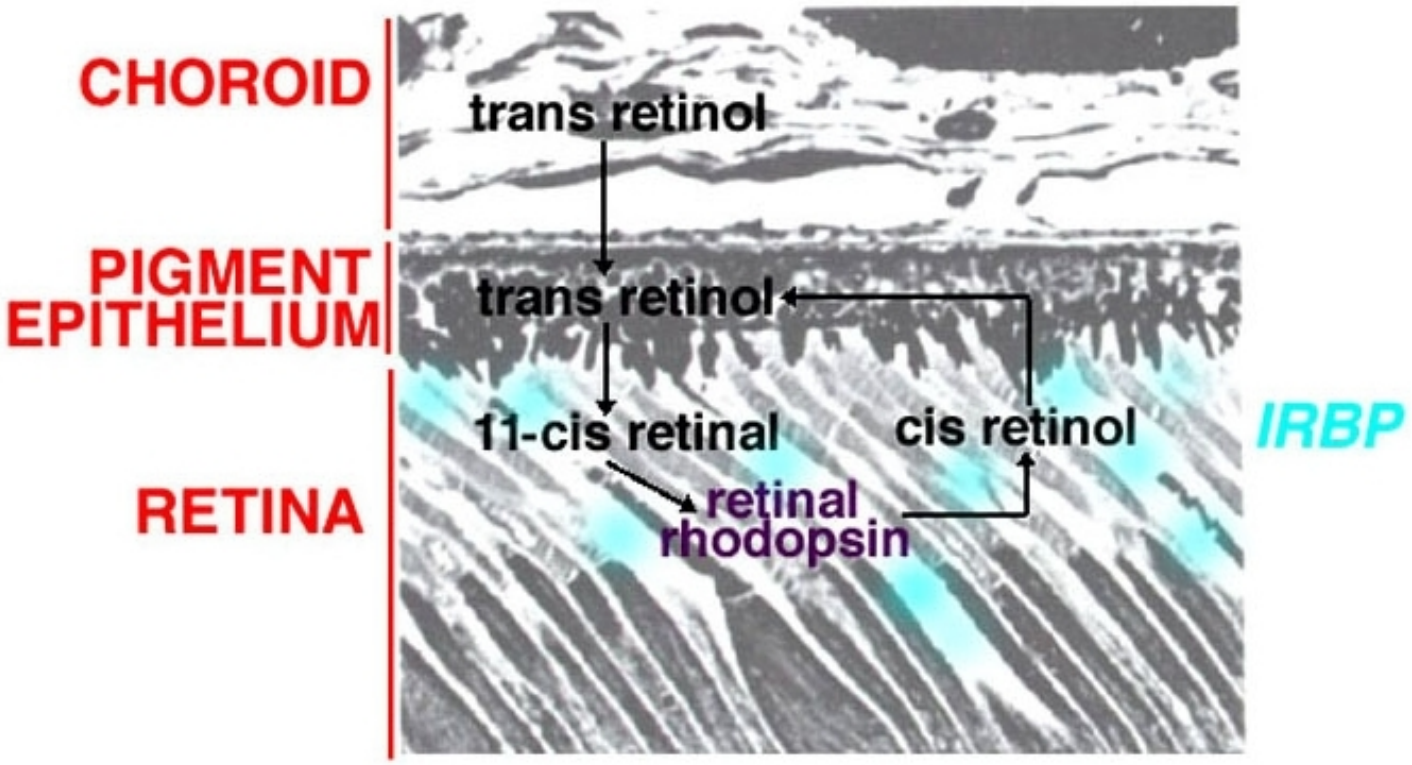

Figure 7. The location of interphotoreceptor retinal binding proteins (6) lies between the pigment epithelium and the photoreceptor outer segments. This region is know as the interphotoreceptor matrix..

short wavelength (blue). To do, this nature splits the long-wave system into two similar systems with slightly different spectral sensitivities with relatively similar opsins (Fig. 14B). One cone opsin is most sensitive to yellow-green and the other to yellow-red. This splits the brightest and yellow part of the visible spectrum into two color bands, one green and the other red. This red-green system works in parallel with that for blue-yellow.

Figure 14B shows the subtle difference in the molecular structure of the red and green cone photopigments compared with either the blue-cone pigment or the rhodopsin rod pigment (21).

To understand color vision and how the colored visual message is processed in the retina we need to be able to start with a morphological distinction of the three (or more) cone types, so they can then, hopefully be identified with any color specific connections they make, i.e. connections to bipolar, horizontal cell and finally ganglion cells of the retina. Fortunately, certain vertebrate species have distinctly different morphological cone types in their retinas and it has recently become possible to correlate these morphologies with spectral sensitivity. Now we can distinguish short, medium and long wavelength cones in retinas of some fish, frogs, birds, and reptiles (turtles) based on distinct morphological differences. Turtle retinas for example have colored oil droplets in their different spectral types of cone which identify them rather readily (Fig. 15, Fig. 16) (22, 23).

However, primate and human retinas still contain cone types which look essentially the same morphologically, but here too with anatomical techniques we are beginning to be able to see at least a difference between the short wavelength cone and the two longer wavelength cones. Specialized histochemical techniques (24), dye uptake studies (25) or use of antibodies specific for visual pigments (26) have allowed identification of the different spectral types of cone in most mammalian species now. In primate retina antibodies against visual pigments stain outer segments of the L/M-cones together or the S-cones only.

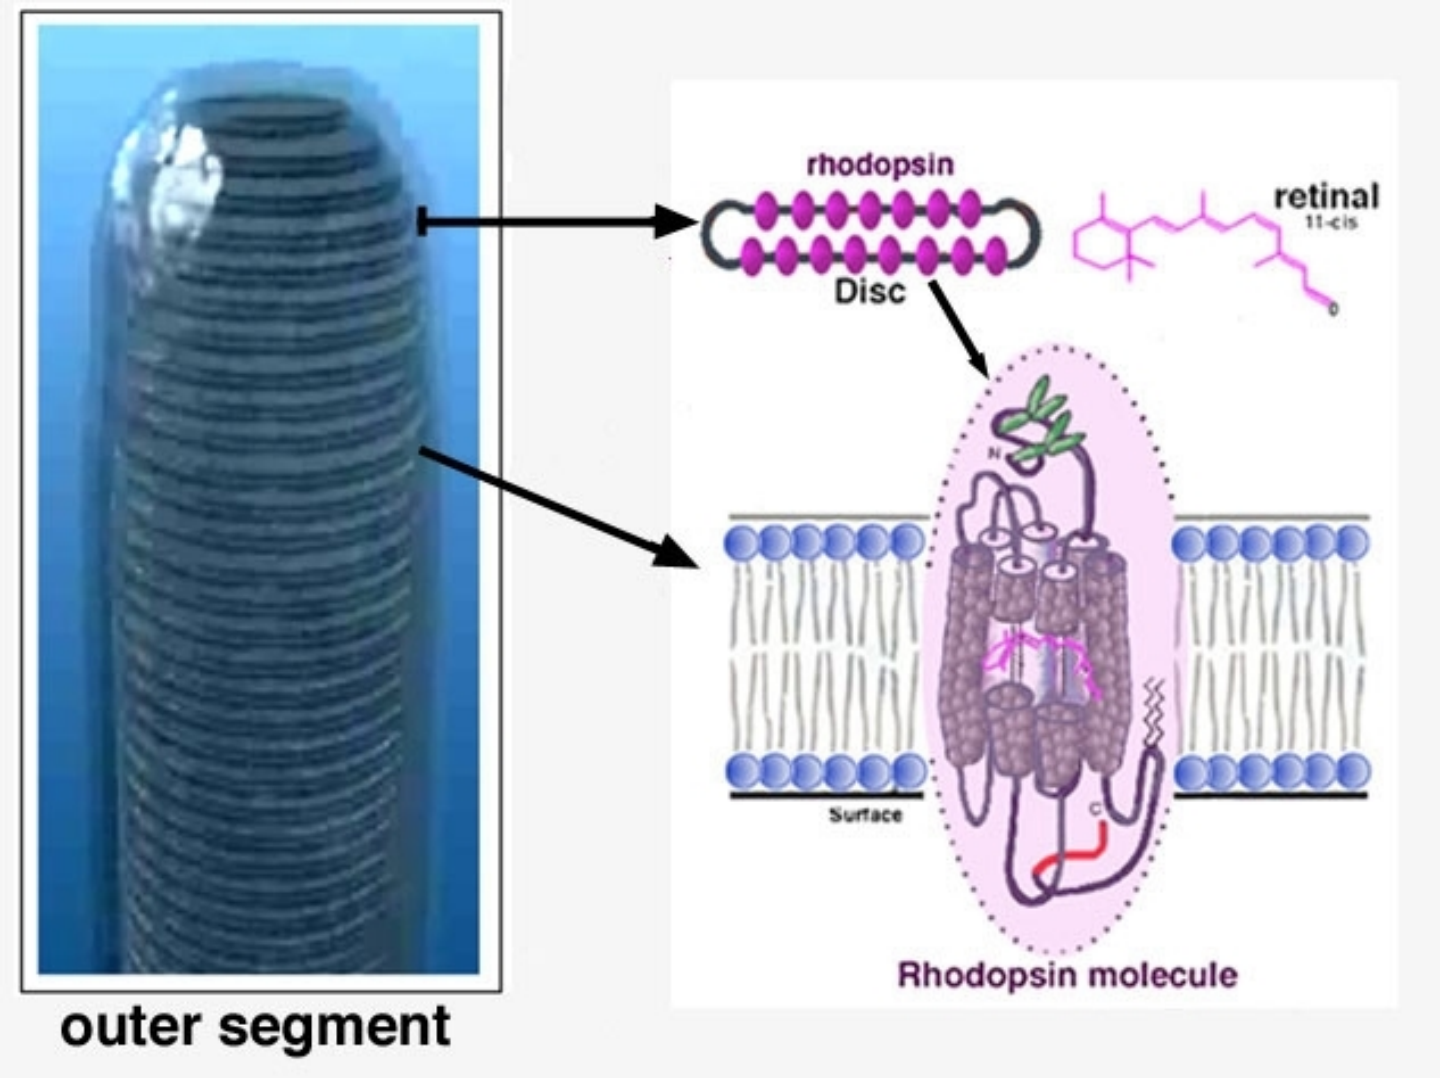

Figure 8. Schematic diagram of rhodopsin in the outer segment discs.

In Figure 17, in anti-visual pigment antibody stained tissue, the S-cones stand out as the cones that are not stained because the antibody recognizes only L- and M-cone visual pigment. i.e. the brown stained cone profiles are L- and M-cone types while the unstained profiles surrounded by blue circles are the S-cones (27).

6. Morphology of the blue or S-cones

Careful morphological studies have enabled us to distinguish the short wavelength specific (blue) cone from the medium and long wavelength specific cones in the human retina even without special antibody staining techniques (28).

Thus, we now know that S-cones have longer inner segments that project further into subretinal space than do the longer wavelength cones (Fig 18). S-cone inner segment diameters do not vary much across the entire retina, thus they are fatter in the foveal area but thinner in the peripheral retina than longer wavelength cones. These S-cones also have smaller and morphologically different pedicles than the other two wavelength cones (29). Furthermore, throughout the retina, the S-cones have a different distribution and do not fit into the regular hexagonal mosaic of cones typical of the other two types.

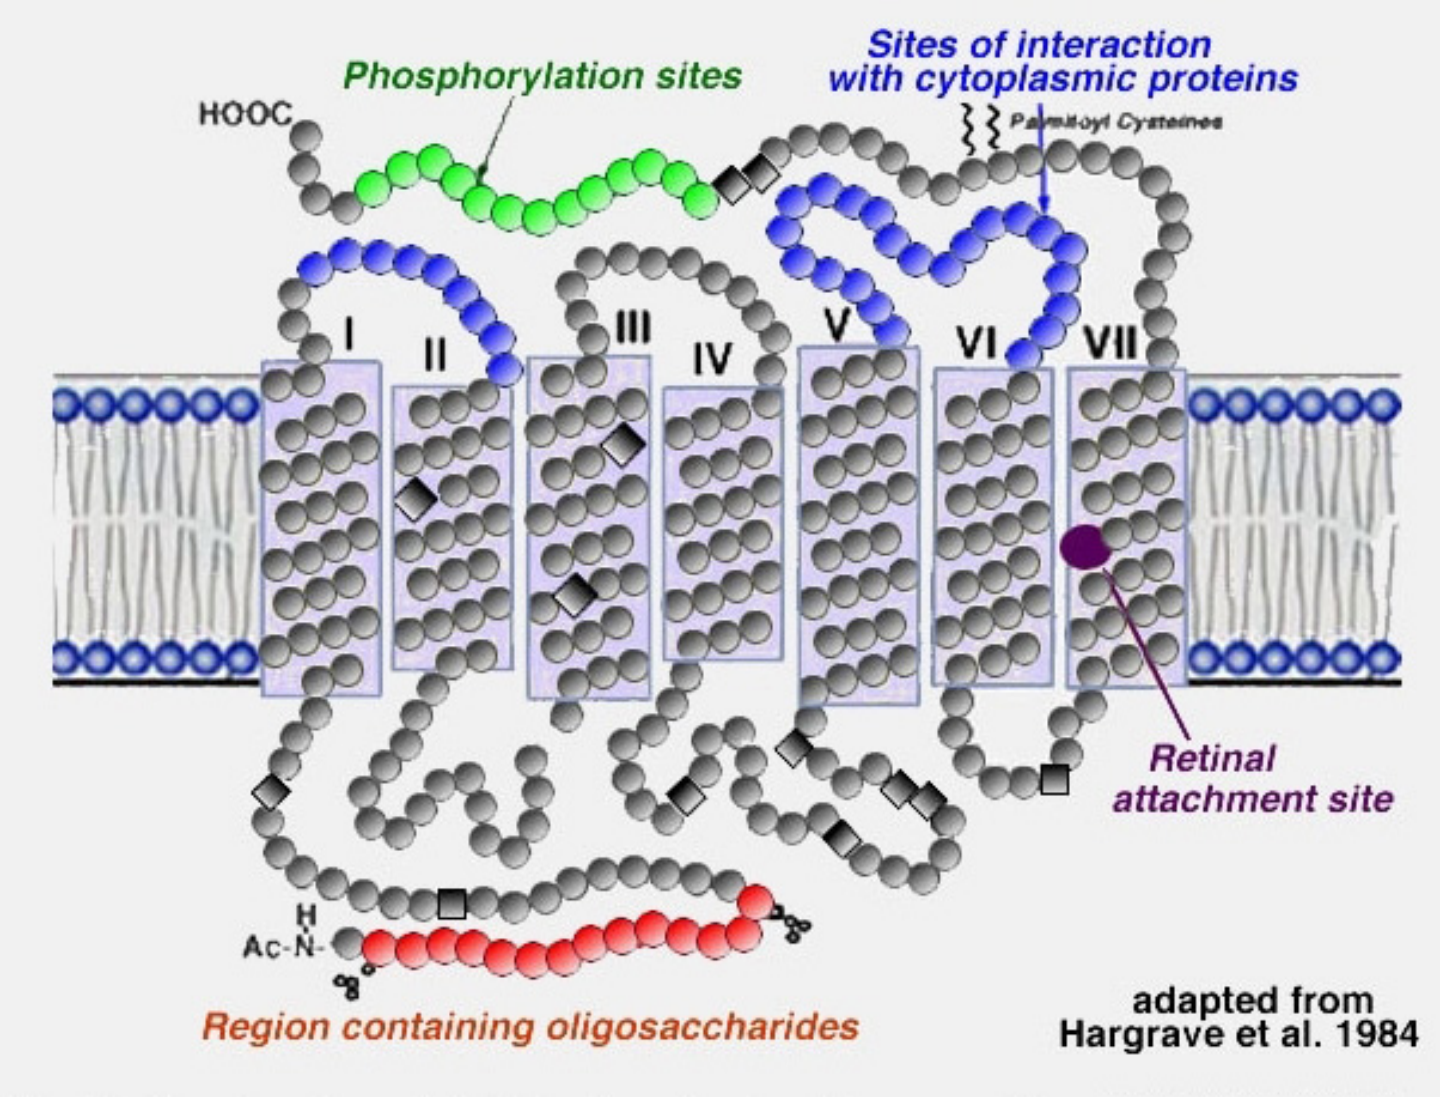

Figure 9. Structural model of rhodopsin showing seven transmembrane domains and the attachment site for retinal. The figure is adapted from Hargrave et al, 1984 (8)

This is illustrated in the tangential section of the foveal cone mosaic (Fig. 19) where the hexagonal packing is distorted in many places by a larger-diameter cone (arrowed cones) breaking up the perfect mosaic into irregular subunits. The larger-diameter cones are S-cones. These cones have their lowest density in the foveal pit at 3-5% of the cones, reach a maximum density of 15% on the foveal slope (1 degree from the foveal pit) and then form an even 8% of the total population elsewhere in the retina (28).

Analogous information concerning relative distributions of the M- and L-cones in the human retina is not easily available because we cannot tell them apart by morphological features or even by anti-visual pigment staining. In the monkey retina, Marc and Sperling (24), performed a colored light-dependent histochemical staining technique on freshly excised monkey eyes. They found that L-cones (red) occur as about 33% of the cones throughout the retina, while M-cones (green) peak in the fovea at 64% and vary between 52% and 59% elsewhere in the retina. However, others have found the L-cones to outnumber the M-cones in fovea and perifoveal psychophysical testing paradigms (30). Laser interferometry techniques (31, 32), measuring the distribution of the red and green cones in the living human fovea, show there to be considerable variation amongst individuals. Some have an equal distribution of L- and M-cones, but others have a larger number of red cones even up to the ratio of 16 L-cones:1 M-cone. Both Roorda and Williams and Hofer et al's (31, 32) data in

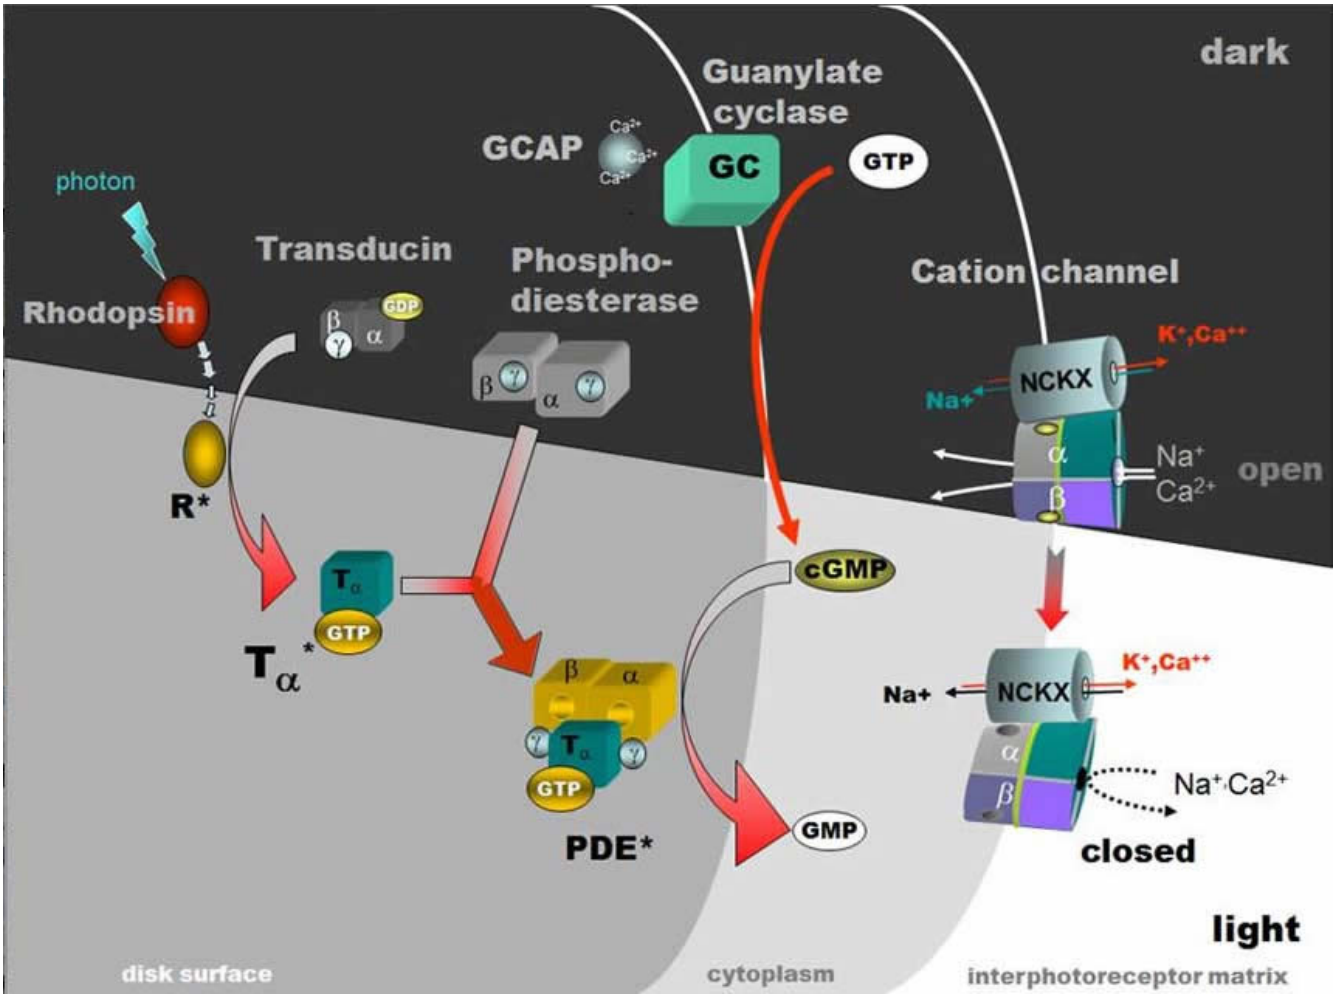

Figure 10. Activation of rhodopsin by light and the phototransduction cascade. Light transduces the visual pigment via the following enzyme cascade: photons – rhodopsin – activated rhodopsin (R^+) (metarhodopsin II) – a GTP binding protein ($T\alpha^*$) (transducin) – an enzyme hydrolyzing cGMP (cGMP-phosphodiesterase, PDE*) – closes membrane bound cGMP-gated cation channel (lower right). human and Mollon and Bowmaker (33) in monkey fovea show an irregular and patchwork nature of the L- and M-cone distribution (see chapter on midget pathways, Figure 5).

7. Densities of rods and cones in the human retina

It is important for our understanding of the organization of the visual connections for us to know the spatial distribution of the different cell types in the retina. Photoreceptors, we know, are organized in a fairly exact mosaic. As we saw in the fovea, the mosaic is a hexagonal packing of cones. Outside the fovea, the rods break up the close hexagonal packing of the cones but still allow an organized architecture with cones rather evenly spaced surrounded by rings of rods. Thus in terms of densities of the different photoreceptor populations in the human retina, it is clear that the cone density is highest in the foveal pit and falls rapidly outside the fovea to a fairly even density into the peripheral retina (Fig. 20, Fig. 21) (34, 35). There is a peak of the rod photoreceptors in a ring around the fovea at about 4.5 mm or 18 degrees from the foveal pit. The optic nerve (blind spot) is of course photoreceptor free (see below).

8. Rods and Night Vision

Rods convey the ability to see at night, under conditions of very dim illumination. Animals with high densities of rods tend to be nocturnal, whereas those with mainly cones tend to be diurnal. The nature of dim light is important both to physicists and to biologists. In 1905 Einstein proposed that light propagated only in discrete irreducible packets or quanta (36). This explained the non-classical features of the 'photoelectric effect', a process by which light facilitates the release of electrons from metal surfaces, described by Heinrich Hertz in 1887 (37). Rods are so sensitive that they actually detect single quanta of light, much as do the most sensitive of physical instruments. In 1942 Selig Hecht argued that human rods must be capable of detecting individual light quanta because light flashes so dim that only 1 in 100 rods were likely to absorb a quantum were yet reliably seen by careful observers (38). A century after the original discovery of the photoelectric effect it has become possible to record directly the minute electrical voltages in rods induced by absorption of individual light quanta. An excellent example is shown in the suction electrode recordings of monkey rods by Schneeweis and Schnapf (39) (Fig. 22). Each dot in the figure below represents delivery of a very dim pulse of light containing only a few quanta. Voltage responses appear to come in 3 sizes: none, small, and large, representing the detection of 0, 1 or 2 quanta in each flash. The granularity of response to dim light stimuli is evident.

Rod sensitivity appears to be bought at a price, however, since rods are much slower to respond to light stimulation than cones. This is one reason why sporting events such as baseball become progressively more difficult as daylight fails. Both electrical recordings and human observations suggest that signals from rods may arrive as much as 1/10 second later than those from cones under lighting conditions where both can be simultaneously activated (40).

9. Ultrastructure of rod and cone synaptic endings

The job of the photoreceptor cell in the retina is to catch quanta of light in the visual pigment-containing membranes of the outer segment and pass a message, concerning numbers of quanta of light and sensitivities to the different wavelengths, to the next stage of integration and processing at the outer plexiform layer. The way in which quanta are transformed into electrical signals is developed in the Webvsion chapter on Phototransduction.

The information transmitting end of the cone cell is known as the pedicle and of the rod cell as the spherule. Cone pedicles are large, conical, flat end-feet (8-10 µm diameter) of the cone axon that lie more or less side by side on the same plane at the outer edge of the outer plexiform layer (OPL) (Fig. 23A, Fig. 23B). The more numerous rod spherules, in contrast, are small round enlargements of the axon (3-5 µm diameter) or even extensions of the cell body. They lie packed between and above the cone pedicles (Fig. 23A, Fig. 23B). The synaptic endings of both photoreceptor types are filled with synaptic vesicles. At their synapses to second-order neurons (bipolar and horizontal cells), both rod spherules and cone pedicles exhibit dense structures known as synaptic ribbons pointing to the postsynaptic invaginated processes (asterisks in Fig. 24). In the cone pedicle approximately 30 of these ribbons occur and are associated with 30 "triads" of invaginated processes (29). In the rod spherule 2 ribbons are associated with 4 invaginated second-order neurites while the cone pedicle delivers information to over a hundred second-order neurons (Fig. 23B).

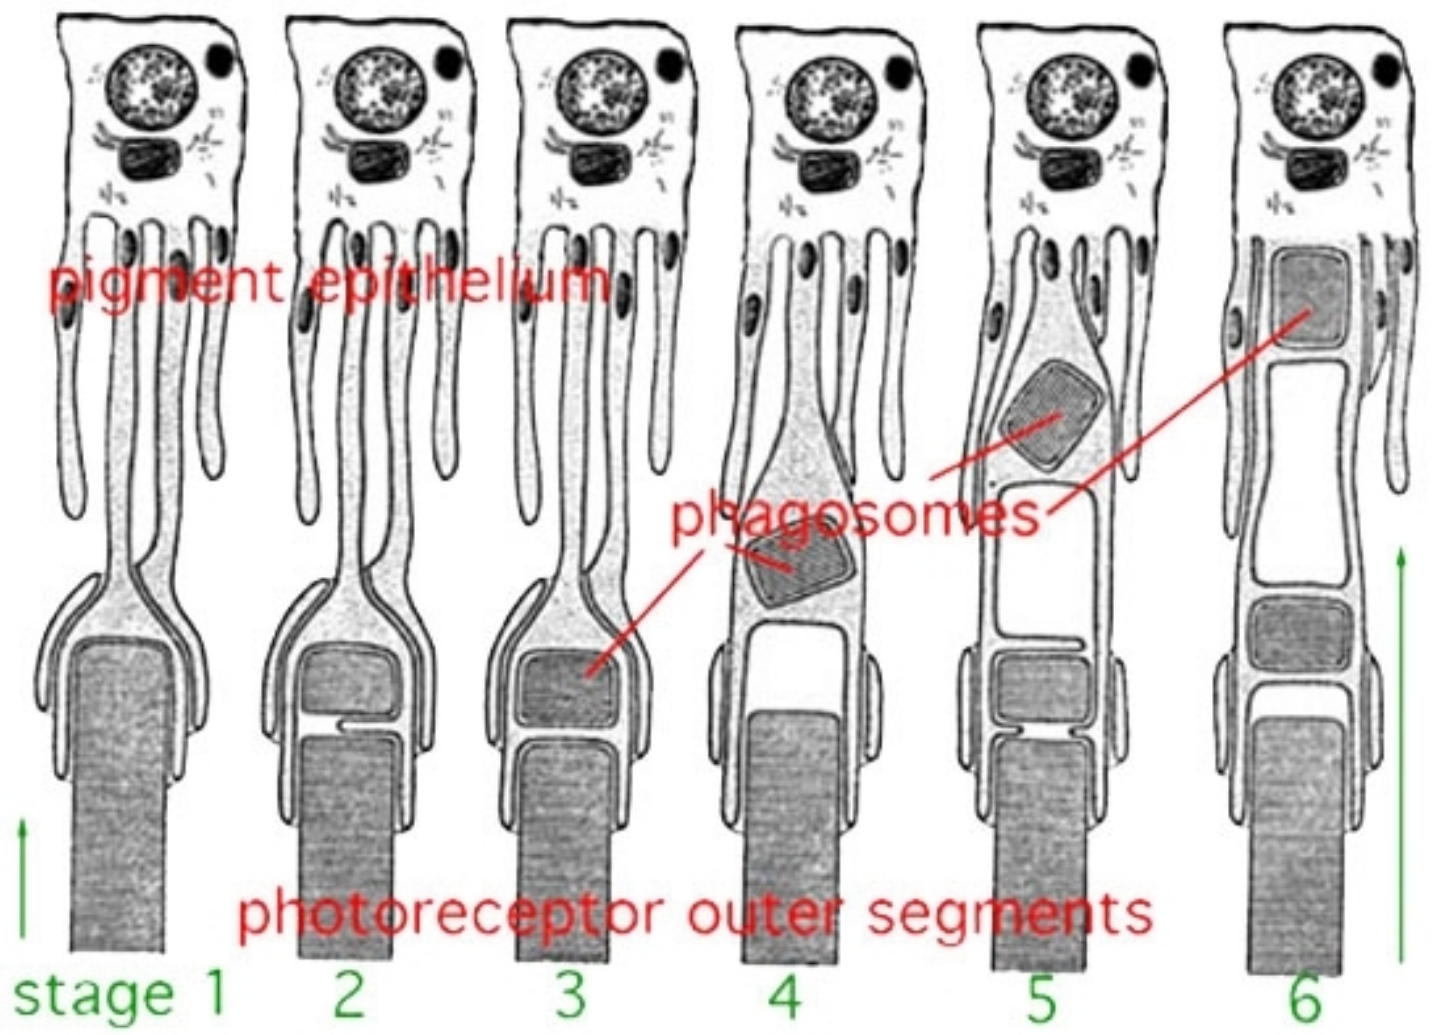

Figure 12. Diagrammatic representation of disc shedding and phagosome retrieval into the pigment epithelial cell.

The cone "triad" of invaginated second-order processes consists typically of a central element which is a dendritic terminal of an invaginating bipolar cell (IBC), and two lateral elements which are dendritic terminals of horizontal cells (HC) (Figs. 24, 25, and 27). In addition, other varieties of bipolar cell have dendrites making synaptic contacts on the under surface of the cone pedicle at what were first called flat contacts (FBC) (41-43) (Fig. 27), but then were better characterized and defined by Lasansky (44) as basal junctions (Fig. 26).

Rods spherules have only two synaptic ribbons associated with two lateral elements that are horizontal cell axon terminals (HC) and two central invaginating dendrites of rod bipolar cells (Fig. 28) (35) (41-43). There are no basal junctions on rod spherules.

10. Interphotoreceptor contacts at gap junctions

There also appears to be a pathway for crosstalk between cones and between cones and rods in the human retina. Cone pedicles have small projections from their sides or bases that pass to neighboring rod spherules and cone pedicles. Where these projections, called telodendria, meet they have a specialized junction known to be typical of electrical synaptic transmission. These are minute gap junctions (Fig. 29) (45, 46).

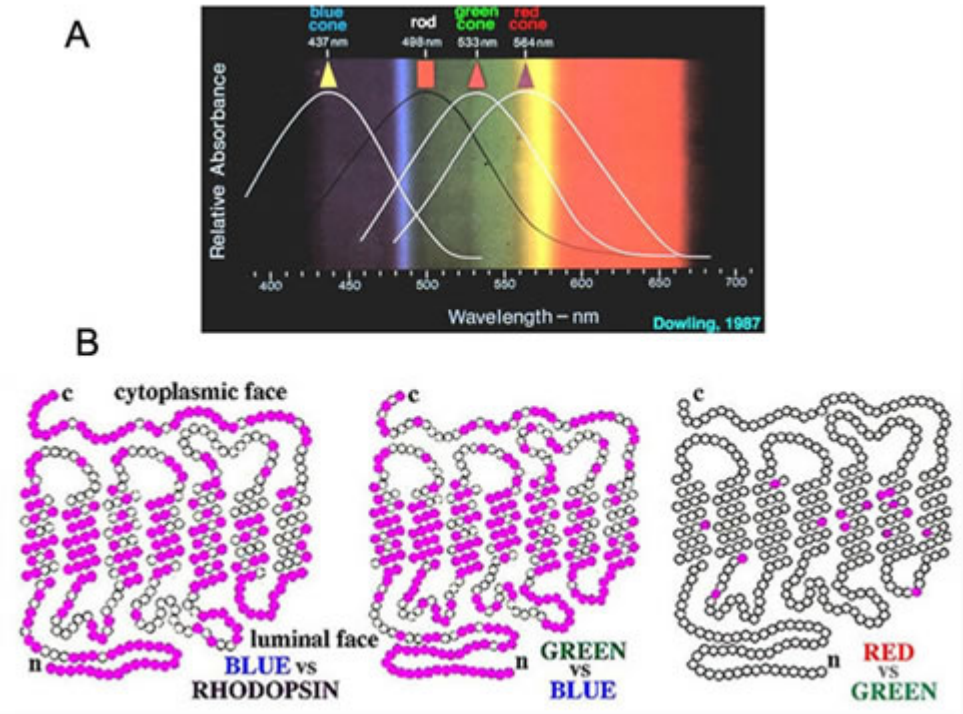

Figure 14. Opsin molecules: different spectra and different amino acid sequences. *A.* Light Spectra and visual pigment absorbance. The peak spectral sensitivities of the 3 cone types and the rods in the primate retina first published by Brown and Wald, 1963 (49). The illustration is from Dowling, 1987 (50). *B.* The closely related molecular structures of cone opsins. The blue-cone opsin compared with rhodopsin (left). The blue-cone opsin compared with the green-cone opsin (center). A comparison of red and green-cone opsins (right) reveals only minimal differences. The pink filled circles represent amino acid substitutions between compared opsins. The open circles indicate identical amino acids. The illustration is adapted from Nathans et al., 1986 (21).

As many as 3-5 gap junctions occur on a single rod spherule from neighboring cone telodendria, and a single cone pedicle can have as many as 10 contacts to neighboring rods. Pedicles of S-cones do not have as many telodendrial gap junctions with either neighboring rods or cones (29) and thus, this cone type remains relatively isolated in the cone mosaic, and, as we shall see later, remains isolated to the ganglion cell level too, due to connections with a specific 'S-cone bipolar cell'.

Direct interactions between different functional classes of photoreceptors were not anticipated based on any known or theoretical needs of the visual system. In fact such connections would appear to degrade spatial resolution, and, potentially, color perception by mixing signals from photoreceptors at different locations or with different photopigments. Nonetheless, in agreement with anatomical findings, mammalian cones appear to carry rod signals. The slow wave forms of rod signals are easily distinguished from the rapid wave forms of cone signals in voltage recordings from single cones. Examples of voltage responses from monkey cones are illustrated in Figure 30 (39). Voltage records resulting from red and green stimuli balanced to produce equal peak responses are illustrated.

Both records exhibit the same initial peak hyperpolarization in response to the brief stimulus, however the green stimulus (solid trace) also evokes a slower hyperpolarizing phase after the initial response which the red stimulus (dotted trace) does not (Fig. 30). This latter electrical wave has the characteristics of a rod signal. Such signals have also been observed in cat cones (47). One theory of the utility of this arrangement is that it allows rods to utilize neural pathways devoted to both cones and rods in sending visual information to the inner plexiform layer. Cone pathways may be tuned to faster temporal characteristics than rod pathways, and so by utilizing both pathways, rods may transmit a wider bandwidth of temporal information. There is evidence for two rod pathways with different dynamic signatures in perceptual experiments (48). Although the functional role of

interreceptor junctions is still a matter of debate, they perhaps serve as a philosophical warning to studies of biological sensory systems: Not even the receptor cells themselves stand in isolation of the activity and influence of neighboring neurons.

Outer Plexiform Layer

Helga Kolb

Created: May 1, 2005; Updated: May 1, 2007.

A certain degree of integration of the visual message takes place at the first synapse in the retina, in the outer plexiform layer. Here cone pedicles and rod spherules are synaptic upon various bipolar cell and horizontal cell types. In addition, as mentioned in the previous section, cone pedicles pass electrical messages between each other and between rod spherules so that a small amount of rod and cone signal mixing occurs at this layer (1, 2).

Two important synaptic interactions that occur at the outer plexiform layer are:

1. the splitting of the visual signal into two separate channels of information flow, one for detecting objects lighter than background and one for detecting objects darker that background
2. the instillation of pathways to create simultaneous contrast of visual objects

In the first synaptic interactions, the channels of information flow are known as the basis of successive contrast, or ON and OFF pathways, respectively, whereas the second interaction puts light and dark boundaries in simultaneous contrast and forms a receptive field structure, with a center contrasted to an inhibitory surround. We shall see how these two necessary, visual information processes are created by synaptic interactions at the outer plexiform layer.

Techniques That Have Been Used to Understand Neural Pathways in the Retina

By using various anatomical techniques, the morphologies of individual neurons that make up the retina and contribute processes for synaptic interaction in the plexiform layers have been discovered and described over the years. The most important technique among these is a specific neural stain named after a famous early Italian neuroanatomist, Camillo Golgi (1885), who lived at the end of the last century (3). This staining method was used most extensively and with extraordinary success by the great Spanish anatomist, Ramon y Cajal (1892) (Fig. 1) (4).

In fact, the monumental studies of Ramon y Cajal form the basis of neuroanatomy for the vertebrate nervous system in general and the retina in particular. One of Cajal's drawings of nerve cells in the retina stained by Golgi techniques (4) is shown in Fig. 2. In this one figure from Cajal's book on the vertebrate retina, we see photoreceptors, bipolar cells, horizontal cells, and some amacrine cell types. Cajal pointed out that photoreceptors-bipolar cells-ganglion cells were involved in passing rod or cone information through the vertical pathways, and that horizontal and amacrine cells were involved in lateral interactions. He introduced the idea that synaptic connections were set up between specific cell types in the plexiform layers by virtue of nerve cells' dendrites and axons costratifying precisely to ensure that the correct presynaptic cell talked to the correct postsynaptic cell.

In 1941, Stephen Polyak authored landmark books concerning the organization of the primate retina and visual system and was the man most responsible for applying the Golgi stain to monkeys and chimpanzees (5). Even today, we continue to use the Golgi method in research on cat, monkey, and human retinas (6-12).

Some of the cells we have described since Cajal and Polyak are shown in Fig. 3. It becomes immediately obvious that our drawings of Golgi-stained cells differ from those of Cajal, in that we have drawn complete cells from a surface or wholemount view looking into the retina mounted flat. Being able to prepare wholemounts of retinas was a great advance for our understanding of the morphologies of nerve cells in the retina becauser it allowed us to see complete dendritic tree spreads of stained cell, which were often truncated in the sectioned retinas that Cajal and Polyak studied. Thus, we have been able to add significant numbers of new cell types to the original

descriptions. Also, with the advent of electron microscopy, histochemical and immunocytochemical staining, and electrophysiological single-cell recording and staining, we can now direct these techniques at elucidating neural circuits in the retina in a way not available to our predecessors. All of the descriptions of cells and circuits that follow in this chapter come from experiments over the years using a combination of these techniques but always with the morphological data from Golgi staining as a basis.

Bipolar Cells

In human retina, 11 different bipolar cell types are revealed by Golgi staining (10, 12-14). Ten are for cones, and one type is for rods (Fig. 4).

Human retina, like most mammalian retinas, is rod dominated outside of the fovea. Therefore, rod bipolar cells form the numerically superior part of the bipolar population in human retinas.

The rod bipolar is typically a stout bipolar, with a cell body situated middle to high in the inner nuclear layer and producing a tuft of dendrites entering the OPL and reaching up to different levels between cone pedicles to reach the stacked rod spherules (Fig. 5 and Fig. 6).

The rod bipolar dendritic terminals end one to a rod spherule as the central invaginating dendrite (shown by electron microscopy in Fig. 5 and Fig. 6) (7). In the central retina, rod bipolar dendritic trees are small (15 μm across), and 15–20 rods are contacted. In the peripheral retina, the dendritic tree is 30 μm across and contacts 40–50 rods.

Ten different types of cone bipolar are present in human retina. Seven of them are concerned with converging information from many cones. They are known as diffuse-cone bipolar types (DBs). Three cone bipolar types are concerned only with single-cone contacts in a one-to-one relationship. These are known as midget bipolars, and blue-cone-specific types.

Some of the diffuse-cone bipolars are very wide field (giant) in dendritic spread (70–100 μm) and connect with as many as 15–20 cones (8). Little is known concerning the wide-field cells and and their role in retinal processing. These cells need further exploration. Commonly, the smaller diffuse bipolar cells collect information from 5 to 7 cones in the central retina and from 12 to 14 cones in the peripheral retina. The midget bipolar cells contact single cones, but there are two different varieties of them per cone. Thus, cones of the fovea have output to two midget bipolar cells, and of course, some still output to the diffuse bipolar cells as well. The two types of midget bipolar differ in their contact with the cone pedicle (Fig. 7).

The invaginating midget bipolar type (IMB) connects with the cone pedicle as central invaginating dendrites (Fig. 7, red profiles) at ribbon synapses in the cone pedicles (7). Flat midget bipolar cells (FMBs) contact the cone pedicle by means of semi-invaginating, wide-cleft basal junctions (Fig. 7, green profiles). Often, FMB dendrites make two contacts with the cone pedicle on either side of the central invaginating dendrite from the other midget bipolar cell (7).

A cone bipolar cell that is thought to be specific for the short-wavelength cones, or blue cones (S-cones), has been described in monkey (10, 15) and in human retina (12). This blue S-cone bipolar (Fig. 8) typically contacts one cone heavily, by several dendrites converging on that particular cone pedicle as central elements at the ribbons; thus, it is essentially another type of midget bipolar cell, but it differs from regular IMBs and FMBs in having also two or more wispy dendrites contacting either another cone pedicle or ending blindly in the OPL (see the later chapter on S-cone pathways). There is also a type of giant, bistratified cone bipolar cell in primate retina (Fig. 8, GBB) that has been proposed to be involved in the blue-cone system, because its axonal branching level in the IPL corresponds exactly to the dendritic branching levels of the bistratified blue/yellow ganglion cell of the S-cone pathways through the retina (see the later chapter on the S-cone pathways) (16).

Figure 1. Picture of Cajal.

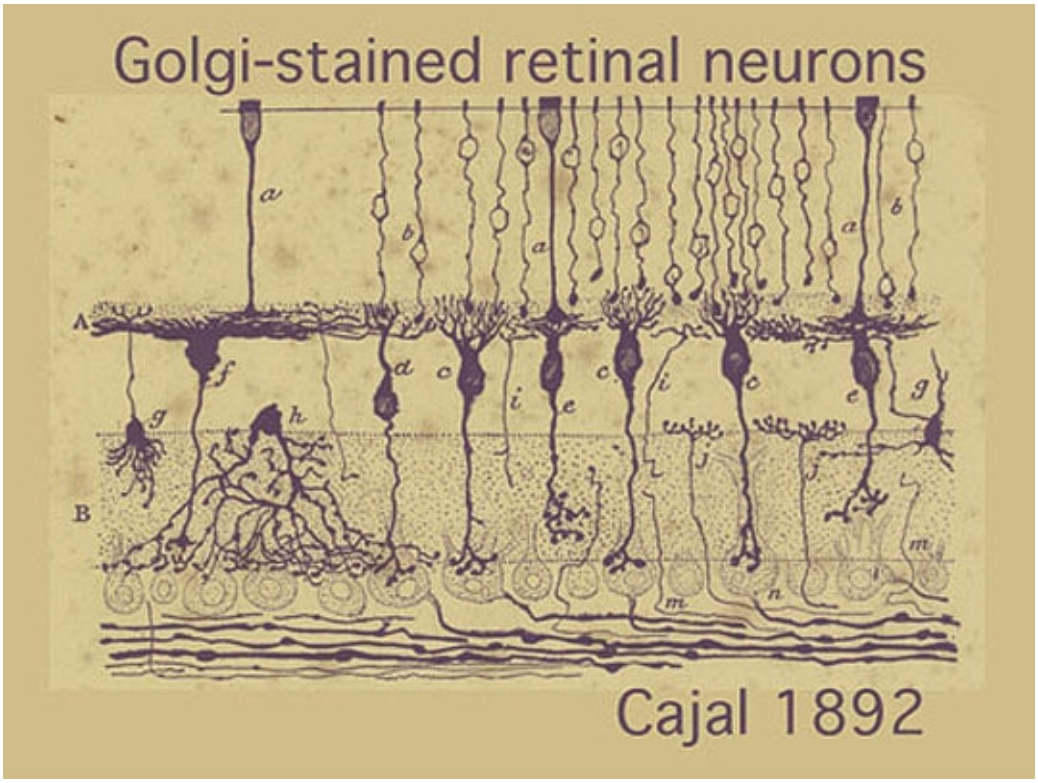

Figure 2. Cajal's drawing.

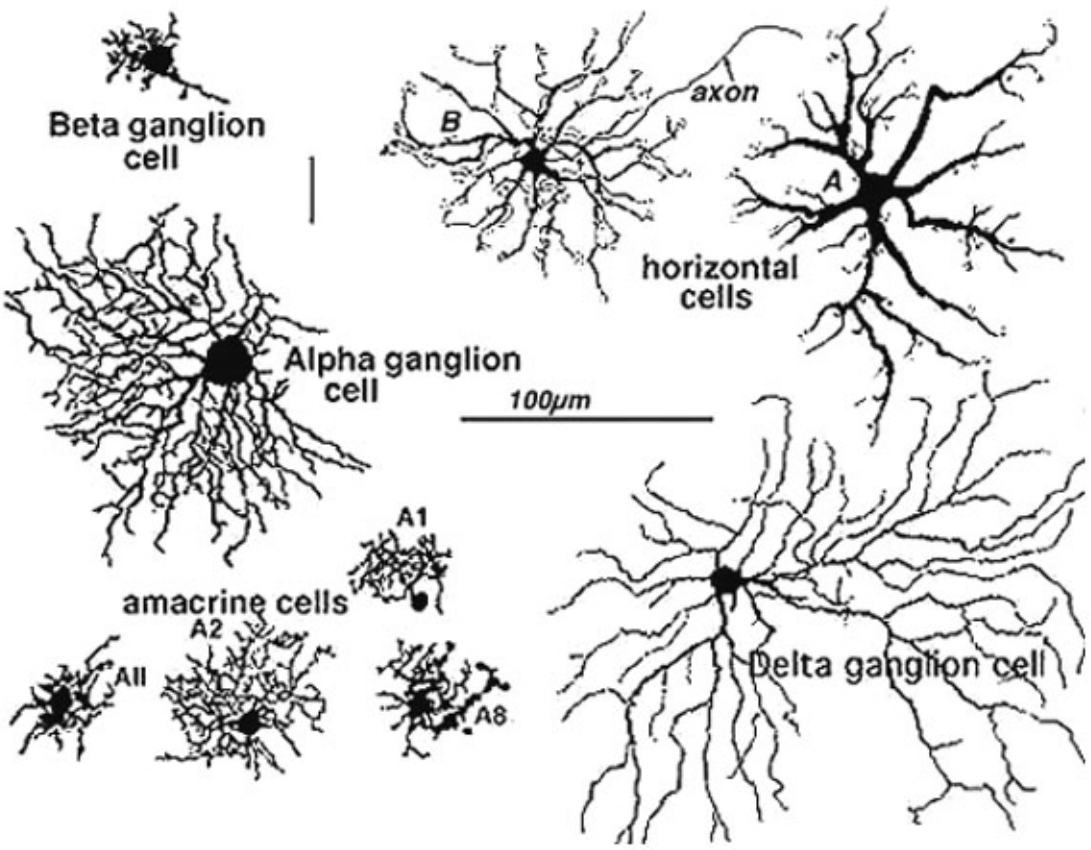

Figure 3. Golgi-stained neurons of cat retina.

The remaining diffuse bipolar types in primate retinas (Fig. 8) are analogous to cone bipolar cells of other mammalian retinas in contacting clusters of cone pedicles, as mentioned above. Similar to the midget bipolar cells, though, these diffuse types also differ in their types of synaptic contacts with cone pedicles, being either flat-contacting types (making basal junctions with cone pedicles) or invaginating and ribbon-contacting types, or even being types that mix these types of contacts (17) (see also Kolb and Nelson (18) for a review on photoreceptor to bipolar contacts in the vertebrate retina).

Horizontal Cells

All mammalian retinas have two types of horizontal cell (HC) as the laterally interconnecting neurons in the outer plexiform layer (14). The cat has been studied extensively as a model mammalian retina, and the two types, known as A-type and B-type, are illustrated in Fig. 9 (19). The A- and B-type HCs are very similar in appearance in the rabbit retina as well.

The A-type HC is a large, sturdy cell with radiating dendrites covering a dendritic field of 150–250 μm, depending on area of retina (all neurons of the retina are small in dendritic expanse in the central or foveal retina and increase in dendritic tree size with eccentricity from the central area). The B-type HC in the mammalian retina differs from the A-type in having a smaller, bushier (in general) dendritic tree (75–150 μm in diameter) and bearing an axon that travels 300 μm or more before ending in a huge, expansive axon terminal tree. The dendrites of both A-type and B-type HCs end in cone pedicles, whereas the axon terminals of the B-type HCs end in rod spherules (Fig. 9) (19).

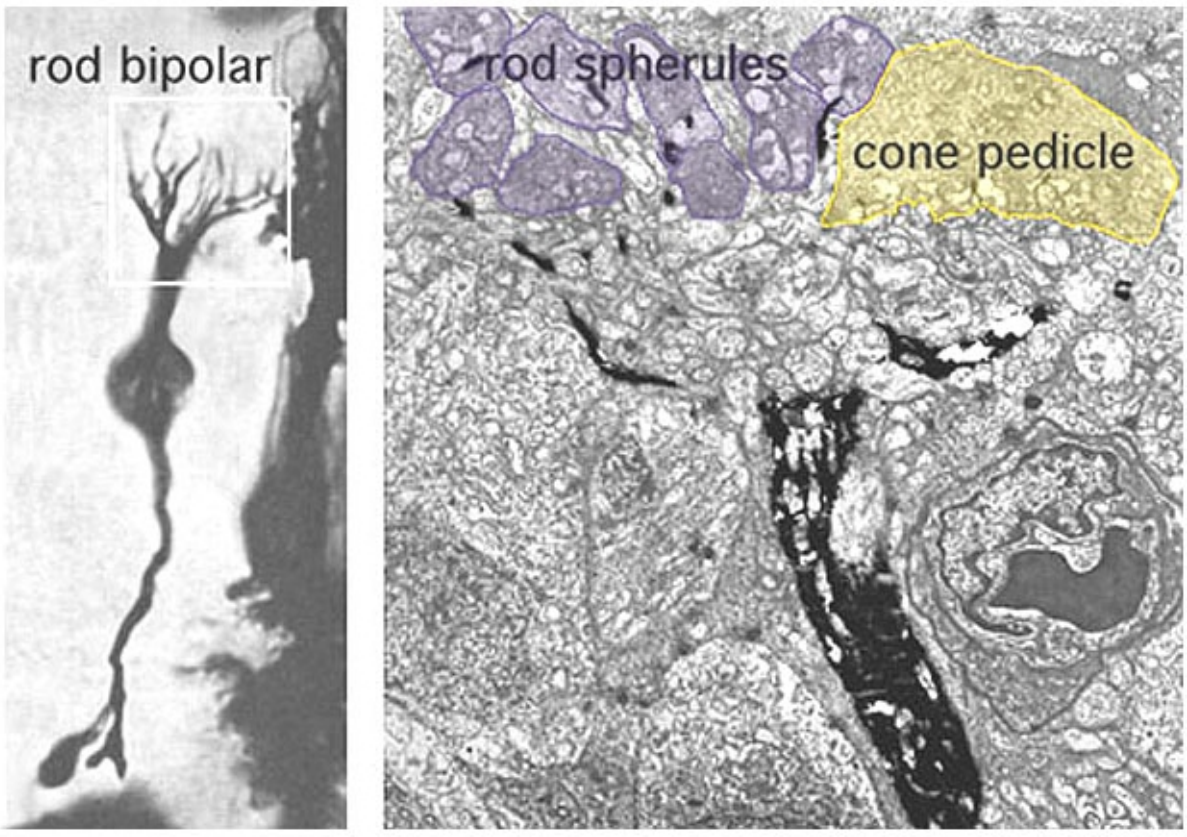

Figure 5. Rod bipolar cell at low magnification.

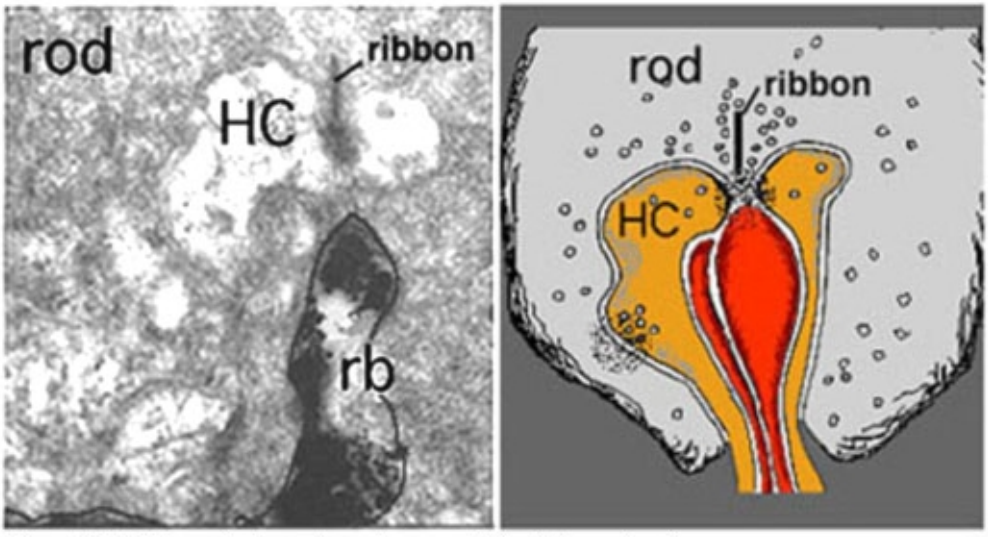

Figure 6. EM and drawing of a rod triad (monkey). rb, rod bipolar dendrite; HC, horizontal cell axon terminals.

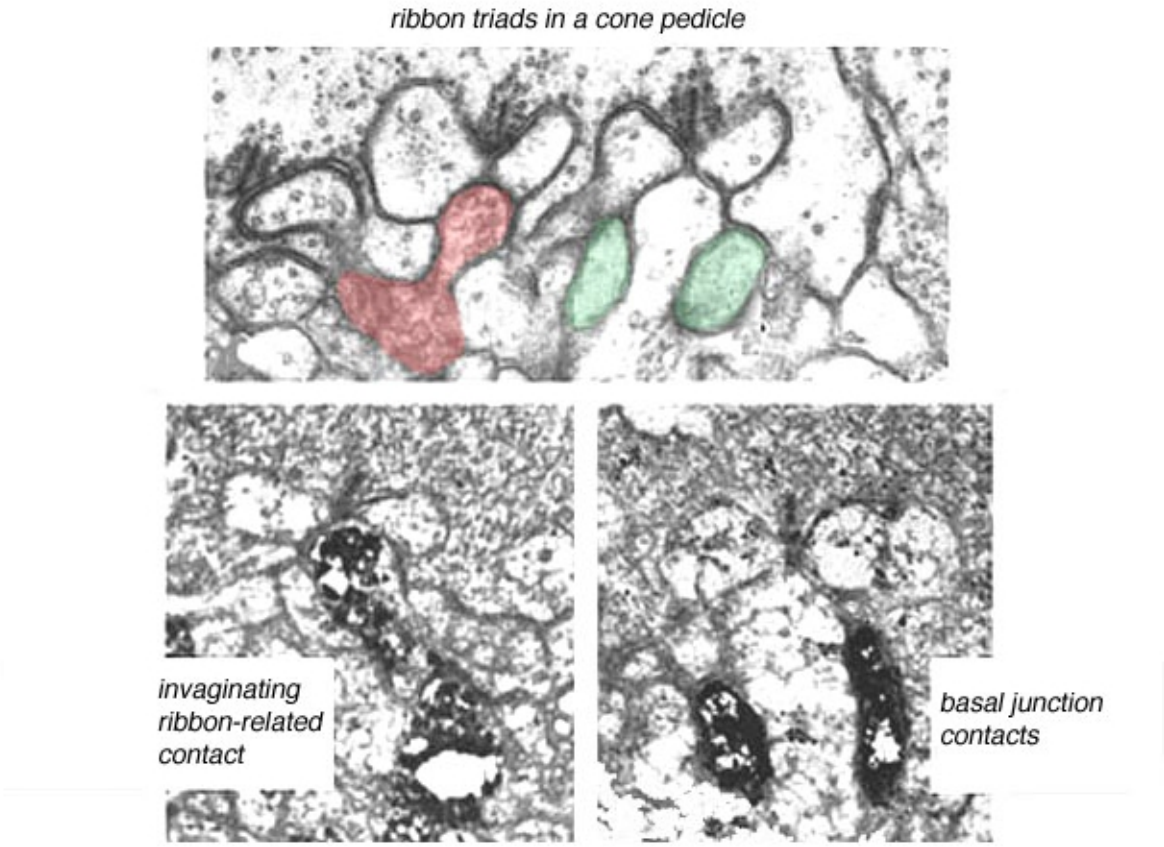

Figure 7. Midget bipolar cell contacts.

Primates, although obviously mammals, have been thought of as somewhat different in their HC make-up compared with cats. Originally, there was thought to be only one HC type, called an HI, that looked like a miniature version of the cat B-type HC (5). In 1980, we described a second type of HC in the rhesus monkey retina and called it the HII type (20). Most recently, we have been able to distinguish a third type, the HIII type,

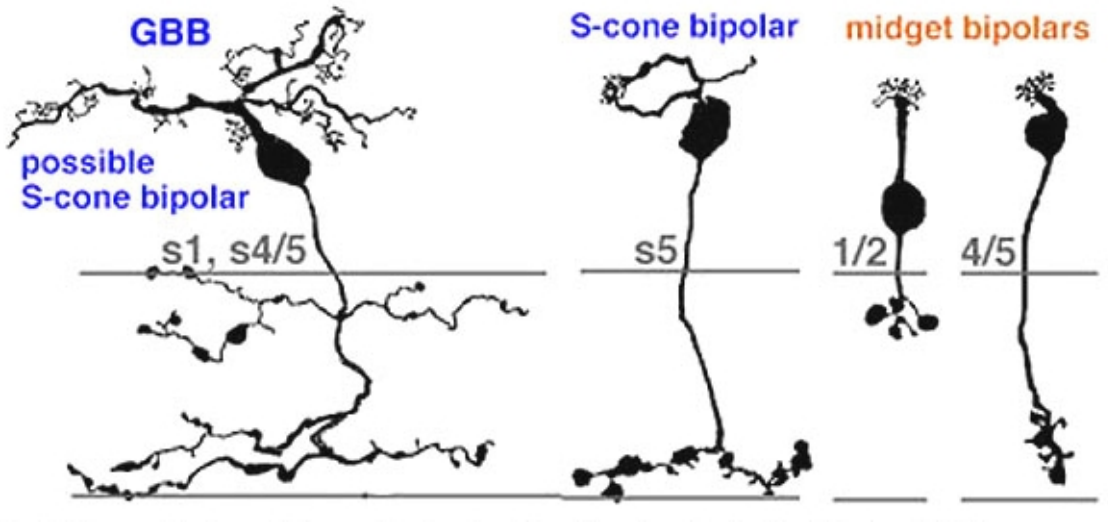

Figure 8. S-cone bipolar cell types of primate retina.

of HC in the human retina (21). Light micrographs and drawings of Golgi-stained examples of these three types are illustrated in Fig. 10 and Fig. 11.

HI is the classic HC of primate retina (5). It is a small-field cell (15-μm-diameter dendritic tree in the fovea, 80–100-μm in the periphery) with stout dendrites, giving rise to distinct clusters of round or donut-shaped terminals contacting cones as lateral elements of the ribbon synapses (Fig. 12).

In peripheral retina, the HI cells have much bigger dendritic trees, and their radiating dendrites contact as many as 18 cones. The HI cell has a single, thick axon that passes laterally in the outer plexiform layer to terminate more than 1 mm away in a thickened axon terminal stalk that bears a fan-shaped profusion of lollipop-like terminals. HI axon terminals end in rod spherules as lateral elements of the ribbon synapses (Fig. 13) (7).

HIII cells are similar in appearance to HI cells, but everywhere in the retina, HIII cells are one-third bigger in dendritic tree size and typically, particularly in the peripheral retina, asymmetrical in shape (one or two dendrites are much longer than others). The clusters of terminals contact cones in the same manner as the HI cell terminals, and because of their bigger field size, they contact more cone pedicles (9–12 in the foveal retina, 20–25 in the peripheral retina). The axon of the HIII has not been conclusively followed to a terminal yet, so we know nothing of the nature of the photoreceptor type it contacts, although we suspect it is a mixture of rods and cones.

HII cells are more spidery and intricate in dendritic field characteristics than either of the other types (20). Their terminals are not clearly seen as clusters approaching cone pedicles, but they are known to end in cone pedicles (20, 22, 23). HII cells also bear an axon, but this is quite different from that of the other two HC types. It is short (100–200 μm), curled instead of straight, and has contacts to cone pedicles by means of small, wispy terminals.

Recent findings from electron microscopic studies of Golgi-stained HCs of the human retina show that there is some color-specific wiring going on for the three cell types (Fig. 14) (22, 23).

Thus, HIs contact medium- and long-wavelength cones primarily, but with a small number of contacts to any short-wavelength cones in the dendritic field. HII cells contact short-wavelength cones, directing major dendrites to these cones in their dendritic fields where they occur and contacting with lesser numbers of terminals of other types of non-short-wavelength cone. The HII cells axon contacts short-wavelength cones only. HIII cells have large dendritic terminals in medium- and long-wavelength cones, seemingly avoiding short-

wavelength cones in their dendritic tree (23). Thus, a wiring diagram can be made (Fig. 15) that summarizes our present understanding of the spectral connections of the three HC cell types of the primate retina.

ON and OFF Center Pathways and Center Surround Organization of the Retina

We know that a photoreceptor neurotransmitter (which is glutamate, see Dowling (24) and Massey (25) for reviews) is released in the dark in the vertebrate retina (26). Thus, the photoreceptor, whether it be rod or cone, is in a depolarized state in the dark. On light stimulation, the photoreceptor responds with a hyperpolarization; transmitter release ceases, but the postsynaptic bipolar cells respond with either hyperpolarization or depolarization of their membranes. The hyperpolarizing type of bipolar cell is called an OFF-center cell, whereas the depolarizing bipolar cell is called an ON-center cell (27, 28).

The origin of these two important ON-center and OFF-center channels is determined by the types of synaptic contacts that these bipolars make with cone pedicles or rod spherules. Thus, the type of bipolar cell making invaginating contacts (several cone bipolar types, among them the IMB type and the rod bipolar type) responds to light with an inverted sign compared with the photoreceptor. They give depolarizing responses to light and are thought to be stimulated via metabotropic glutamate receptors, specifically mGluR6, and signal via a G protein cascade (29, 30) (see chapters on rod and cone pathways). These depolarizing bipolar cells have an APB-sensitive glutamate receptor (Fig. 16 and Fig. 17) (31).

On the other hand, the type of bipolar cell that makes contact with the photoreceptor at a basal junction responds to light just like the photoreceptor by hyperpolarizing (see above). The hyperpolarizing types are driven via ionotropic (iGluR) AMPA-kainate glutamate channels in their synapses with photoreceptors (33). Hyperpolarizing (basal junction-contacting) bipolar cells are the start of OFF-center channels, and the depolarizing (invaginating, ribbon-related) bipolar types are the start of ON-center channels throughout the whole retina and visual system. In a later chapter, we find out that only excitatory channels are present at the level of information transfer between cone bipolar cells and ganglion cells in the inner plexiform layer. Therefore, the status of the signal transmitted by the ganglion cell to the brain is essentially determined by the nature of the cone bipolar contacting it, which in turn is determined by its photoreceptor synapse.

In submammalian species, intracellular recordings from the cones have indicated that they receive a feedback inhibitory message from horizontal cells (see a movie of the intracellular recordings of a cone and bipolar cells) (33). In fish retinas, there is morphological evidence that the horizontal cell lateral elements at the triad synapse produce spinules at which feedback signaling occurs to the cone (see Djamgoz and Kolb (34) for a review). In mammalian cones, there is no unequivocal morphological evidence for this feedback synapse, but some kind of feedback is expected at this site (see above).

Horizontal cell lateral elements, i.e., horizontal cell dendrites, have vesicles within them that could be directed at the cone membrane. This arrangement of horizontal cell dendrites on either side of the ribbon synapse in the triad, with the bipolar cell dendrites forming the central or basal junction position, is very important (Fig. 18). A small local circuit is formed here, that influences the flow of information throughout the whole retina.

We know that a photoreceptor neurotransmitter is released in the dark in the vertebrate retina. Thus, the photoreceptor, whether it be rod or cone, is in a depolarized state in the dark. On light stimulation, the photoreceptor reacts with a hyperpolarization; transmitter release ceases, but the postsynaptic bipolar cells respond with either hyperpolarization or depolarization of their membranes. The horizontal cells respond with a hyperpolarization as well, but a feedback synapse from the horizontal cell to the photoreceptor is also thought to occur. The feedback signal sums information from a network of horizontal cells connected over a wide spatial area of the outer plexiform layer. Thus, this large spatial area influences the photoreceptor and the bipolar cell to

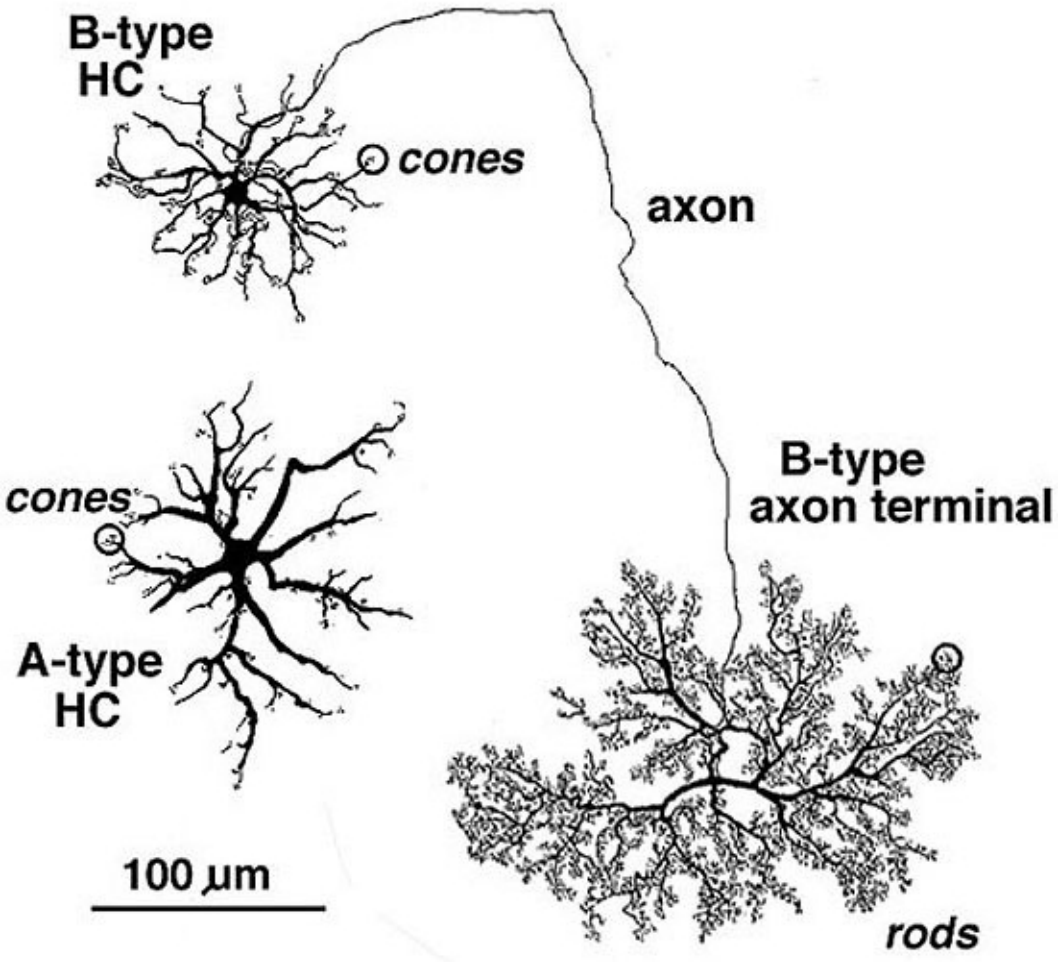

Figure 9. Horizontal cells in cat retina.

include a response coming from a surround region of retina. This local circuit provides the bipolar cell with a center-surround organization.

Inner Plexiform Layer

Helga Kolb

Created: January 1, 2001; Updated: March 30, 2007.

Bipolar, Amacrine, and Ganglion Cells Interact in the Inner Plexiform Layer

The axonal endings of bipolar cells bring information from the outer plexiform layer (OPL) to the neuropil of the inner plexiform layer (IPL) (Figure 1). Here bipolar cells talk to different varieties of functionally specialized amacrine cells and to dendrites of the various ganglion cells. The neuropil is a confusing network of interconnecting profiles that, to be understood, has to be investigated at the higher magnification afforded by the electron microscope (over the light microscope) (Figure 2) and with knowledge gained from Golgi-staining for morphology and intracellular electrophysiology for function of individual cells in the network.

Ultrastructure of the Neuropil of the Inner Plexiform Layer

A view of a small part of the neuropil of the inner plexiform layer is shown in the electron micrograph (Figure 3). Bipolar cell axon terminals (Figure 3, red profiles) are vesicle-filled profiles, containing irregular, long mitochondria and neurotubules. Their synapses are typified by a small synaptic ribbon pointing into a wedge with two post synaptic profiles (known as a dyad) at the apex (Figure 4, red dots in bipolar cell profiles) (1). Amacrine cell dendrites are also vesicle filled and have round mitochondria and sometimes neurofilaments as well as neurotubules. Amacrine profiles vary between being very small cross-sections through thin straight tubes and being larger varicosities budding off the dendrites.

Typically, amacrine cells synapse upon other profiles (bipolar axons, amacrine cells, or ganglion cell dendrites) in the enlarged varicosities at what is known as a conventional synapse: the synapse consists of synaptic vesicles clustered at a pre- and post-membrane density (Figure 4, yellow dots in amacrine profile) (1). Ganglion cell dendrites (Figure 3, yellow profiles) are recognizable as profiles lacking synaptic vesicles but containing ribosomes, neurotubules, and filaments. Ganglion cell dendrites are seen to be postsynaptic to bipolar ribbon synapses and amacrine conventional synapses. Bipolar cells are also postsynaptic to many amacrine synapses. Often amacrine cells make what are called reciprocal synapses to the bipolar cell axons from which they receive ribbon synapses (Figure 4, yellow dots).

This reciprocal synapse is in essence a feedback synapse to the bipolar cell axon in the inner plexiform layer, with the same strategic importance as the horizontal cell dendrite making a feedback synapse at the photoreceptor ribbon synapse, in the outer plexiform layer. It will be remembered that such a local circuit in the outer plexiform layer was thought to provide the bipolar cell response with a center-surround organization. It has been suggested that another surround mechanism coming from the amacrine cells could be added at this reciprocal (feed-back) synapse in the inner plexiform layer.

Different Morphological Types of Amacrine and Ganglion Cells

It is clear that there are many different kinds of amacrine cell and ganglion cell branchings in the IPL of the human retina. From Golgi-staining studies, we know that there are at least 25 different amacrine cell types in the monkey and human retinas (2, 3). Some drawings of different amacrine cells as seen after Golgi-staining in wholemounts of human retina are shown in Figure 5.

The amacrine cells are classified into different types based on morphological characteristics of dendritic tree size, such as small, medium, and large branching characteristics (i.e., tufted, varicose, linear, beaded, and radiate) and, most importantly, on the stratification of their dendrites in the IPL (2, 3). The neuropil of the IPL was arbitrarily

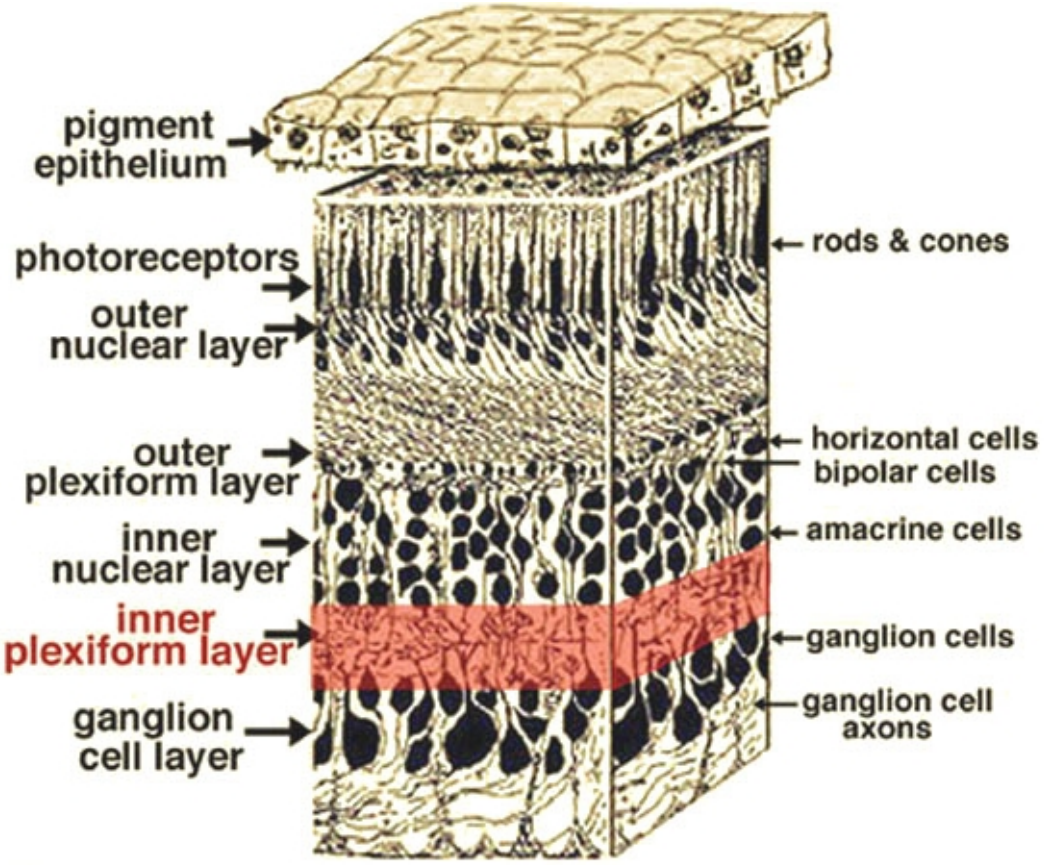

Figure 1. 3-D block of retina with the inner plexiform layer highlighted (red).

divided into five strata by Cajal (4), because he appreciated the fact that cells branching in disparate strata could **not** make synaptic interactions, whereas those that costratified could. This five-strata, descriptive classification scheme has been used by morphologists since that time to classify retinal cells on their dendritic branching level. See, for example, that in Figure 6, some amacrine cells have dendrites in strata 1 and 2 (called broadly stratified types; Figure 6, cell 8) or strata 1 and 5 (called bistratified types; Figure 6, cell 1), stratum 1, or any of the five strata (called monostratified; Figure 6, cell 13) or dendrites through all strata 1 to 5 (called diffuse types; Figure 6, cells 12 and 14).

In Figure 6, the amacrine cells have been stained by the Golgi procedure which, as we have seen, is very good for showing the isolated complete shape and size of a nerve cell. Newer techniques are also providing valuable information on cell shapes and sizes: techniques such as using intracellular staining through a microelectrode, and immunocytochemistry to stain cells with antibodies to their neurotransmitter or synthesizing enzymes.

These are some different amacrine cell types stained by injection of dyes through a microelectrode inserted into the cell body. The cells that look like exploding fireworks are called "starburst" cells and are known to use acetylcholine as their neurotransmitter (Figure 7) (5-7).

Another type of amacrine cell, thought to contain serotonin as a neurotransmitter, has been stained by the same technique (Figure 8) (8).

Using similar morphological techniques of Golgi staining, immunocytochemisry, and intracellular staining, the ganglion cells of the retina have been classified into various different types (Figure 9, Figure 10). As many as 25 different types exist in mammalian and human retinas, a few of which are shown in both sectioned view (Figure 9) and wholemount view (Figure 10). As with the amacrine cells, ganglion cells are classified onto the different

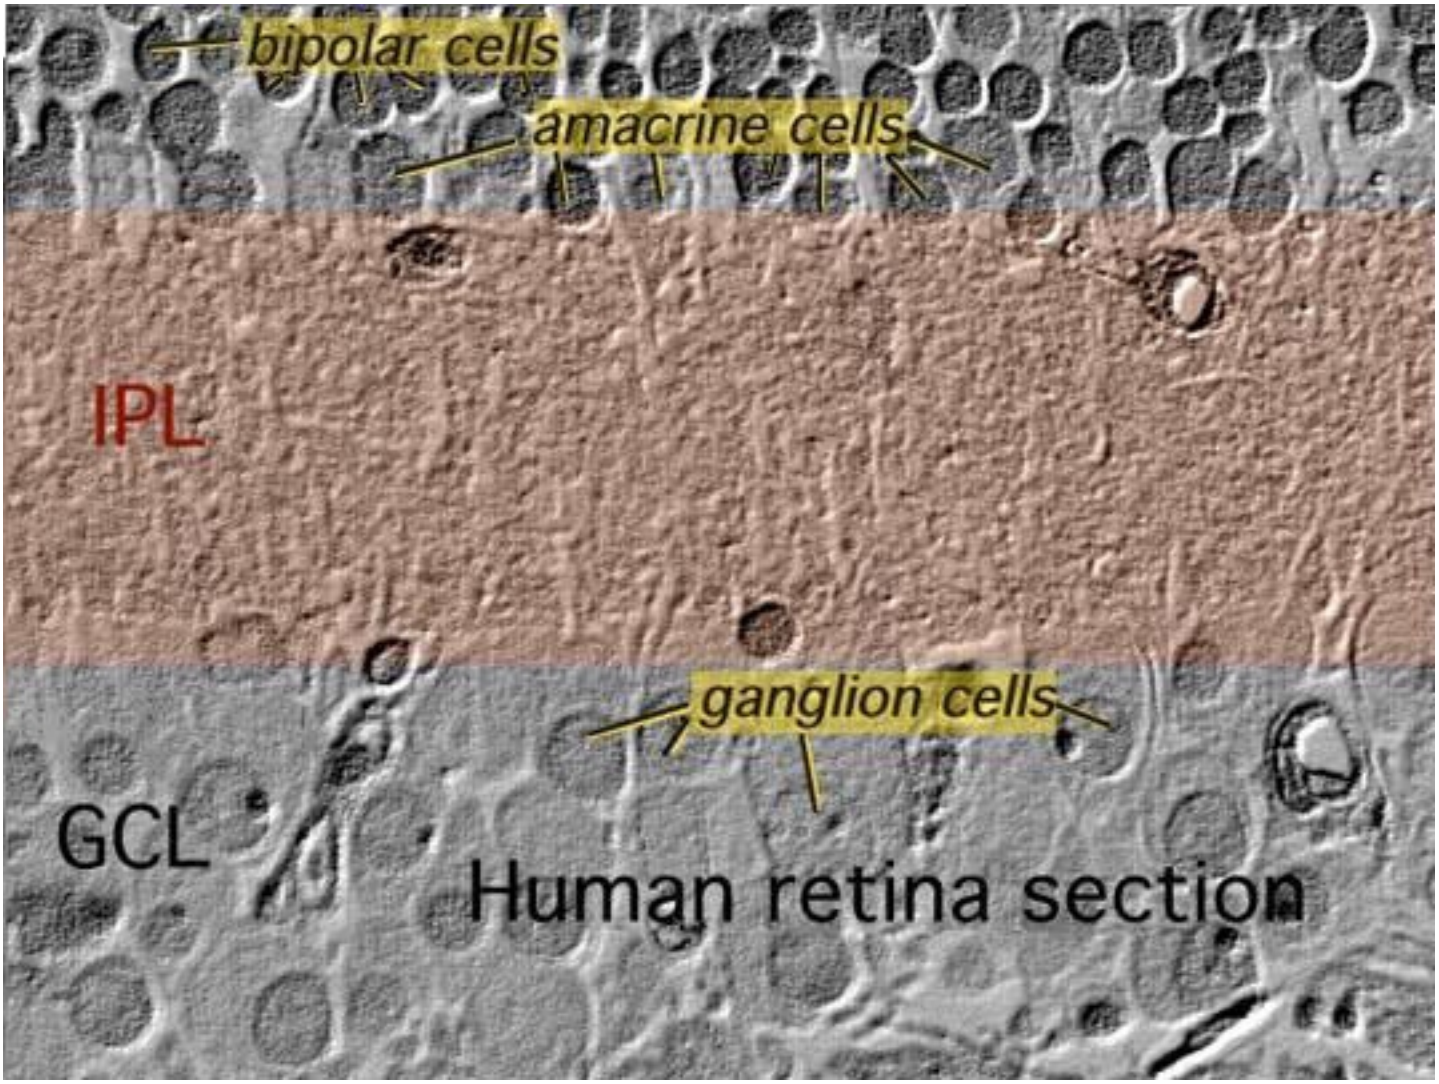

Figure 2. Light micrograph of a vertical section of the human retina to show the inner plexiform layer (IPL).

types by cell body size, dendritic tree spread, branching patterns (e.g., radiate or tufted), and branching level in the five strata of the IPL. In both cat and human retinas, ganglion cells can be from small to large, diffuse, bistratified, and various monostratified, large-field types with different stratification levels in the inner plexiform layer.

Both amacrine and ganglion cells increase in dendritic tree span with eccentricity from the fovea. The very smallest dendritic fields for all cells types being possessed by cells of the fovea or area centralis are shown in Figure 11 for the common ganglion cells of the cat retina (alpha and beta types). The same ganglion cell types are ten times the size in dendritic tree spread in peripheral retina (9, 10). For this reason, classification of amacrines and ganglion cells has to always take eccentricity from the fovea into account and compare cells in similar areas of retina to be sure that they are indeed different cell types.

In the human retina, the commonest ganglion cell types are the parasol and the midget ganglion cells, shown in Figure 12 (3, 11-13). They are also known as P cells (midget ganglion cells), because of their projection to the parvocellular layers, and M cells (parasol ganglion cells), because of their projection to the magnocellular layers of the lateral geniculate nucleus (14). We shall return to these ganglion cell types in a later chapter.

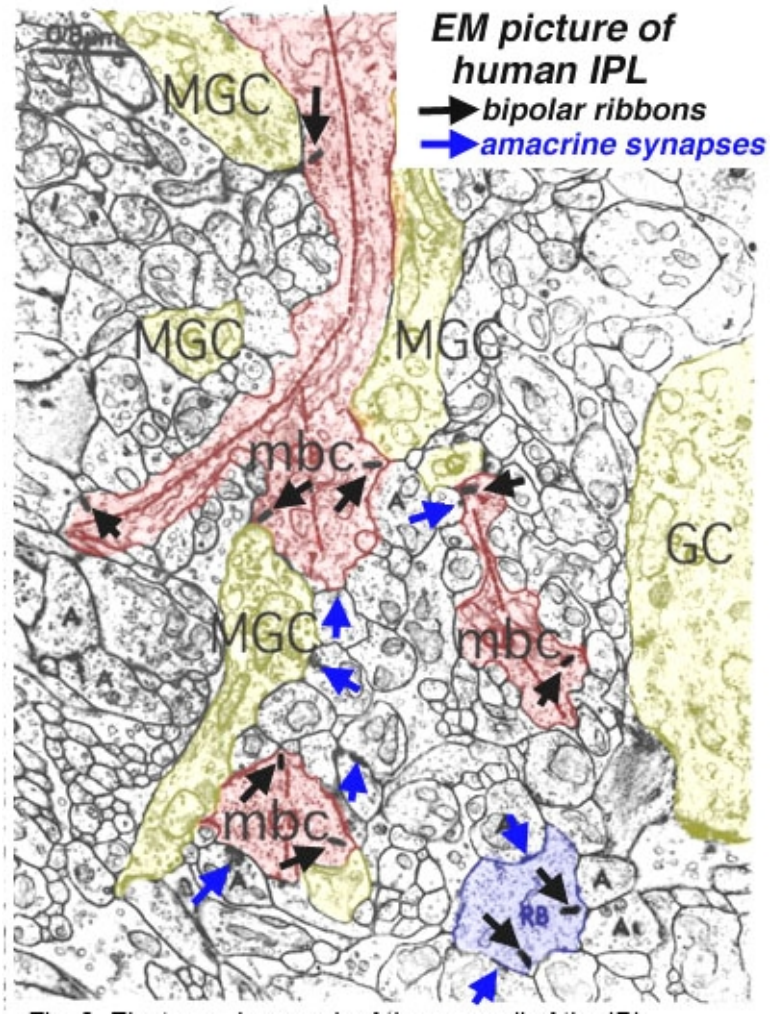

Figure 3. Electron micrograph of the neuropil of the IPL.

Stratification of Amacrine and Ganglion Cells in Relationship to Bipolar Cell Axons

One may ask why amacrine cells and ganglion cells should be classified on stratification level of their dendrites, particularly if they look the same in other respects, such as field size, cell body size, and dendritic morphology. It was already clear to Cajal (4) 100 years ago that dendrites of amacrine and ganglion cells and axons of bipolar cells were arranged to costratify in some meaningful manner. The meaning of costratifications and orderly arrangements of branching levels, other than the obvious of making sure certain cell types made synapses with certain other cell types, escaped him though.

We had to wait for 70 years before the answer was found in the physiological responses of the different nerve cells of the retina. In the 1970s, it became possible to make intracellular recordings from the neurons of the retina with dye-filled glass microelectrodes. Physiologists were able to record both the response of the impaled cell to light and to fill the cell with a fluorescent dye, such as Lucifer, to see what type of cell it was (Figure 13, left) (see the animation of the ionotophoresis of Lucifer dye into a ganglion cell via a microelectrode and see the animation of the physiological recording procedure).

In the 1950s and 1960s, it became apparent from ganglion cell recordings in the mammalian retina that the visual message leaving the retina was in the form of ganglion cell axon spike discharges that occurred either

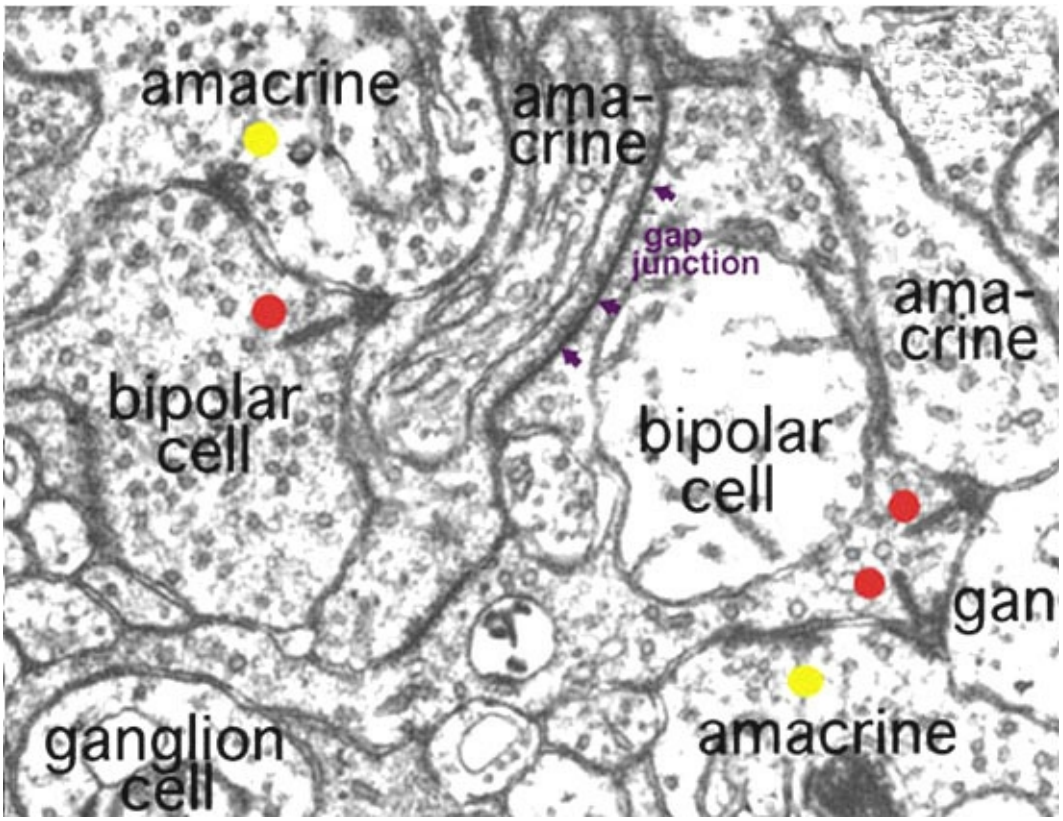

Figure 4. Electron micrograph of reciprocal synapses in the IPL.

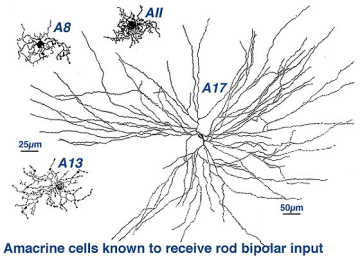

Figure 5. Amacrine cells in human retina.

when a spot of light stimulated the retina (ON discharge to light) or when the spot of light was turned off (OFF discharge). Ganglion cells were responding to either one or the other of the change of state of light. The one group was stimulated by the light brighter than background and the other by light darker than background (15, 16). Next came intracellular recordings from the five basic cell types in a mudpuppy retina, which revealed that cells preceding ganglion cells also fell into the two physiological types, i.e., bipolar and amacrine cells could give ON or OFF discharges (17, 18). Knowing now that bipolar cells could be ON- or OFF-center to a spot of light (they could have the opposite response in a surround concentrically around their central receptive field; mentioned in the chapter on the outer plexiform layer and dealt with in detail in later chapters on circuitry for rod and cone signals), it was reasonable to suggest that OFF-center bipolar chains excited OFF ganglion cells, and that ON-center bipolar cell chains excited ON ganglion cells. The typical bipolar cell types that might form the bipolar chains driving ganglion cells of the primate retina are shown in Figure 14.

These bipolar cells, as described in the previous section on the outer plexiform layer, make different types of synapses with cone pedicles and rod spherules. Some types make basal contacts on the surface of the cone

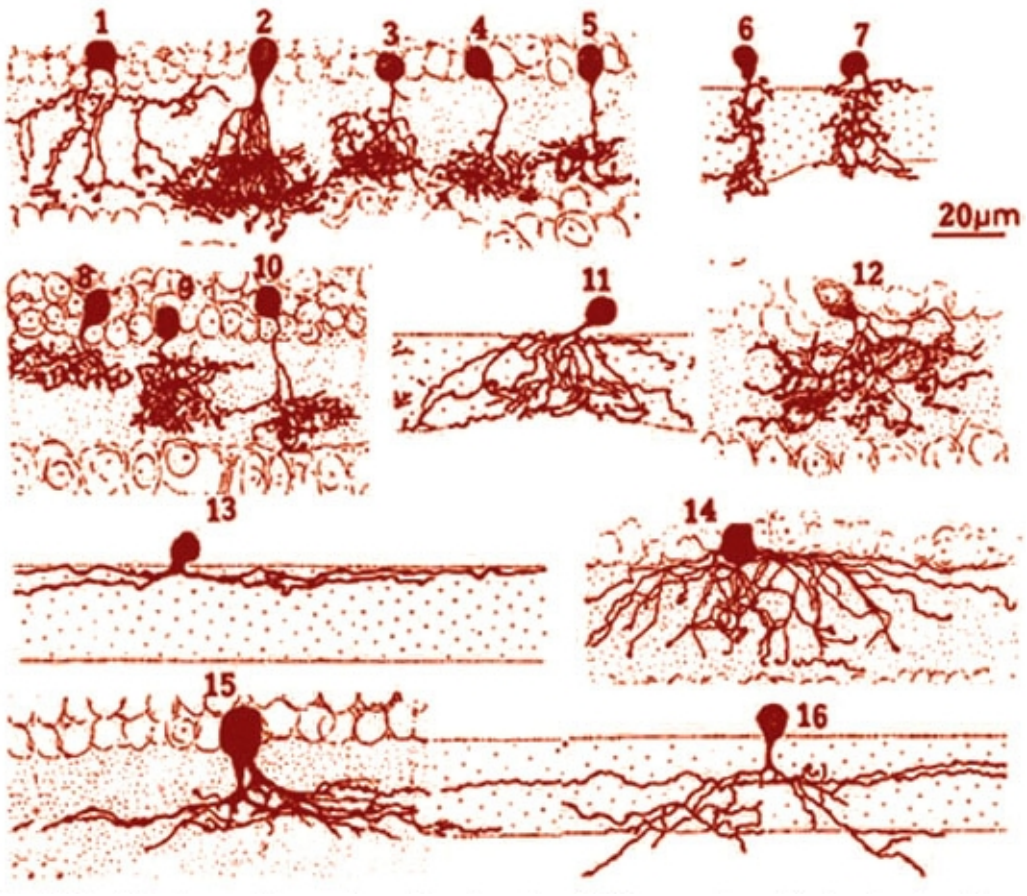

Figure 6. Stratification of amacrine cells in human retina.

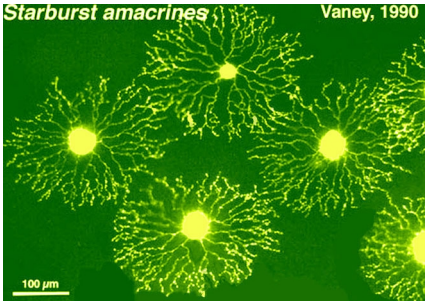

Figure 7. Starbust amacrine cells.

pedicles, and others make invaginating contact to end close to the synaptic ribbons in both rod spherules and cone pedicles.

It is now thought that bipolar cells respond to light just like the photoreceptor, with a slow hyperpolarization when the bipolar dendrite is in the basal junction position. In contrast, the other type of contact, invaginating to the ribbon synapse, causes the bipolar to respond to light with an inverted sign compared with the photoreceptor. It gives a slow depolarizing response. Thus, the nature of the postsynaptic membrane channels on the cone bipolar cell dendrite is the important designator of the response sign the bipolar will have. The hyperpolarizing bipolar types are the start of OFF-center channels, and the depolarizing types are the start of ON-center channels through the retina.

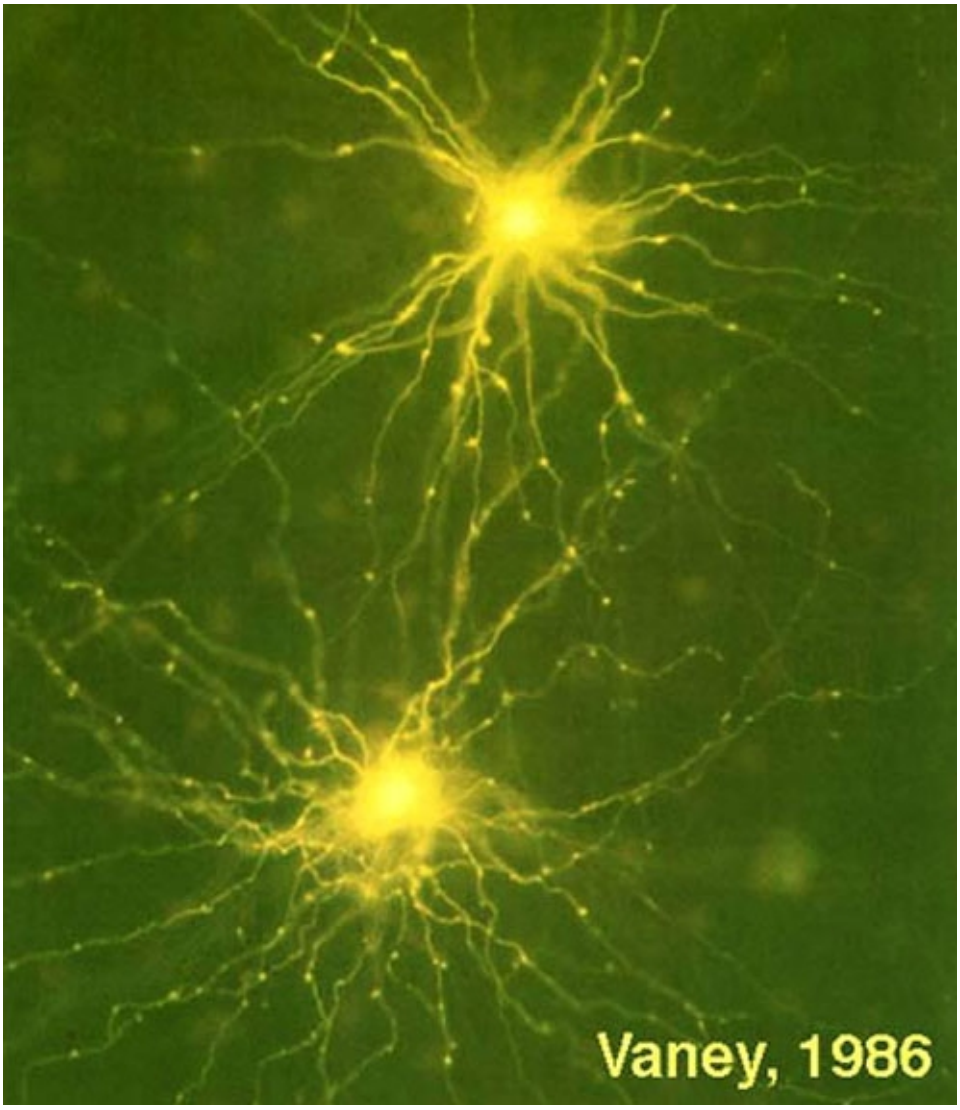

Figure 8. Serotonin-containing amacrine cells.

The bipolar cells shown in Figure 14 will be noticed to have different axonal ending levels in the inner plexiform layer, e.g., DB1 has an axon ending in the stratum 1 neuropil close to the amacrine cell layer of the inner nucelar layer, while imb has an axon ending at the opposite side of the inner plexiform layer in straum 5 against the ganglion cell bodies. It seems obvious now, but it took a lot of painstaking serial section recontruction to show (19, 20) that DB1 and imb made contacts only with ganglion cells that had dendritic stratification in the same neuropil as the respective bipolar axonal terminals. At the level of information transfer between bipolar cells and ganglion cells in the IPL, only excitatory channels are present (21), so the type of signal transmitted to the ganglion cell, as either ON- or OFF-center, is essentially determined by the bipolar cells contacting it (Figure 15).

To keep the ON and OFF channels separate through the ganglion cells to the brain, the inner plexiform layer is divided into two functionally discrete sublaminae, called **a** (the two strata below the amacrine cell bodies) and **b** (the other three strata stretching to the ganglion cell bodies) (22). Interactions are only allowed between basal-contacting cone bipolar types and one set of ganglion cells in sublamina **a**, whereas invaginating-contacting cone bipolar cells can interact only with another set of ganglion cells branching in sublamina **b** (see above). Gouras (1971) (23) was the first to suggest that this specificity of bipolar-to-ganglion-cell contacts underlay ON-center and OFF-center midget ganglion cell responses in monkey. Later, Nelson et al. (24) conclusively proved this

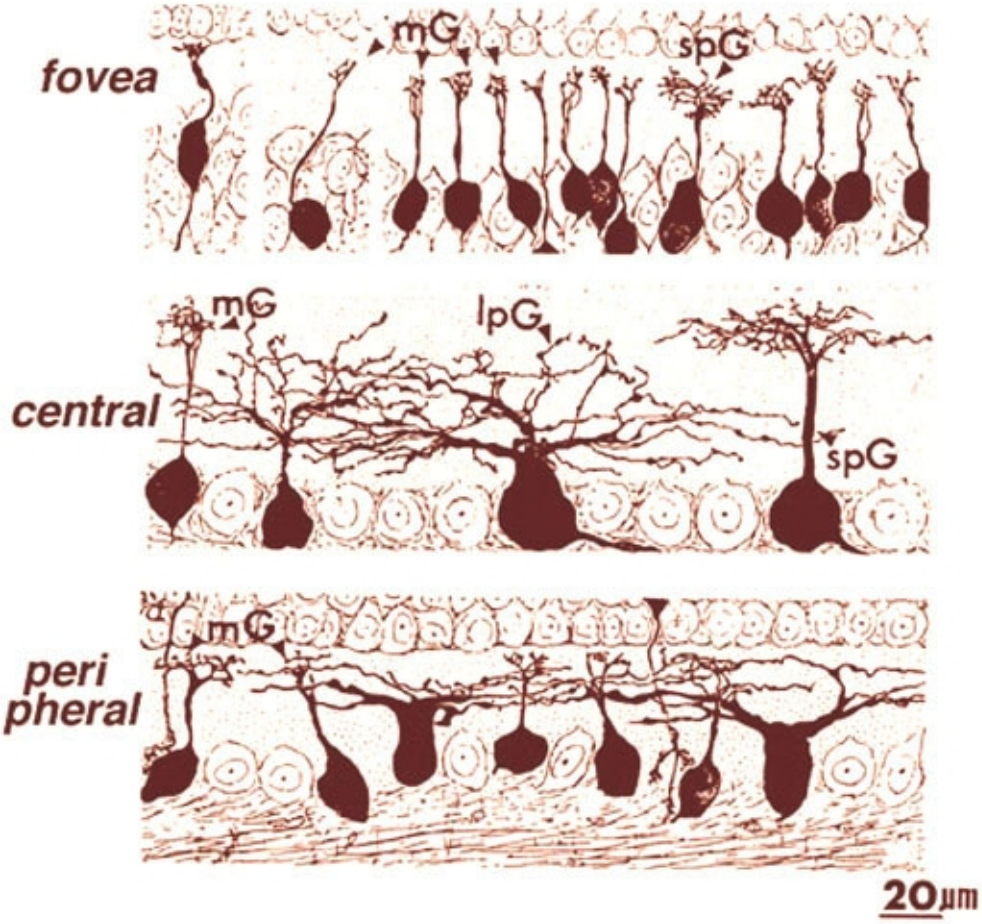

Figure 9. Sectioned view of ganglion cells.

hypothesis by means of intracellular recording and marking experiments in ganglion cells of cat (Figure 16) (see the animation of the physiological recording of ON and OFF beta ganglion cells).

Figure 16 shows the intracellular recordings made from two different ganglion cells of Nelson and coauthors' study (24). One cell proves to be ON-center, giving a burst of spikes riding on a depolarization of the membrane as soon as the light flash goes on. In contrast, the other cell is OFF-center, giving a hyperpolarization to the membrane when the light flash is on, but a burst of spikes riding on the depolarization when the light flash is over. The ON-center ganglion cell has dendrites restricted to branching in sublamina **b** and has synaptic input from invaginating types of bipolar cell. The OFF-center cell has dendrites reaching higher to branch only in sublamina **a** and gets synapses from basal junction contacting types of bipolar cell.

There is a definite functional architecture to the inner plexiform layer of the mammalian retina and, in fact, to all vertebrate retinas. Stratification of the neuropil is formed by specific levels of branching of bipolar, amacrine, and ganglion cells so that specialized circuits of interactions are set up. In addition, there has, during the course of evolution, been an imposition of a broad division of the two halves of the inner plexiform layer into the top half, allowing only interactions for the OFF-center ganglion cell pathways and in the bottom half, only for the ON-center ganglion cell pathways. Bipolar and ganglion cells are chiefly responsible for the bisublaminar organization, but amacrine cells, particularly if they are of the sustained physiological types, are also drawn in. However, many amacrine cells are diffuse or bistratified and serve to connect the ON- and OFF-center neuropils, whereas still others stratify in such a manner at the border between the two functional neuropils, to receive both ON and OFF inputs to drive them. Such amacrine cells may be in the majority in the vertebrate retina and are thought to be involved more in temporal facets of retinal performance. They may be important for fast transfer

of information, i.e., for speeding up signals The role of some of these amacrine cells will become clearer in later chapters.

Morphology and Circuitry of Ganglion Cells

Helga Kolb

Created: May 1, 2001; Updated: April 4, 2007.

General Morphology

Ganglion cells are the final output neurons of the vertebrate retina. The ganglion cell collects the electrical messages concerning the visual signal from the two layers of nerve cells preceding it in the retinal wiring scheme. A great deal of preprocessing has been accomplished by the neurons of the vertical pathways (photoreceptor to bipolar to ganglion cell chain), and by the lateral pathways (photoreceptor to horizontal cell to bipolar to a macrine to ganglion cell chain), before presentation to the ganglion cell, and so it represents the ultimate signaler to the brain of retinal information. Ganglion cells are larger on average than most preceding retinal inter neurons and have large diameter axons capable of passing the electrical signal, in the form of transient spike trains, to the retinal recipient areas of the brain many millimeters or centimeters distant from the retina. The optic nerve collects all of the axons of the ganglion cells, and this bundle of more than a million fibers (in humans, at least) then passes information to the next relay station in the brain for sorting and integrating into additional information-processing channels.

Cajal (1), in his monumental work on Golgi staining of the vertebrate retina, was able to classify many different varieties of ganglion cell based on form (dendritic morphology), extent (cell body and dendritic tree size), and number of sub layers in which they arborize (stratification levels in the inner plexiform layer). He considered the retina to be remarkably uniform across all vertebrates, differing only in respect to rod and cone specializations for **the visual sense of the animal**. Looking at Cajal's (1) drawings of dog ganglion cells as compared with the frog ganglion cell, for example, the former seem simpler in form than the latter cells (see Fig. 1 and Fig. 2), but we actually now know that there is a common evolutionary path taken by different ganglion cell types so that different morphological and functional classes are similar throughout the species. For example, the large ganglion cells, with open radiate branching patterns, process fast, transient impulse trains and, in all vertebrate retinas, are concerned with motion detection and alerting the animal to threatening, moving visual imagery, wherease small bushy ganglion cell types are concerned with processing small stationary, fine detail in tonically activated messages in all species.

In the 1940s, Polyak (2) produced a phenomenal description of the Golgi-impregnated neurons of the primate retina and therein he gave us a good classification of ganglion cell types (see chapter on Midget Pathways). So by the 1960s, we had a fairly extensive description and classification of the ganglion cells in mammalian and monkey retinas, but all the data were based on vertical sections of stained ganglion cells (1-6). The advent of a technique to perform Golgi staining on whole mount retinas allowed a reinterpretation of many of the earlier classifications, because now we could see the entire dendritic tree of a ganglion cell. The whole mounts could also be compared with images of intracellularly injected cells after physiological recordings (Fig. 3 and Fig. 4, and see the animation of the iontophoresis of Lucifer dye into a ganglion cell via a microlectrode).

A particularly successful morphological classification scheme was proposed by Boycott and Wassle (7). Three main classes of physiological response type were correlated with three morphological classes of ganglion cell in cat retina. Thus, the alpha, beta, gamma and delta morphological ganglion cell types were considered to be the equivalents of the Y, X, and W types of the physiology (reviewed in 7-11) (Fig. 5). By comparison with Cajal's drawings, it was clear that alpha and beta types were already described (see Cajal drawing of dog and ox retinal ganglion cells) and another 10 or more of Cajal's (1) types were lumped under the umbrella of gamma and delta groups.

By 1978, we knew that alpha and beta cells of Boycott and Wassle (7) could be subdivided into separate subtypes, depending on whether they branch in sublamina **a** or sublamina **b** of the inner plexiform layer (12) (see chapter

on Inner Plexiform Layer). Sublamina **a** contained dendrites of cells with physiologically defined OFF-center receptive fields and sublamina **b** dendrites of cell with ON-center receptive fields (13). A new classification of Golgi-stained ganglion cells (14) could now relate both alpha and beta cells to the functionally important sublamina scheme and further, described many new types of cells including and going beyond the gamma and delta cells. The 20 cell types over and above the alpha, beta, and gamma cells were named from G4 to G23 in order of cell body size and dendritic form (i.e., from smallest types, G4 to largest types at G23) (14).

Alpha and Beta Ganglion Cell Types of Mammalian Retinas

Alpha and beta ganglion cells of the cat retina are arranged in regular, superimposed bi-level mosaics across the whole retina (15, 16). Both OFF-center (branching in sublamina **a**) and ON-center (branching in sublamina **b**) varieties of alpha and beta cells are arranged in a closely packed pattern with minimal overlap of their peripheral dendrites. ON and OFF varieties are always paired as shown in the Wassle and coauthors elegant papers (15, 16) (Fig. 6 and Fig. 7), and between an ON/OFF pair there is sampling of almost the same retinal space (Fig. 7).

Both cell types have their smallest dendritic tree sizes at the area centralis of the cat retina (equivalent to the fovea of primate retinas) and radiate out from this central point with gradually expanding circular dendritic trees. To maintain the low overlap ratio of their dendritic trees, the cells with larger fields are consequently spaced at greater intervals from each other, i.e., density of the cells/mm^2 of retina is inversely proportional to distance from the area centralis. This is shown in Fig. 8, where the increase of ganglion cell size as shown with distance from the area centralis (a.c.): peripheral alpha and beta retinal ganglion cells are 10-fold larger than their area centralis relatives.

Non-Alpha and Non-Beta Ganglion Cell Types in Mammalian Retinas

It has been estimated that between 50% and 60% of all ganglion cells in the cat retina are cells other than alpha and beta types (17, 18). Alpha cells form 3% and beta cells 45-50%. A Golgi study by Kolb and coauthors (14) indicated that 21 different morphological types of ganglion cell were of the non-alpha/non-beta cells classes (some of them are shown in Fig. 9, and others are shown in the human ganglion cell section). The G3 was the equivalent of the gamma cell of Boycott and Wassle (7) (Fig. 5). G3 may be a concentrically organized type of W cell (9, 18), and according to Kolb and coauthors (14), comes in ON- and OFF-sublaminal branching subtypes. G19 cells equivalent to delta cells of Boycott and Wassle (7) (Fig. 5) probably also come in the ON- and OFF subtypes (19-21). Diffuse wide-field G4 and monostratifying G18 cells are probably equivalent to two different OFF-tonic cells and G15 to an ON-directional cell (22). G19, which is similar to one type of delta cell of Boycott and Wassle (7), may be an ON-tonic cell, whereas G22 is almost certainly an ON/OFF phasic type (22). The newly described Q cell of Troy et al (23). may also be the physiological correlate of an ON-delta morphological type. Ganglion cells with the morphology of G21 and G23 are labeled by retrograde transport of tracers from brain visual centers: G21 from the accessory optic system (24). The speculation is that G21 is a directionally selective ganglion cell, because cells of the accessory optic system are reported to be directionally selective (25). A ganglion cell type that could be a G23 type has been labeled from retrograde markers injected into the retinal recipient zone (RRZ) in the pulvinar (26) and has been named the epsilon cell. However, the staining of epsilon cells has never been good enough to be sure which Golgi type it really is.

Other ganglion cell types that have been reported using tracer or other staining techniques than the Golgi method include the medium-gamma cells, g1 and g2 cells (not clear which Golgi types these are) (27), Neuropeptide Y immunoreactive (NPY-IR) cells (28), ganglion cells of the geniculate wing (29), and indoleamine-containing ganglion cells likened to delta cells (21, 30).

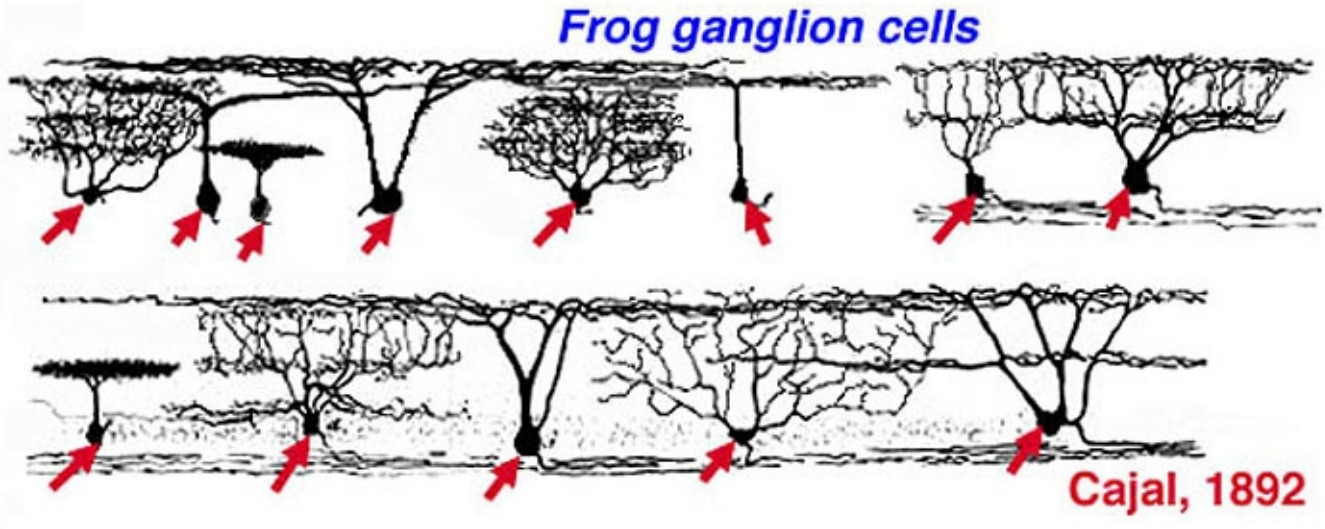

Figure 1. Cajal's drawing of ganglion cells of the frog's retina.

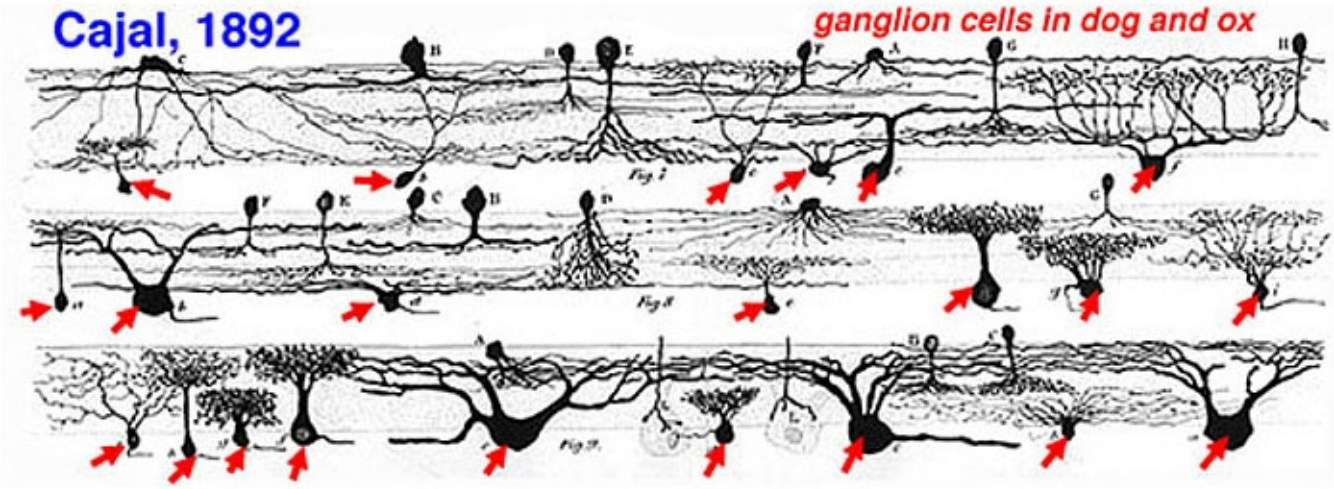

Figure 2. Cajal's drawing of ganglion cells of ox and dog retinas.

Convergence of Photoreceptors and Second-Order Neurons to Cat Retinal Ganglion Cells

The organization of the cat retina with a concentration of small-field beta cells in the area centralis allows the lowest convergence ratio of cone photoreceptors to ganglion cells. This is presumed to be the substrate for the high-acuity pathways. The human (primate) retina culminates this trend with the development of the midget system and the photoreceptor to ganglion cell pathway to a one-to-one relationship of course (see chapter on midget pathways).

An electron microscope analysis, of two area centralis beta cells in the cat, showed that each ganglion cell received input from three or four cone bipolars which, in turn, received input from four to eight cones (15, 16, 31) (Fig. 10). Another OFF-center beta ganglion cell has been calculated to have 14 definite bipolar cell axon terminals inputting the dendrites (Fig. 11, four bipolar axons shown in red, arrows). Thus, this type of ganglion

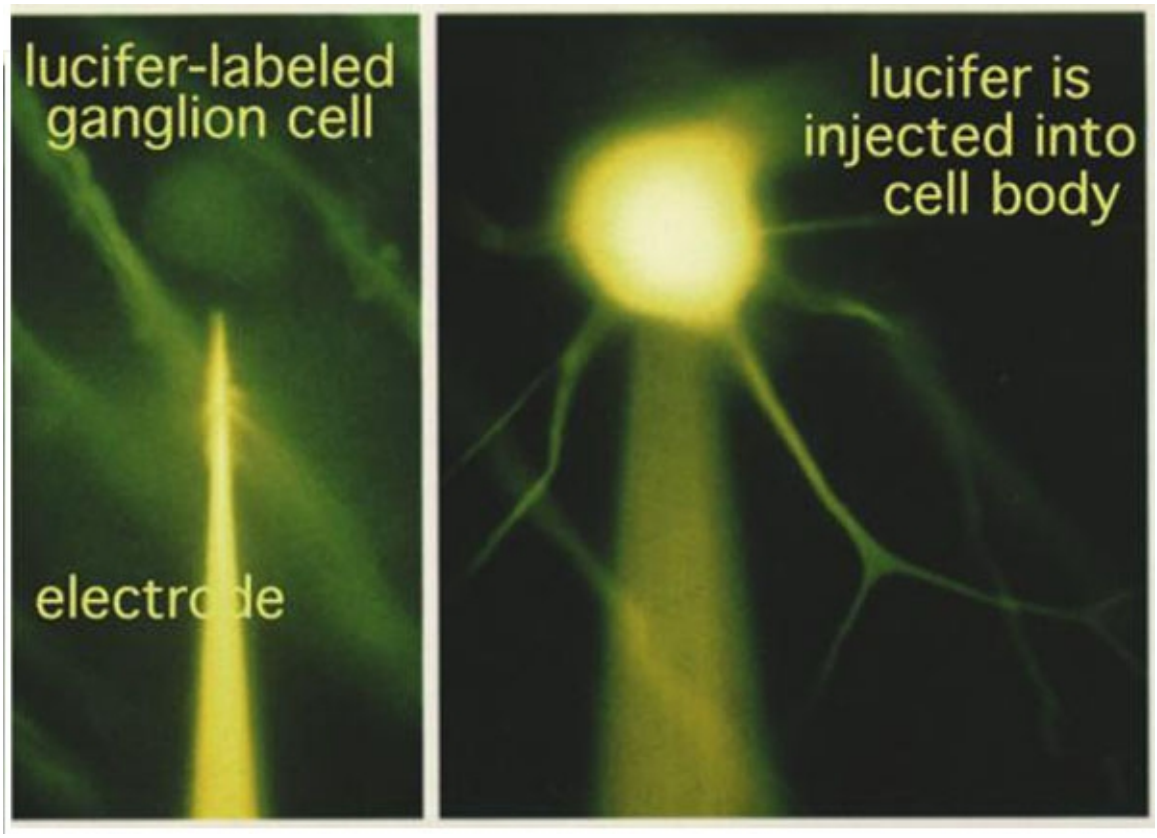

Figure 3. Experimental procedure for impaling ganglion cells and injecting lucifer dye in the retina. (Courtesy of Josef Ammermuller.)

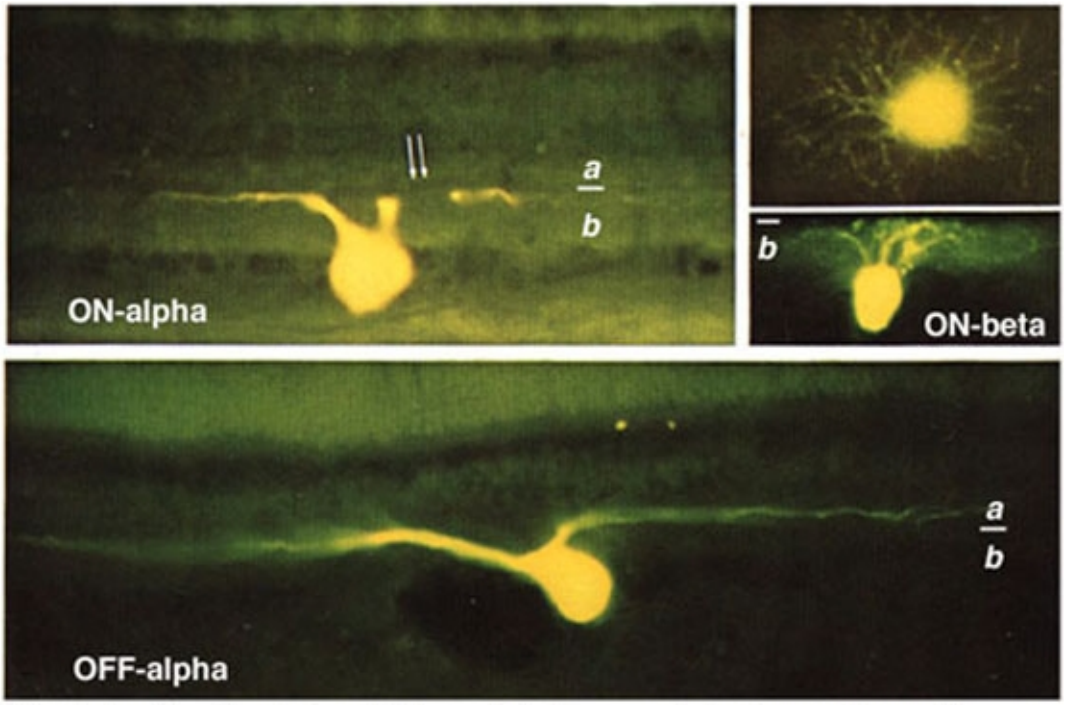

Figure 4. Lucifer-injected and intracellularly recorded cat ganglion cells.

cell would have convergence of approximately 100 cones through the 14 bipolar cells of two subtypes (see Fig. 12 and Fig. 13, small-field (yellow) and large-field (red) types of cone bipolar).

Movie 1. An animation of the iontophoresis of Lucifer dye into a ganglion cell.
Download video

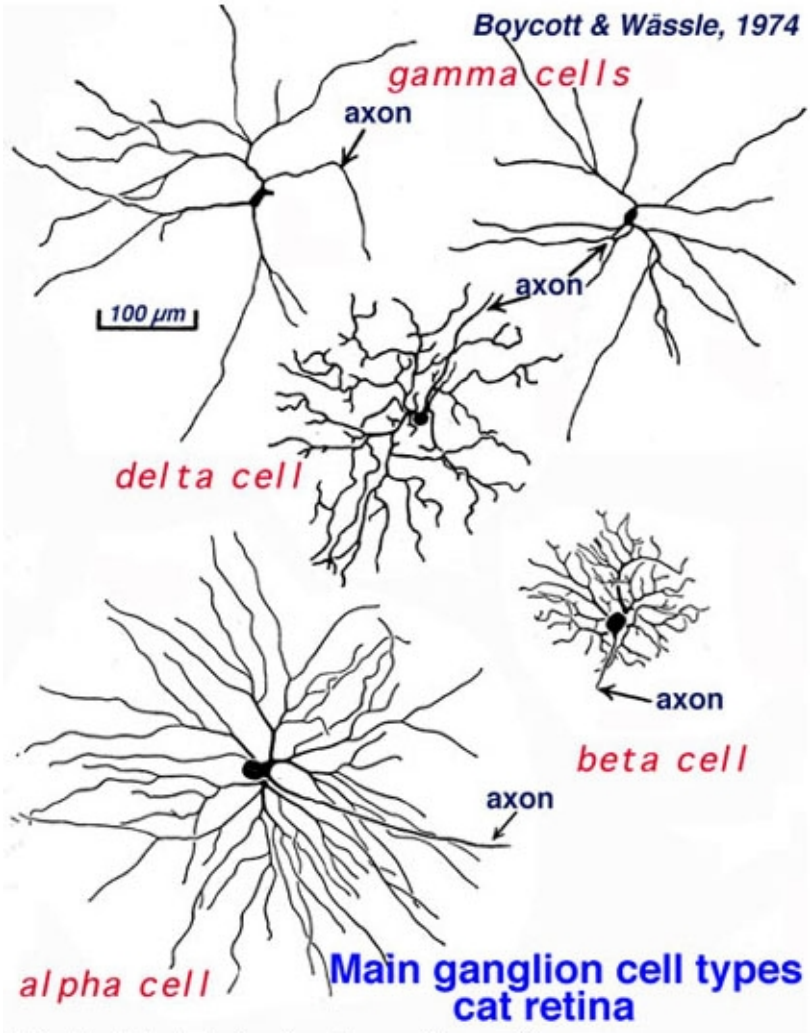

Figure 5. Golgi-stained cat ganglion cells.

It is also calculated that about 14 AII amacrine cells (Fig. 13, purple cells) would also have input, thereby converging 4200 rods through 280 rod bipolar cells to the 14 AII cells of input (Fig. 18). In addition, 28 to 41

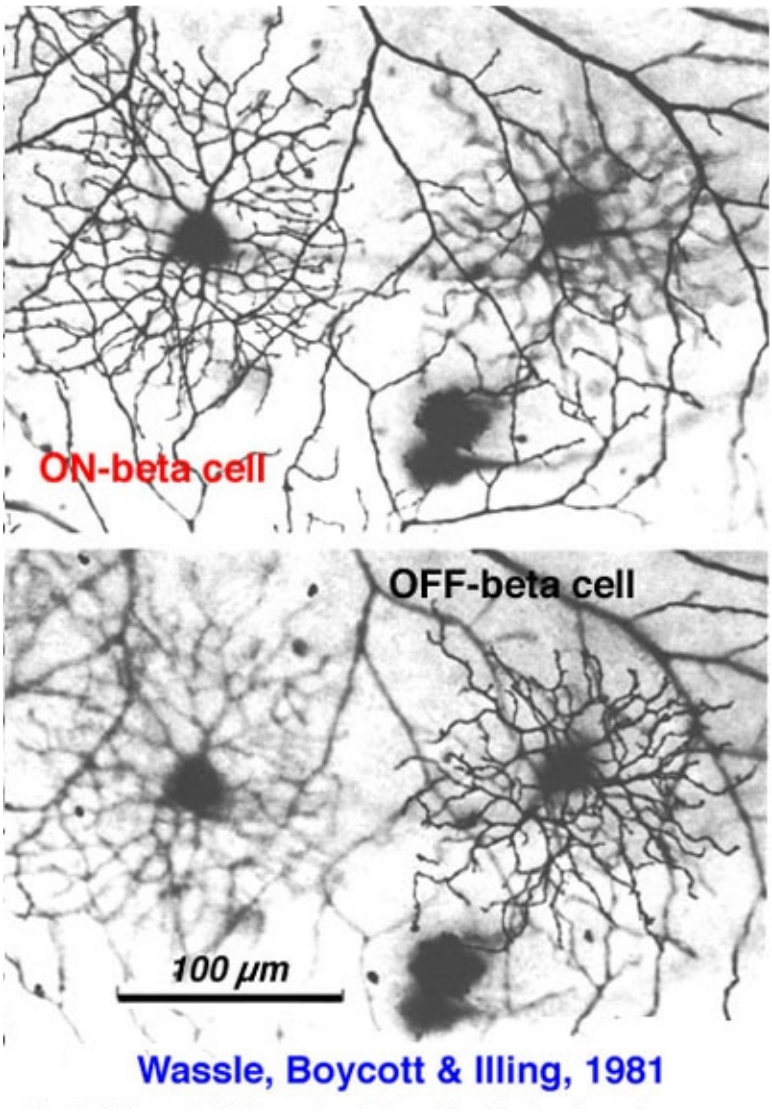

Figure 6. ON- and OFF-center beta cells of cat retina shown at different planes of focus.

other amacrine cells probably have synapses, allowing even more convergence over a greater laterally spreading area than the ganglion cells dendritic tree diameter would have.

In the same vein, we have information on convergence of bipolar cells and amacrine cells upon both ON-center and OFF-center alpha ganglion cells (32, 33). In the model of the OFF-center alpha cell seen in Fig. 14 and Fig. 15, cone bipolar synapses, from only one type of OFF-center cone bipolar (cb2 type, red dots), form 20% of the total synaptic input, and the rest of the input is from various kinds of amacrine cells. A minimum of 142 bipolar cells, 256 AII amacrine cells, and 1,011 other amacrine cells, together, provide between 6,000 and 10,000 synapses on the dendritic tree of this OFF-center alpha ganglion cell. With a potential cone convergence of 5-15 cones per bipolar cell, it is possible that 15,000 cones could ultimately be involved in the capture area of this type of ganglion cell.

In the case of the rod system, the convergence of preceding neurons to the ganglion cell is enormous, i.e., calculated by Sterling et al. (34) to be 75,000 rods through 5,000 rod bipolar cells to 250 AII amacrine cells to a single alpha cell (Fig. 11). The other amacrine cell input and their corresponding convergences are not capable of being assessed at the present time. Interestingly though, physiological measures of receptive field center sizes of

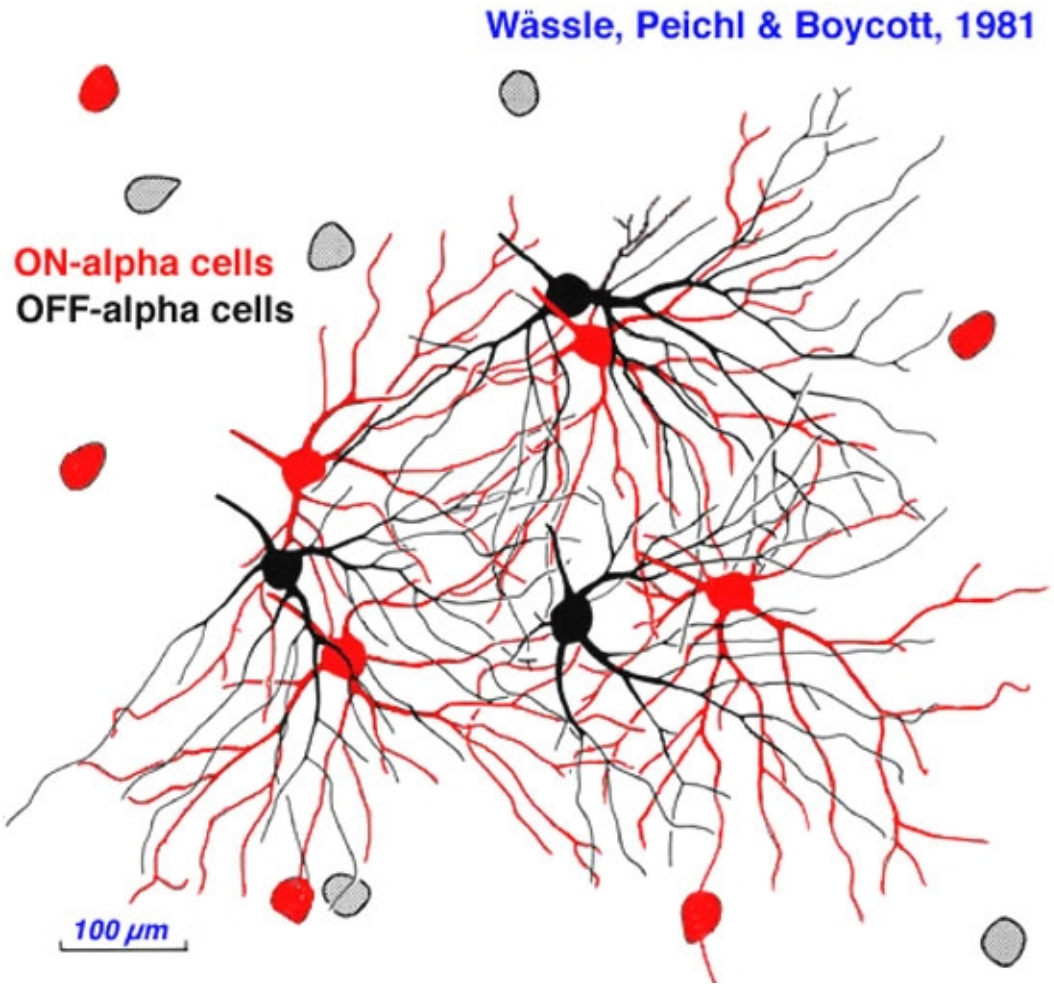

Figure 7. HRP-filled ON- and OFF-center alpha cell mosaics in cat retina.

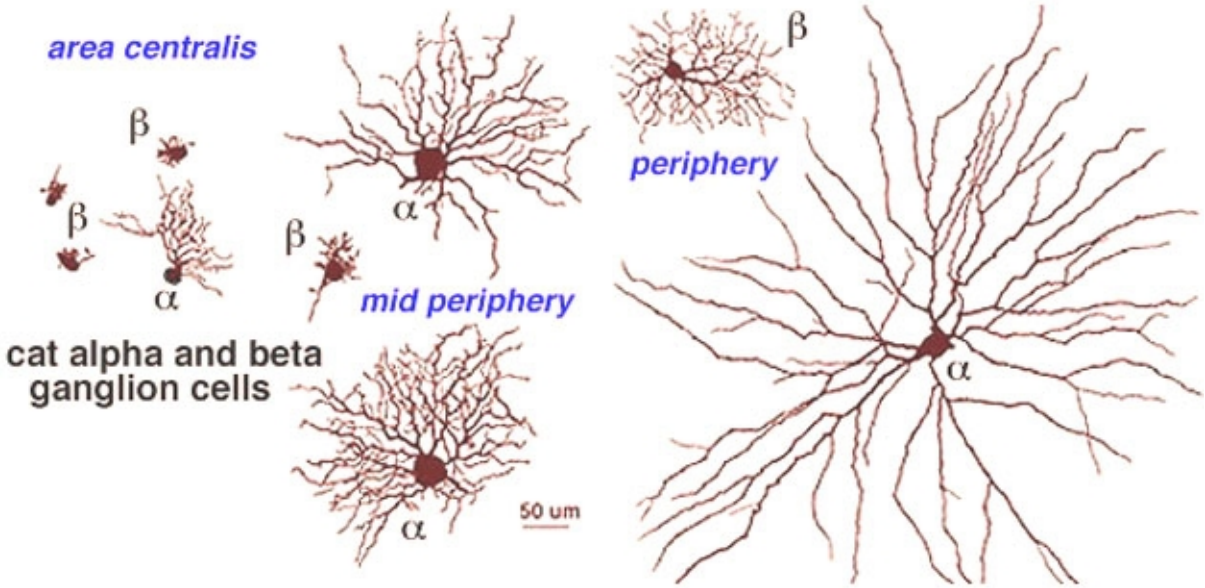

Figure 8. Cat ganglion cells (Golgi-stained wholemount views).

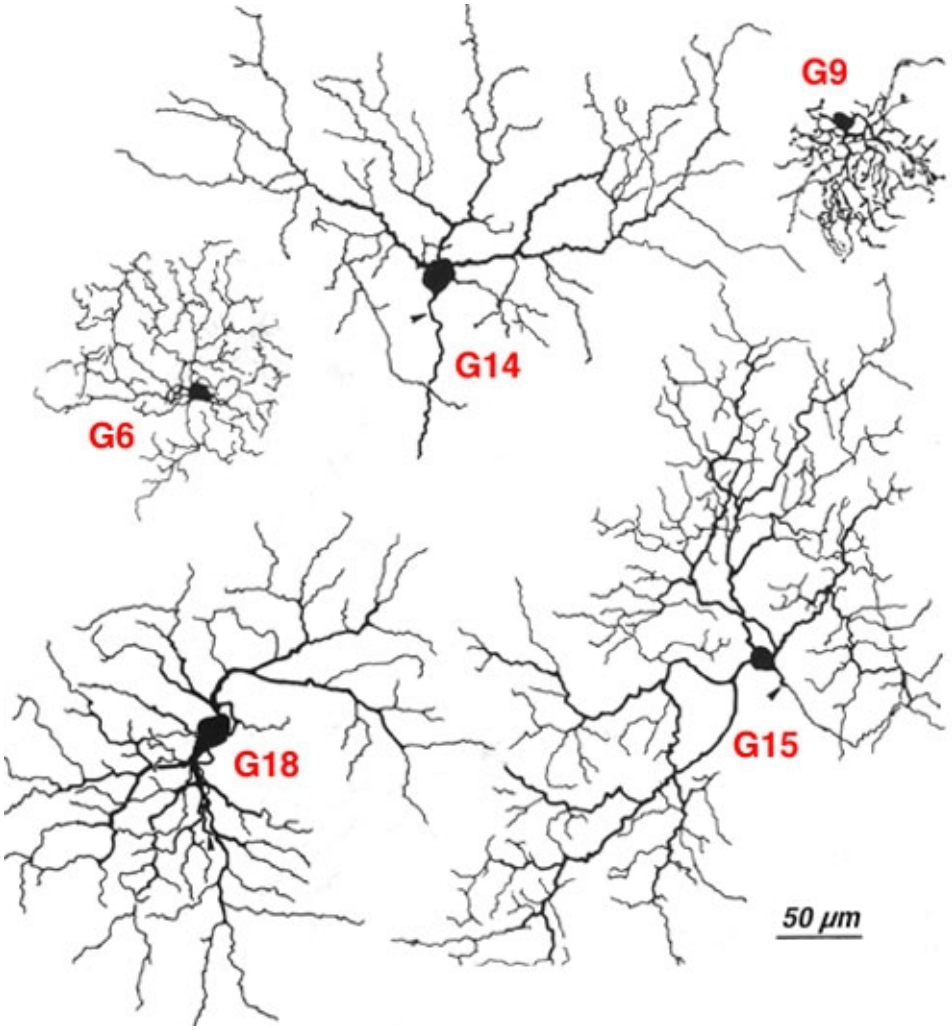

Figure 9. Some of non-alpha/non-beta ganglion cells of cat retina.

alpha cells are not much larger than their dendritic tree sizes (21, 35) (see below), despite enormous convergence and very wide lateral interactive potential.

Identity of Amacrine Cell Types Inputing Cat Alpha and Beta Ganglion Cells

As shown in the summary diagrams (Fig. 17 and Fig. 18), recent evidence suggests that several different morphological types of amacrine cells, as well as bipolar cell types, have synaptic input to the OFF-beta and OFF-alpha ganglion cells.

AII amacrine cells are particularly evident to both OFF-center ganglion cell types (Fig. 17 and Fig. 18, AII) and as mentioned above (see Fig. 13 and Fig. 15, previous section). AII cells are known to be glycinergic (36, 37). A small-field, bistratified amacrine cell with morphological characteristics complementary to the AII known as A8 (14) (see chapter on roles of amacrine cells) has been studied for transmitter content (37) and in intracellular recordings and marking (38). A8 is considered a glycinergic cell (37). It synapses in sublamina a upon tufted dendrites and dendritic varicosities typical of the OFF-beta ganglion cell (Fig. 17, A8). However, these A8 amacrine profiles have not been seen to input large-diameter, OFF-alpha ganglion cell dendrites (Fig. 18). A13 cells are considered GABAergic cells (37) and known to be postsynaptic to rod and cone bipolars and make

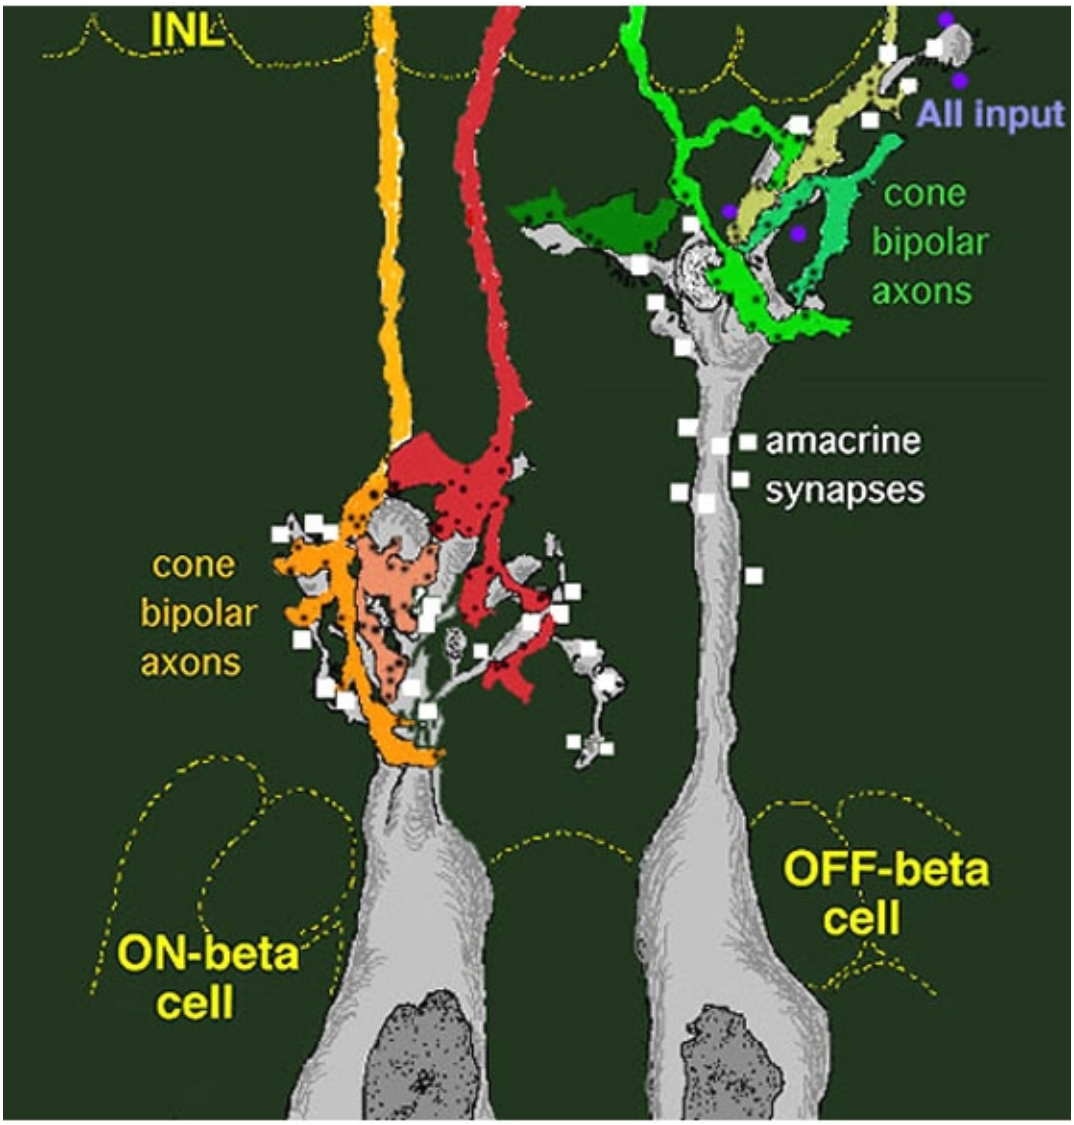

Figure 10. Reconstructions from electron microscopy of ON- and OFF-center beta cells of cat area centralis.

synapses with the cell body and primary dendrites in sublamina **a** and **b** of both ganglion cell types as well (33, 38) (Fig. 17 and Fig. 18, A13).

Small amacrine cells marked as A2/3 are shown on the summary diagrams (Fig. 17 and Fig. 18, A2/3). Poucho and Goebel (37, 39) have clearly subdivided types A2, A3 and A4 by their neurotransmitter content. Thus, A2 is probably GABAergic, whereas A3 and A4 are apparently medium-intensity glycinergic. Because only A2 and A3 cell types branch in strata 1 and 2 while A4 branches deeper in stratum 3, it is more likely that the former two cells are the candidates for synaptic input to the OFF-alpha and OFF-beta cells. Freed and Sterling (40) propose that glycinergic A4 amacrines are presynaptic to ON-center alpha cells: it is thus possible then that A3 are glycinergic counterpart amacrines reserved for the OFF-center variety of ganglion cell.

Some of the amacrine profiles synapsing upon the OFF-alpha ganglion cell have the morphology of A19 amacrine cells (32, 41, 42) (Fig. 18, A19, arrows). They are large-field with large-diameter dendrites tapering to fine, long processes covering 500 µm or more of field. Like most wide-field amacrine cells of the mammalian retina, A19 cells are thought to be GABAergic (37) and ON-OFF in physiology (32). They run in lower sublamina **a** in S2 co-stratifying with OFF-center alpha cell dendrites. A19 cells have been characterized, by their content of neurotubules and their gap junctions to other A19s (41, 42). Moreover, HRP-injected A19 cells have

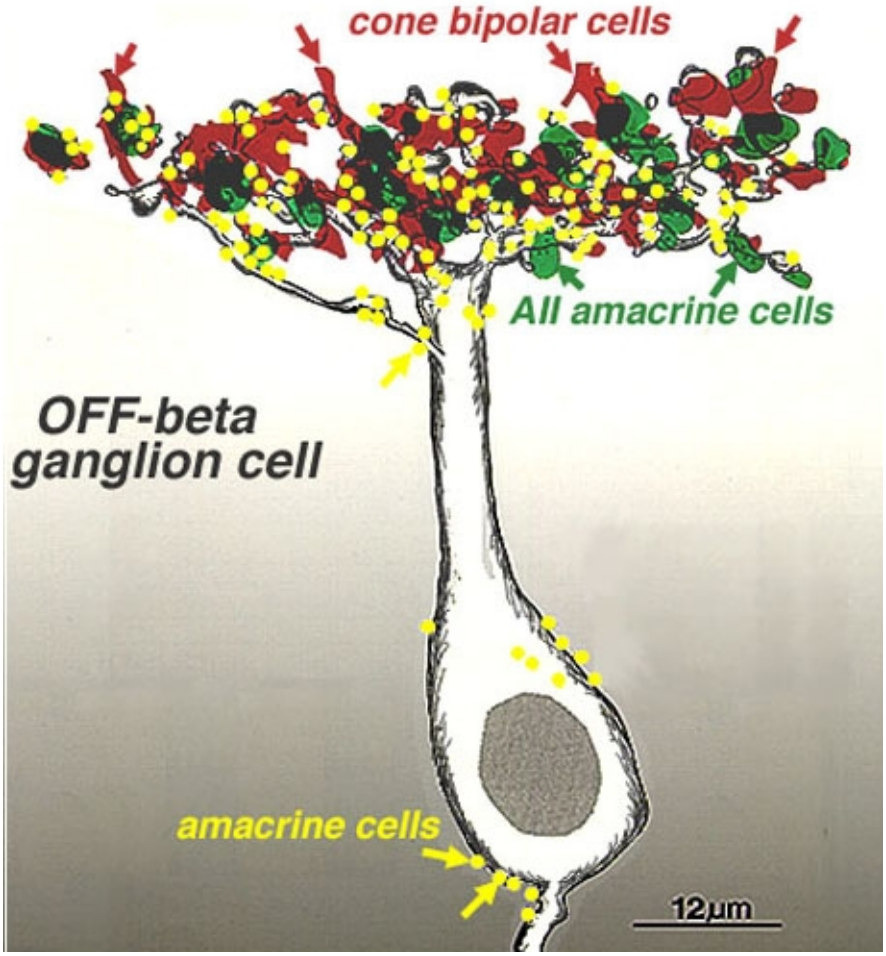

Figure 11. Reconstruction from electron microscopy of an HRP-filled OFF-center beta cell in cat retina.

been seen to run along and across large-diameter alpha cell dendrites in sublamina **a**, making intermittent synapses (32).

Among the many wide-field amacrine synapses upon OFF-center alpha cells, some are probably from acetylcholine containing or "starburst" amacrine cells (43-45) (Fig. 18, ACh, stippled cell). Vardi and co-workers (46) showed, by lucifer filling alpha ganglion cells and immunocytochemically staining cholinergic amacrine cells, that the latter amacrine's distal varicose dendrites run in bundles and loops along and across alpha cell dendrites in strata 2 and 3 of the inner plexiform layer, having ample opportunity for synaptic interaction. There is also convincing evidence for physiological effects of acetylcholine upon Y ganglion cells (47-49) and evidence that alpha cell dendrites contain ACh receptor sites (50). Thus, it seems probable that the two cholinergic amacrine cell types contributing to **a** and **b** sublaminae in cat retina are providing synaptic inputs to OFF- and ON-center alpha ganglion cells, respectively.

Primate Ganglion Cells

There are at least 18 different morphological types of ganglion cell in the human retina. All but three of these correspond to cells in the cat retina and have, where possible, been given the same G number. Some of the cat types have not been seen in human retina but undoubtedly they are there. Special names are reserved for P and M ganglion cells that are specific to the human high visual acuity and color-processing systems. They are thought to be specialized evolutionary correlates of beta and alpha cells, respectively (51) and comprise the major input to the geniculo-striate areas (52-55). Thus, P cells are considered to be mostly midget ganglion cells

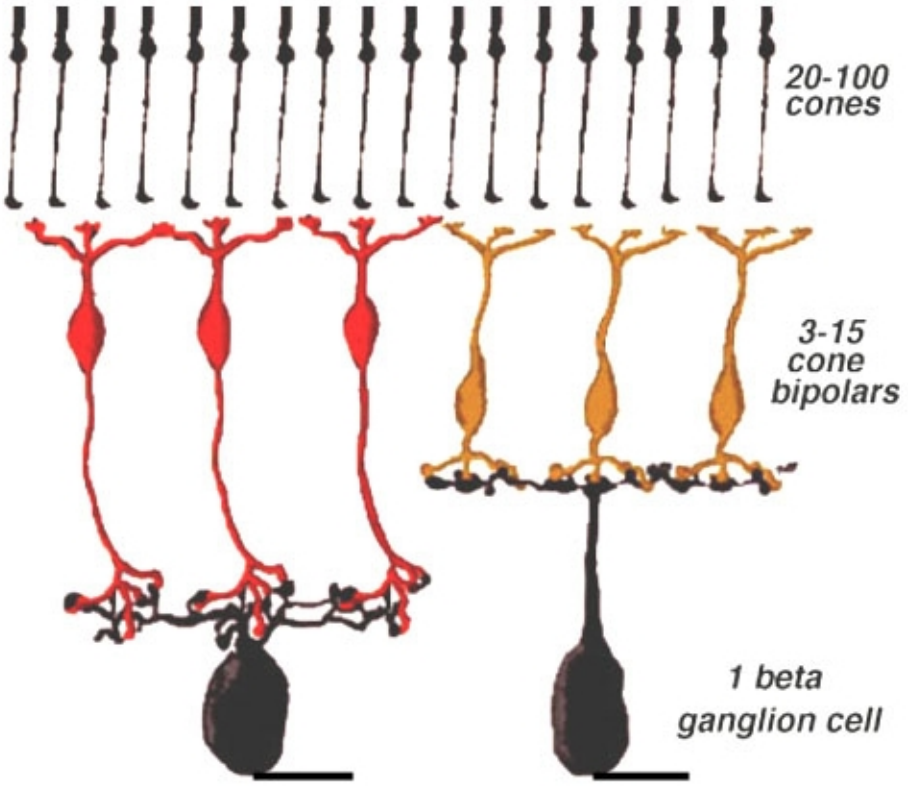

Figure 12. Convergence of cones and bipolar cells upon ON- and OFF-center beta cells.

and equivalent to beta cells of cat and project to the **P**arvocellular layers of the LGN. M cells, on the other hand, probably equivalent to alpha cells of cat and project to the **M**agnocellular layers of the LGN (Fig. 19 and see the animation of two Golgi-stained P cells in the human retina).

Polyak (2) first described the midget ganglion cells and considered them to form the majority of the ganglion cell types of monkey central retina. More recent retrograde staining studies indicate that ganglion cells—with medium-size cell bodies and the smallest dendritic trees, putting them into a "midget" category of cell—comprise 80% of the ganglion cell population in the monkey retina, and these cells project to the parvocellular layers of the LGN (53). The question then arises as to how many cell types correspond to these parvocellular projecting ganglion cells. Polyak (2) described midget ganglion cells quite clearly as the ganglion cells with the smallest dendritic trees, never much exceeding the diameter of their cell body, which is 9-12 μm. It is clear that the cells of the fovea meet this criterion (Fig. 19.1). However, outside of the fovea and beyond 3 mm of eccentricity, the midget ganglion cells can have dendritic tree sizes as large as 100 μm (56-58).

Physiologically, we suspect, by virtue of their being single-cone-connected via their exclusive connection to single midget bipolar cells in the foveal area (59, 60) that P cells are the opponent chromatic units, or the Type 1 cells of Weisel and Hubel of the LGN (61, 62). Outside of the fovea, where they clearly are receiving input from more than one midget bipolar cell by virtue of their increased dendritic tree size, midget ganglion cells or P cells may become broader band (63). We suspect that the P cells always receive input through midget bipolar cells but probably from more than one midget bipolar cell. In peripheral retina, the P cell dendritic trees become large enough for axons of three to five midget bipolar cells to have input. It remains to be seen whether chromatic specificity can remain under these conditions.

There is general agreement that the magnocellular-projecting ganglion cells are the parasol cells that Polyak described (1). Although some of Polyak's giant cells are by cell body size and dendritic tree size characteristics

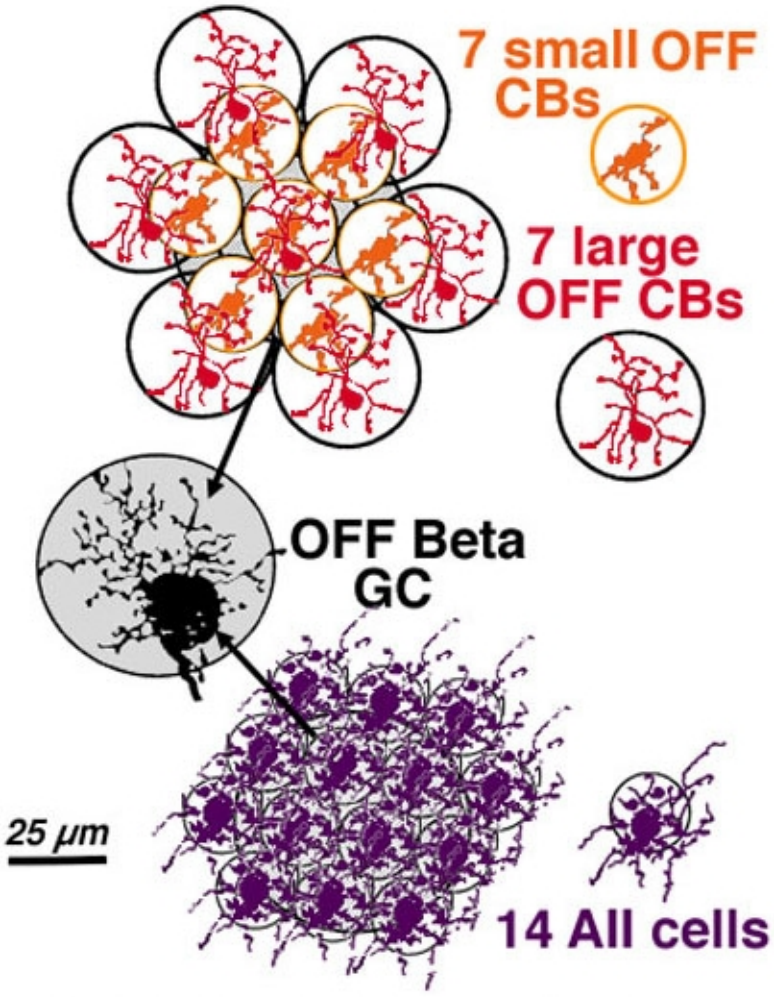

Figure 13. Model of the two cone bipolar types and AII amacrine cell inputs to the dendritic tree of an OFF-beta cell.

undoubtedly are the equivalent of Golgi-stained M cells in the far peripheral retina (57, 58, 64) and of the large-bodied, multibranched, reduced silver-stained cells of Silveira and Perry (65).

The other ganglion cells in human that are not in the geniculo-striate projections correspond to some of those retrogradely filled in Perry and co-workers studies (53, 54) of cells projecting to the midbrain (Fig. 20, Fig. 21, Fig. 22, Fig. 23). Two of these varieties in macaque retina may be G22 and G23 cells (Fig. 23). The G19 is equivalent to the cell in cat retina that has been stained by intracellular dye-injection and is apparently monoamine accumulating (30) (Fig. 22). Ganglion cells with complex receptive field characteristics such as directional selectivity (DS) may be present in human retina, too. Thus, G11 (Fig. 24) is a bistratified cell that could correspond to the rabbit ON-OFF DS cell and G22 (Fig. 23) to an ON directionally selective cell (66). Ganglion cells selective for orientation and uniformity could correspond to G8 (Fig. 24) and G17 (Fig. 22), respectively, in human retina (66). Several of the concentric sluggish cells of the rabbit are also seen in human Golgi-stained counterparts, for example G3 and G20 could be an ON-center varieties and G7 and G4 OFF-center varieties (67) (Fig. 21, Fig. 22, Fig. 23, Fig. 24).

Only two physiologically recorded and stained monkey ganglion cells have been reported thus far. One is the little understood biplexiform ganglion cell (68, 69) (Fig. 25), which gives a sustained ON-center physiology, representative of its direct input from rod photoreceptors. We will return to this fascinating ganglion cell type later (see below). The other ganglion cell that has been recorded from in monkey is the blue/yellow opponent ganglion cell projecting to the parvocellular layers of LGN (70) (see chapter on S-cone pathways).

Rabbit Ganglion Cells

The rabbit retina has been extensively studied because it is a more accessible retina in respect to isolation, staining, and recordings than some other mammalian retinas. The retina can be isolated and kept alive for hours of experimental study with simple perfusion techniques. Rabbit retina was originally studied for the property of directional selectivity in ganglion cells. Because this retina has a visual streak specialization, it was found quite early on (71) that many of the the ganglion cells were sensitive to motion and direction of the movement of visual stimuli.

Interestingly, there has never been a systematic classification of the different types of rabbit ganglion cell based on a morphological technique like the Golgi. However, the intracellular staining and physiological approaches have yielded a very nice functional classification scheme that supercedes the need for a Golgi study nowadays.

Ganglion cells equivalent to ON and OFF-alpha types in cat are also seen in rabbit (19, 67). They have both a similar physiology and dendritic field size and shape, although in rabbit their cell bodies may not be quite as large in size as in cat retina. Equivalent beta cell types in rabbit are a little more equivocal. Cells that respond with the linear, brisk sustained concentric receptive field organization that come in ON- and OFF-center pairs are seen in rabbit, and their appearance is rather similar to peripheral beta cells of cat. They have, however, smaller cell body sizes, again like the alpha cell comparison (67). Because no cell with the exact same morphology as a central beta cell, even on the visual streak of rabbit retina, has been seen (67), some suggest that there is no real equivalent of the beta cell in rabbit (20). The question remains an open one, because the rabbit

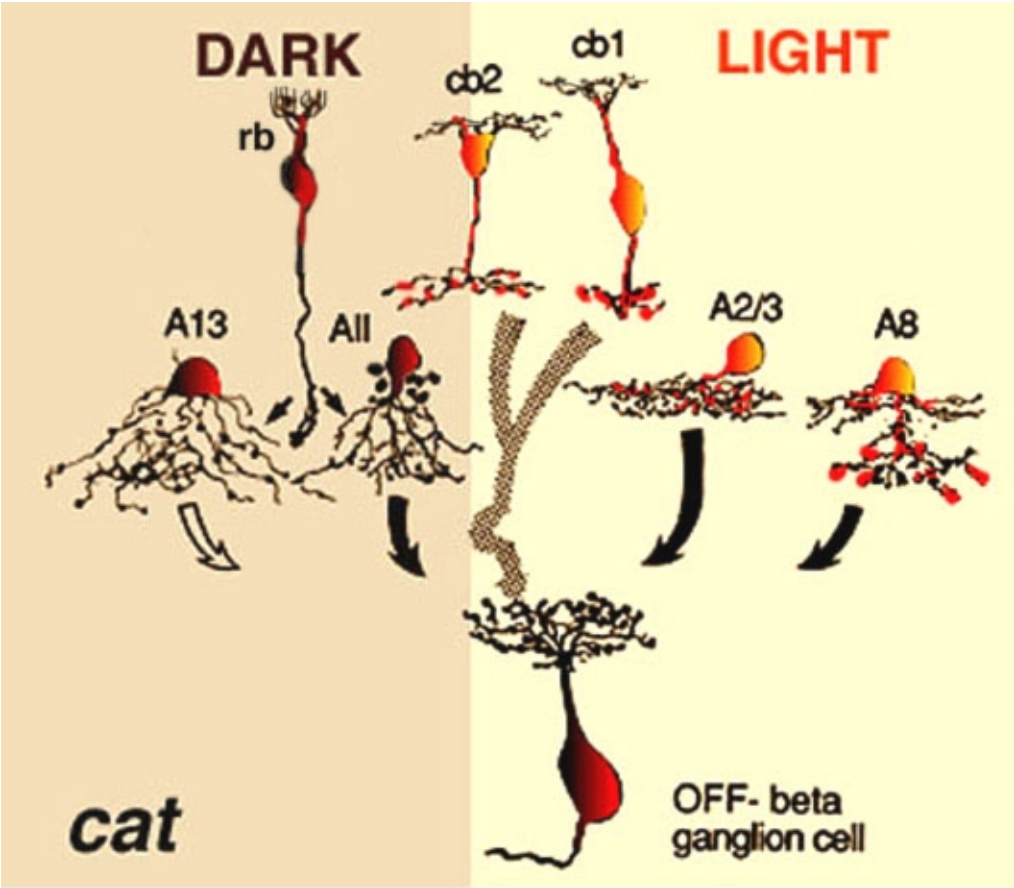

Figure 17. Probable input neurons to OFF-beta cells of cat retina.

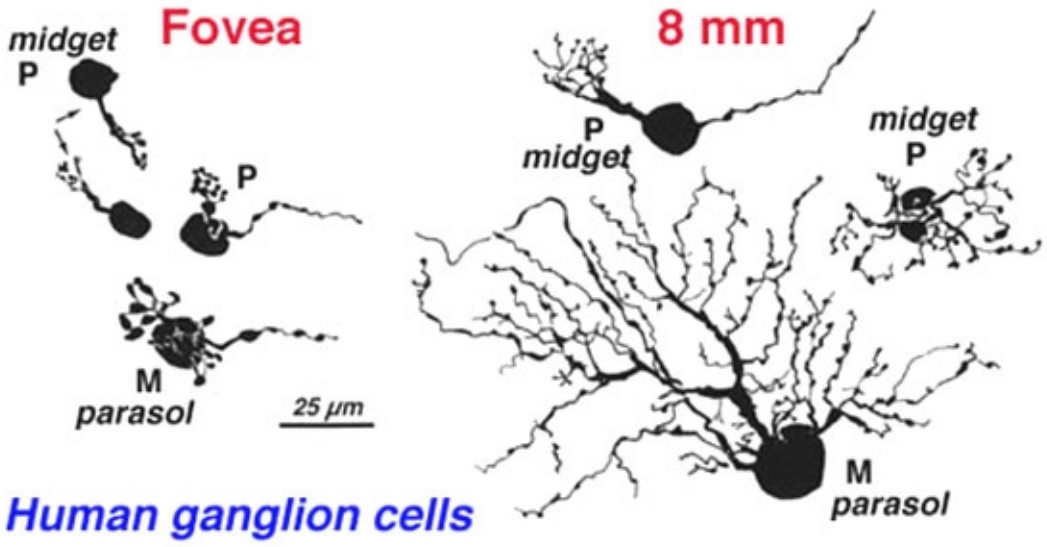

Figure 19. Ganglion cell types involved in geniculate-striate pathways of human retina.

visual system has a different organization than the cats, with a horizontal streak in the retina, no binocular overlap of the visual fields, and projections to visual centers in the tectum rather than the geniculo-striate.

Download video

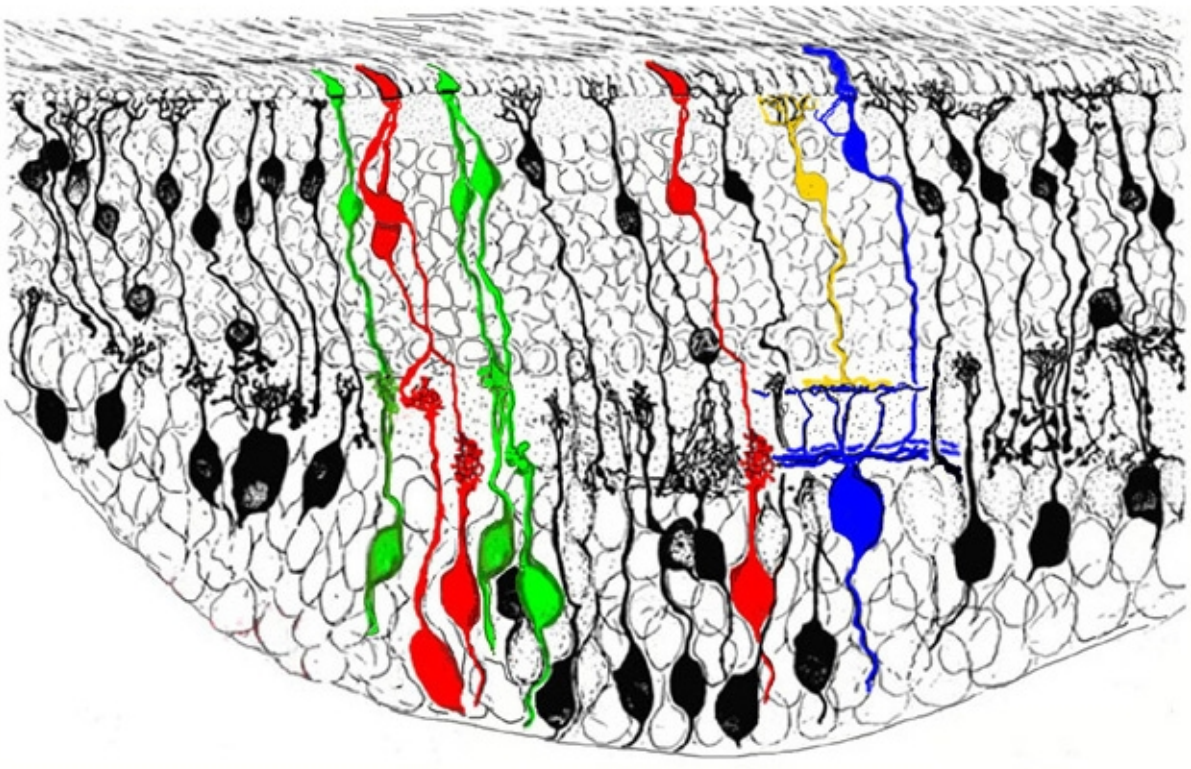

Figure 19.1. The commonest ganglion cells types of the primate fovea are the P cells, or midget ganglion cells, and the bistratified blue-on/yellow-off ganglion cell.

Other ganglion cells of rabbit, with concentric receptive field physiology but more sluggish response patterns, are also demonstrated in Amthor and co-authors' work (67). Many of these types are similar to the non-alpha/non-beta cell types of the cat in morphology. However, the correlation between the ganglion cell physiology of the two species is difficult to make at the present time. Some comparisons between the ganglion cells of the human retina and those of the rabbit have been attempted (64). Interestingly, a great many more similarities exist between ganglion cell types of the ground squirrel and rabbit retinas (72).

The more unusual feature detectors of the rabbit retina are the motion-sensitive, orientation- and direction-sensitive ganglion cells (66). The bistratified ON-OFF directional selective (DS) ganglion cells of the rabbit retina have attracted a lot of attention, mainly because many aspects of the circuitry have been elucidated (Fig. 26). For example, the acetylcholine containing amacrine cells, also called starburst cells, are the major input cells (73-76)

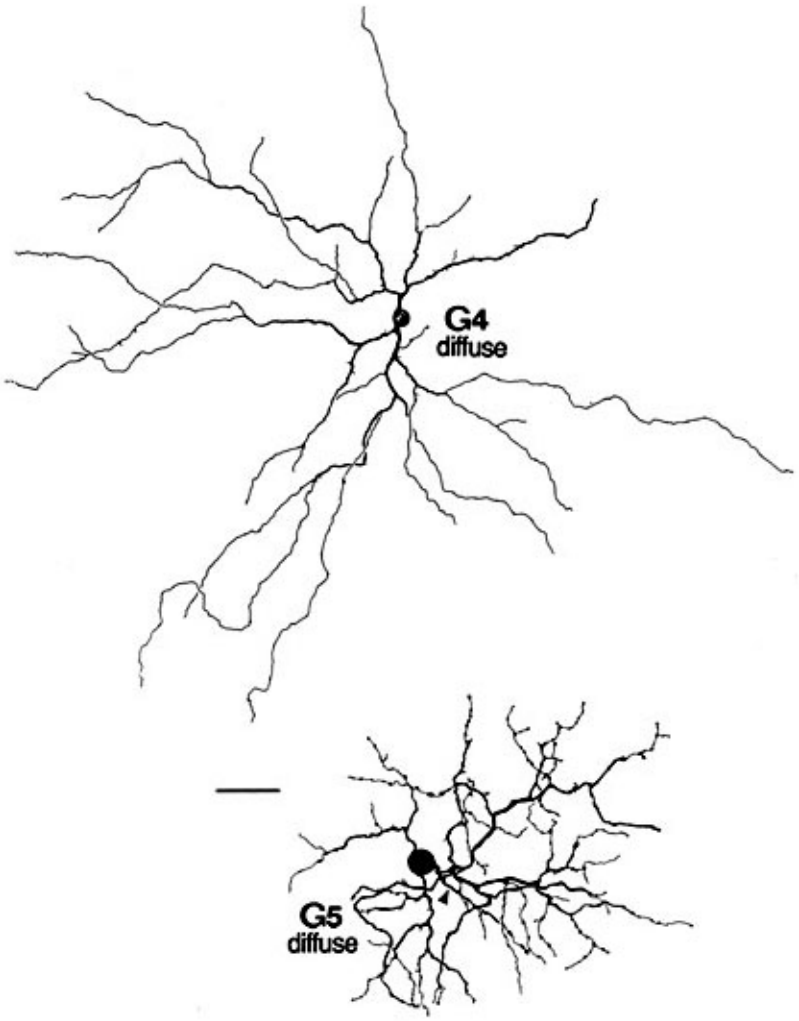

Figure 20. G4 and G5 ganglion cells of human retina.

(see chapter on roles of amacrine cells). The effects of antagonists of acetylcholine have been known for a long time to eliminate directional selectivity in the rabbit retina, and amacrines containing GABA are also known to be involved (77, 78). The fascinating aspect of the ON-OFF directionally selective ganglion cells of rabbit is that they are bistratified and have the two layers of their dendrites oriented orthogonal to each other (see Fig. 26). The orientation of the outer dendritic tree (i.e., the OFF layer of dendrites) is favored to be with the preferred direction of the cells response to a moving target (66).

The other type of directionally selective cell in rabbit is the ON-center type, and its single layered dendritic tree in sublamina **b** (ON layer of the inner pleiform layer) is not as obviously oriented with the preferred direction (Fig. 27). Other ganglion cell types that are prominent and well characterized in Amthor and co-workers (66) in the rabbit retina include orientation selective, local edge detectors and uniformity detectors (suppressed by contrast) (Fig. 28 and Fig. 29). It is particularly interesting that each of the different types of ganglion cells have a distinctly different morphology, primarily concerning the substructure of their dendrites. Many of them have another feature in common in that they typically show an orientation of the whole dendritic tree away from the cell body in an asymmetric pattern (see Fig. 26, Fig. 27, Fig. 28, Fig. 29). All the details of these morphologies can be found in the elegant papers of Amthor et al. (66, 67), and the reader is encouraged to look there.

Visual Responses of Ganglion Cells

Ralph Nelson

Created: May 1, 2001; Updated: April 10, 2007.

Overview

Ganglion cells are the final output neurons of the vertebrate retina. Ganglion cells collect information about the visual world from bipolar cells and amacrine cells (retinal interneurons). This information is in the form of chemical messages sensed by receptors on the ganglion cell membrane. Transmembrane receptors, in turn, transform the chemical messages into intracellular electrical signals. These are integrated within ganglion-cell dendrites and cell body, and "digitized", probably in the initial segment of the ganglion-cell axon, into nerve spikes. Nerve spikes are a time-coded digital form of electrical signaling used to transmit nervous system information over long distances, in this case through the optic nerve and into brain visual centers.

Ganglion cells are also the most complex information processing systems in the vertebrate retina. It is a general experimental truth that an organism as a whole cannot behaviorally respond to visual stimuli that are not also detectable by individual ganglion cells. Different cells become selectively tuned to detect surprisingly subtle "features" of the visual scene, including color, size, and direction and speed of motion. These are called "trigger features". Even so, signals detected by ganglion cells may not have a unique interpretation. Equivalent signals might result from an object changing brightness, changing shape, or moving. It is up to the brain to determine the most likely interpretation of detected events and, in the context of events detected by other ganglion cells, take appropriate action.

Ganglion cell axons terminate in brain visual centers, principally the lateral geniculate nucleus and the superior colliculus. Ganglion cell axons are directed to specific visual centers depending on the visual trigger features they encode. The optic nerve collects all the axons of the ganglion cells. In humans, this optic nerve bundle contains more than one million axons.

History of Electrical Recordings

In 1967, Ragnar Granit and H. Keffer Hartline (1) shared the Nobel prize in physiology and medicine for the first electrical recordings of light responses from individual ganglion cells of the vertebrate retina. In this, both laureates acknowledged the earlier seminal influence of Edgar D. Adrian, winner of the 1932 Nobel prize in physiology and medicine. Adrian pioneered the measurement of impulse discharges from individual peripheral nerve axons and was principally responsible for the discovery that nerve fibers transmit signals in the form of a temporal sequence of "all or none" impulses. Granit (2) also noted the influence of the anatomist Santiago Ramon y Cajal, winner of the 1906 Nobel prize, in illustrating a complex retinal circuitry worthy of physiological investigation.

Hartline (3, 4) pushed experimental technology of the 1930s to its limits in obtaining extracellular recordings of individual ganglion cells. There were no solid state electronics. Special purpose, "direct coupled" vacuum tube amplifiers were designed. There were no oscilloscopes or computers for display and storage of signals. String galvanometers were used; a pencil of light played from a tiny mirror, minutely vibrating in a magnetic field, onto moving photographic film to document electrical events. There were no microelectrodes; ganglion cell axon bundles were teased off the retinal surface with dissecting tools and lifted onto a coarse cotton-wick electrode, such as earlier used for massed potential recordings. Ultimately, this technique proved too difficult to pursue and left no legacy. It remained for Granit (2) to introduce microelectrodes for such recordings, which greatly facilitated the ease of data collection. Granit also made the first ganglion cell recordings from a mammalian retina, the cat retina. This retina, as pursued by his students and others, has been a staple of visual electrophysiology. Yet the experimental designs and approaches provided by Hartline continue to be used. So

many of his findings, such as the multiplicity of ganglion cell response types, have proved accurate, such that the succeeding field of ganglion cell electrophysiology sometimes appears almost as a footnote to his work (Fig. 1 and Fig. 2).

ON and OFF Responses

Hartline's electrical recordings of single optic nerve fiber responses revealed "discharges of impulses", or "action potentials" in response to light stimulation. The discharge patterns were, however, diverse (5). Three unique patterns of light response were described (Fig. 3).

"ON" type fibers responded with a transient burst to light onset and a sustained elevated discharge rate throughout the photic stimulation (Fig. 3). "ON-OFF" fibers responded with discharge bursts at the onset and cessation of light stimuli but were otherwise quiet. "OFF" fibers were quiet until the stimulus light was turned off, whereupon they responded with a sustained burst of impulses. The situation was far different from fibers in the optic nerve of the invertebrate *Limulus polyphemus*, which Hartline also studied. There, all fibers responded with ON-type discharges. The result implied that a relatively high degree of visual processing occurred within the vertebrate retina, and that visual information was filtered by retinal circuitry into a number of subcategories. The exact number of such categories is still difficult to define exactly but now would easily number a dozen (6, 7). Because of the diverse categories of responses found in retinal ganglion cells, these cells are sometimes thought of as "feature detectors" (8).

ON- and OFF-type signal detection remains as the most significant subdivision among visual features extracted by ganglion cells. Combined morphological and physiological studies of individual ON- and OFF-type ganglion cells revealed different inner plexiform layer stratification patterns (9, 10, 11) and suggested a basis in retinal circuitry for these types (Fig. 4). The dendrites of OFF-type ganglion cells branch in the inner plexiform layer zone close to the amacrine cell bodies. Here they come in synaptic contact with the axon terminals of OFF-type bipolar cells. The dendrites of ON-type ganglion cells branch in the inner plexiform layer zone close to the ganglion cell bodies. Here they make synaptic contact with the axon terminals of ON-type bipolar cells (10). Dendritic trees of ON-OFF cells typically arborize in both zones of the inner plexiform layer, presenting a "bistratified" appearance (12).

Receptive Field

Hartline introduced the "nearly definable" concept of "receptive field" to describe the spatial properties of retinal ganglion cells. He used "spot mapping" to define such fields, a technique still widely used. Cells were found to respond to relatively dim spots when the stimulus was positioned in the "center" of the receptive field, but brighter stimuli were required as the spots were moved away from this region. An example of the spot mapping technique, taken from Kuffler (13) shows the reduction in response vigor as stimulus spots are displaced from the center (Fig. 5). Hartline concluded that ganglion cell receptive fields were fixed in space and immobile, typically did not extend beyond 1 mm in diameter, and were graded in sensitivity over this region. Receptive fields were much larger than expected of individual photoreceptors, suggesting signal processing and integration through retinal circuitry.

Evidently, circuitry was the source of a spatial weighting function, shaped so that sensitivity diminished radially with distance from the "receptive field center". Hartline also noted other features suggestive of hidden complexity in this simple concept. Response wave forms tended to become more transient and less sustained as spots were displaced (Fig. 5). Subtle movements, on the order of a few μm, much smaller than the receptive field itself, could evoke vigorous discharges, a kind of ganglion cell "hyperacuity effect" (see also ref. 14).

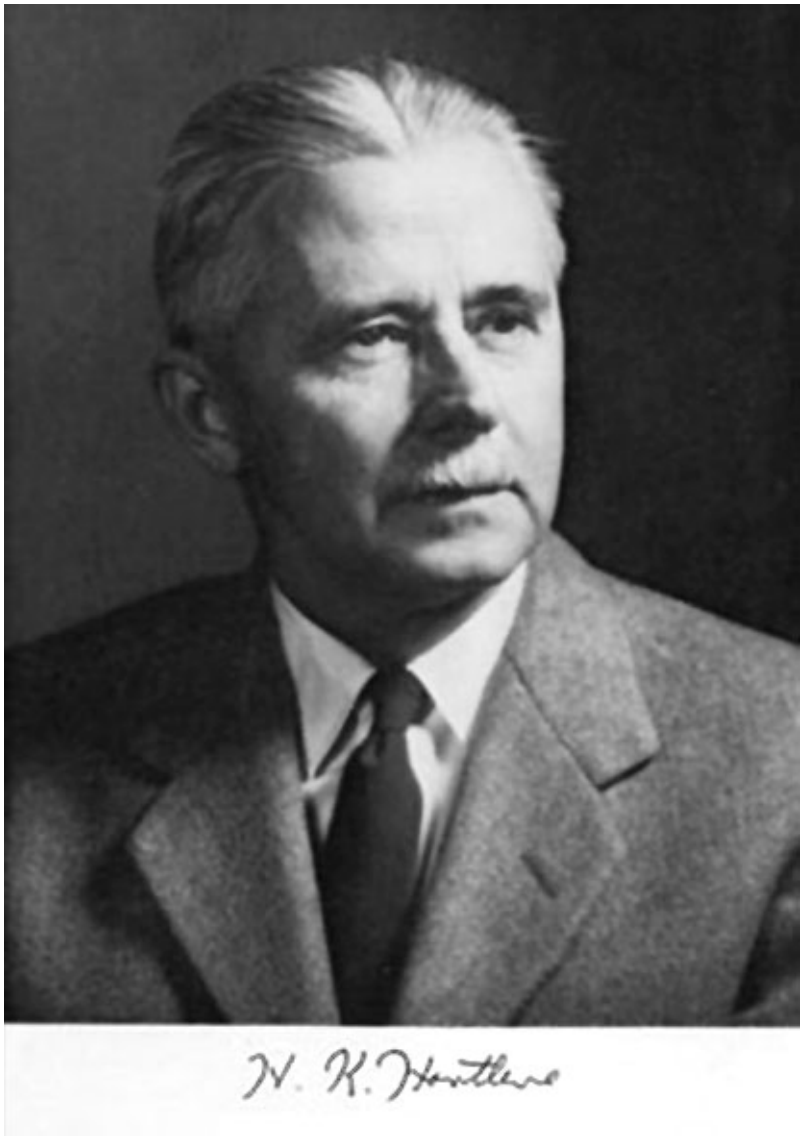

Figure 1. Haldan Keffer Hartline, 1967 Nobel Laureate.

Centers and Surrounds

Although Hartline went on to study lateral inhibition of receptive fields in the *Limulus* retina and his laboratory made other valuable contributions to neurobiology and vision, discovery of lateral inhibitory interactions in vertebrate ganglion cells and the concept of "antagonistic surround" is generally credited to Stephen Kuffler.

As noted by Hartline, not only strength of response,but also a change in form of response occurs as stimuli are moved across ganglion cell receptive fields. Kuffler (13) noted a particularly abrupt change in form, from onset excitation for stimulation in the center of the field to offset excitation for stimulation in the receptive field periphery. An example is illustrated in Fig. 6. In Fig. 6a, a spot, centered near the electrode tip, evokes a burst of impulses at stimulus onset. In Fig. 6b, the spot is displaced by 0.5 mm, where it evokes no impulses at onset but a burst of impulses at offset. In Fig. 6c, an intermediate spot position is found where both actions are evoked by the stimulus. The example (Fig. 6) shows properties of a classic ON-center, receptive field, with OFF surround. Conversely, OFF-center cells, which are excited at stimulus offset by central stimulation, have regions in the peripheral receptive field where ON excitation is evoked. This is the classic center-surround receptive field organization of ganglion cells (see the animation of the center and surround receptive field organization of a beta

Figure 2. Ragnar Granit, 1967 Nobel Laureate.

ganglion cell). Such organization was further examined with intracellular recording techniques. These techniques revealed not only the ganglion cell impulses but also the slow changes in ganglion cell membrane potential, which modulate the impulse rate.

Torstein Wiesel, 1981 winner of the Nobel prize in physiology and medicine, provides an example of such an intracellular recording in Fig. 7, which allows further features of the surround response to be seen. In Fig. 7a, a small spot of light depolarizes the membrane of the cell and evokes a vigorous burst of impulses. This is an ON-center cell. In Fig. 7b, the stimulus is an annulus, a ring of light designed to stimulate the receptive field surround but not the center. Impulses are silenced during stimulus presentation, but a burst appears at annulus offset. This is a classic surround pattern. A hyperpolarization of the membrane occurs while the annulus is ON and impulses are silenced. This is a feature of the response hidden from extracellular recording methods. The surround stimulus actively inhibits the cell by hyperpolarizing its membrane. Finally, the response to the large spot stimulus (Fig. 7c) should not be neglected. The large spot, like the small spot (Fig. 7a), evokes a membrane depolarization and sustained burst of impulses. But the depolarization is smaller and the burst less vigorous. The net impact of the center-surround receptive-field structure is that ganglion cells "prefer" small spots to large

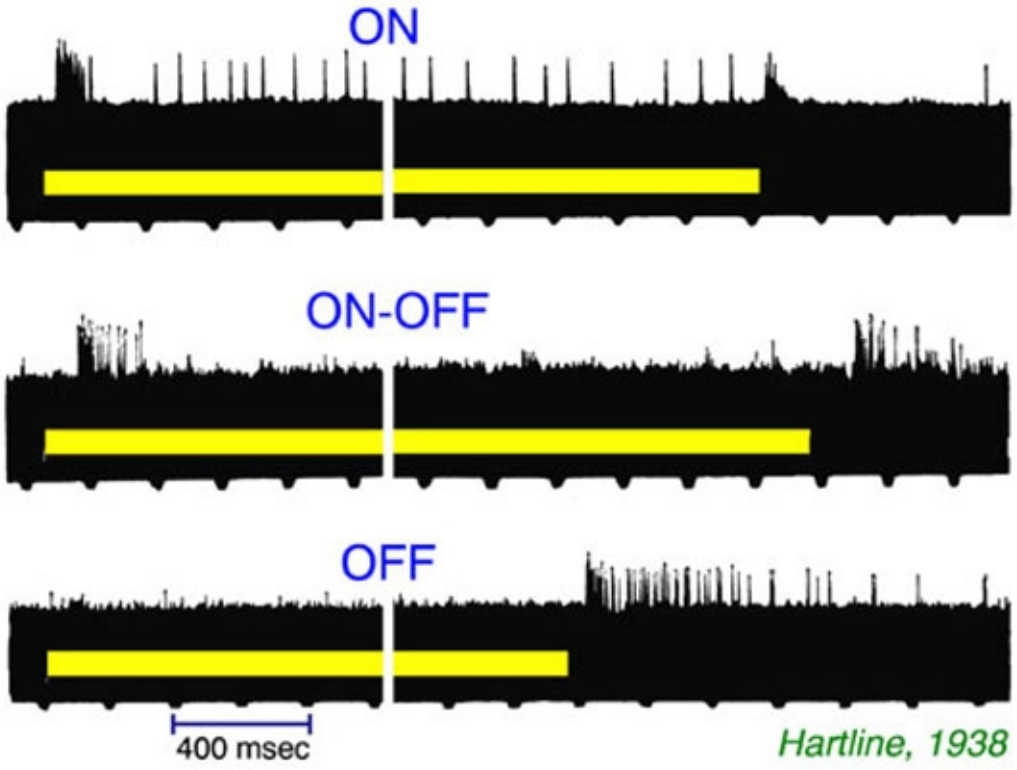

Figure 3. ON, OFF, and ON-OFF ganglion cells. After Hartline (87).

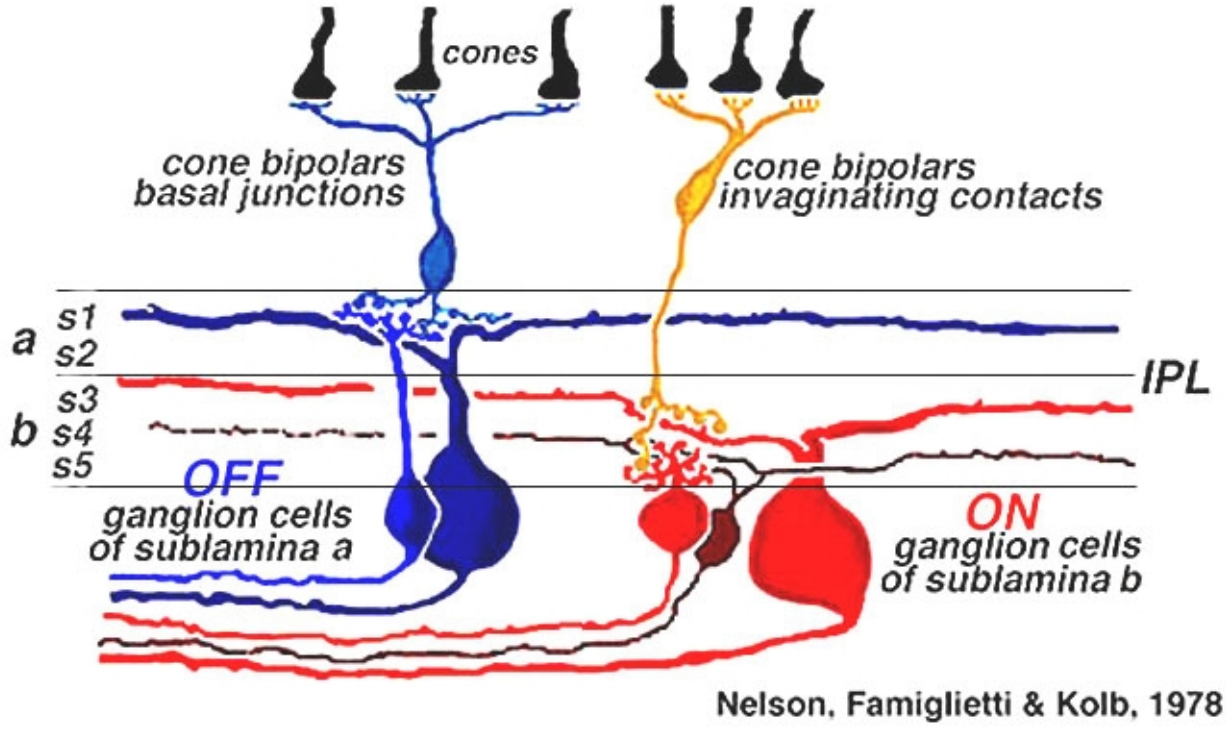

Figure 4. Organization of ON- and OFF-center ganglion cells into sublaminas a and b.

spots! Size selectivity is a unique and telltale characteristic of ganglion cell physiology. To summarize, ganglion cell center-surround interaction is a multifaceted phenomenon.

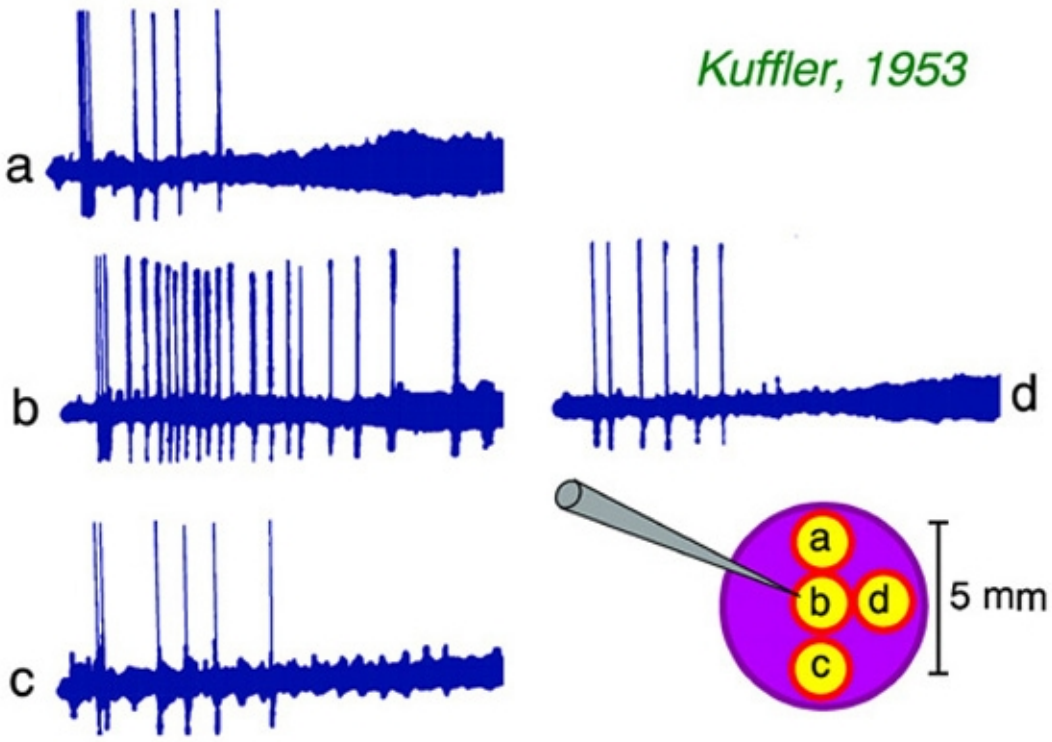

Figure 5. Spot mapping of cat retinal ganglion cell receptive-field center (13).

Features of ganglion cell center-surround interactions include:

- Change from sustained to transient center response as stimuli are displaced from the center.
- Excitatory responses evoked to opposite stimulus phase with surround stimulation.
- Active inhibition of the center response with surround stimulation.
- A maximal response can be evoked only with an optimally sized spot ("spatial tuning").

The question arises whether the four phenomena listed above represent a single mechanism or several. Evidence tends to suggest the latter, because there are many cases where some of these phenomena are present but not others. The most ubiquitous and characteristic feature is the last, however—spatial tuning. Although cells that do not fit into the ON- or OFF-center categories, such as the true ON-OFF center cells as described by Hartline (Fig. 3b), still exhibit spatial tuning.

Contrast Sensitivity Functions and the Difference of Gaussians Receptive Field Model

The characteristic spatial tuning of ganglion cell receptive fields is reflected in peaked contrast sensitivity functions (Fig. 8). Each vertebrate ganglion cell is "tuned" (responds best) for objects of a different size. Among the population of ganglion cells, a wide range of sizes is covered, perhaps corresponding to the wide range of object sizes in the visual image. This tuning reflects in part the variable dendritic span in ganglion cells (as elaborated below). Dendritic span is one of the factors allowing ganglion cells to collect visual signals over a broad reach of visual space. Receptive field centers and dendritic fields can be similar in size (15) (Fig. 9). But dendritic field span in itself does not provide for a decline in sensitivity as stimulus sizes become large. Surrounds are required. Tuning can be modeled as a result of center-surround interaction. In the OFF-center cell of Fig. 9, ON-excitatory surround responses are evoked by slit stimuli placed near the edge of the dendritic field (16).

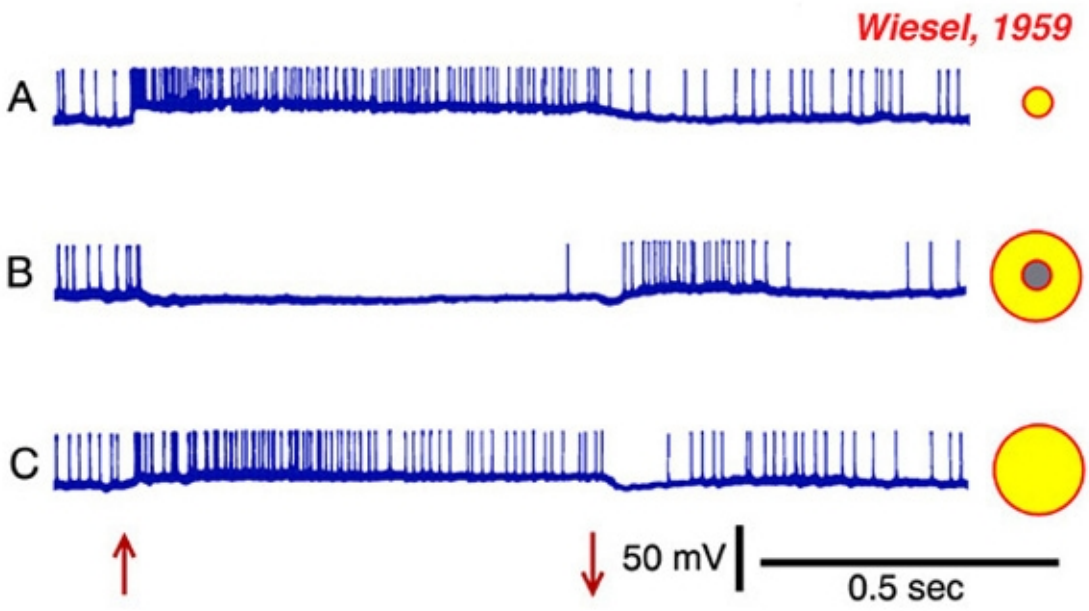

Figure 7. Changes in ganglion cell membrane potential accompanying center and surround responses (93).

Contrast sensitivity functions are a receptive field characterization generated, not using spots or slits of light, but by broad-field stimuli consisting of spatial sine waves. These appear as patterns of alternating, fuzzy-edged, light and dark bars covering all of visual space. "Contrast" is the difference in brightness between the light and dark phases of the pattern. In this receptive field characterization, contrast is reduced until the ganglion cell just barely responds to the introduction of such a stimulus into a featureless field. This is the threshold. The process is then repeated for patterns with different bar widths, or "spatial frequencies" (the reciprocal of the number of bright- and dark bar-pairs per unit distance). The sensitivities (the reciprocals of contrast thresholds) are plotted as a function of spatial frequency. The net result is a curve (Fig. 8), which demonstrates that in ganglion cells there is an optimal spatial frequency of stimulation. Patterns of this frequency can be observed with the highest sensitivity and lowest contrast. In Fig. 8, this frequency is about 0.6 cycles per degree, which scales to a bright-dark bar pair every 350 μm on the retinal surface, or a bright bar width of half this distance (175 μM).

Contrast sensitivity is one measure of size selectivity in ganglion cells. Another measure is "hyperacuity". This is the ability to detect movements within the ganglion cell receptive field. Cat ganglion cells can detect image displacements as small as 1' of arc (about 4 μm on the retinal surface or a movement of about 3 cm at 100 m distance). These displacements are much smaller than one might expect based on receptive field center sizes (which are typically several hundred μm in diameter on the retinal surface) or contrast sensitivity functions (14). Both contrast sensitivity measures and hyperacuity measures have the appeal that they may be applied equally as well to the sensitivity of a whole organism as to a single cell. Comparisons of organism performance to ganglion cell performance generally leads to the conclusion that organisms cannot detect visual stimuli that are not detected at least equally well by ganglion cells.

Peaked contrast sensitivity functions can be successfully modeled as a linear subtraction of two concentric, opposed receptive-field mechanisms (Fig. 10). In a well-studied version, of this model both the center ($W_c(r)$) and the surround ($W_s(r)$) are given Gaussian sensitivity profiles, with greatest sensitivity in the center of the receptive field and a smooth, steep decay of sensitivity away from the center (17). The center mechanism predominates for centrally located stimuli, because it is stronger at this location, but the surround mechanism prevails for peripheral stimulation because the surround radius (r_s) is greater than the center radius (r_c). These radii affect the rates at which sensitivity declines as stimuli are moved away from the center. This model is often referred to as the DOG (Difference of Gaussians) model. The curved line fitting the data in Fig. 8 was generated by a DOG model.

X and Y Receptive Fields

One of the assumptions of the DOG model (18) is that ganglion cells linearly add signals from both center and surround mechanisms for all points in space. This suggested that ganglion cells be tested for spatial linearity. Some cells (X-cells) pass the test, whereas others (Y-cells) do not, despite the fact that all receptive field data are well represented by the DOG model.

In Fig. 11, impulse firing rate is shown for different positions (or spatial phase) of the sine wave stimulus with respect to the receptive field center. To change the spatial phase, the pattern is shifted right and left by incremental amounts. For the X-cell (Fig. 9A), when the pattern is positioned so that the transition from light to dark passes directly through the center of the field, a "null response" is produced. Introduction of the stimulus produces no effect on firing rate. The tendency of the bright bars to excite the cell is exactly compensated by the tendencies of the dark bars to reduce the firing rate. For the Y-cell (Fig. 9B), no such stimulus position can be found. There is always a residual response, in this case the "null phase" results in transient increases in firing at both introduction and removal of the stimulus. The test is a particularly severe one for linearity. Not only is perfect spatial summation required, but the form of response to light increments must be exactly the opposite to the form of response to a light decrement for effects to exactly cancel. Y-cells may have linear spatial summation,

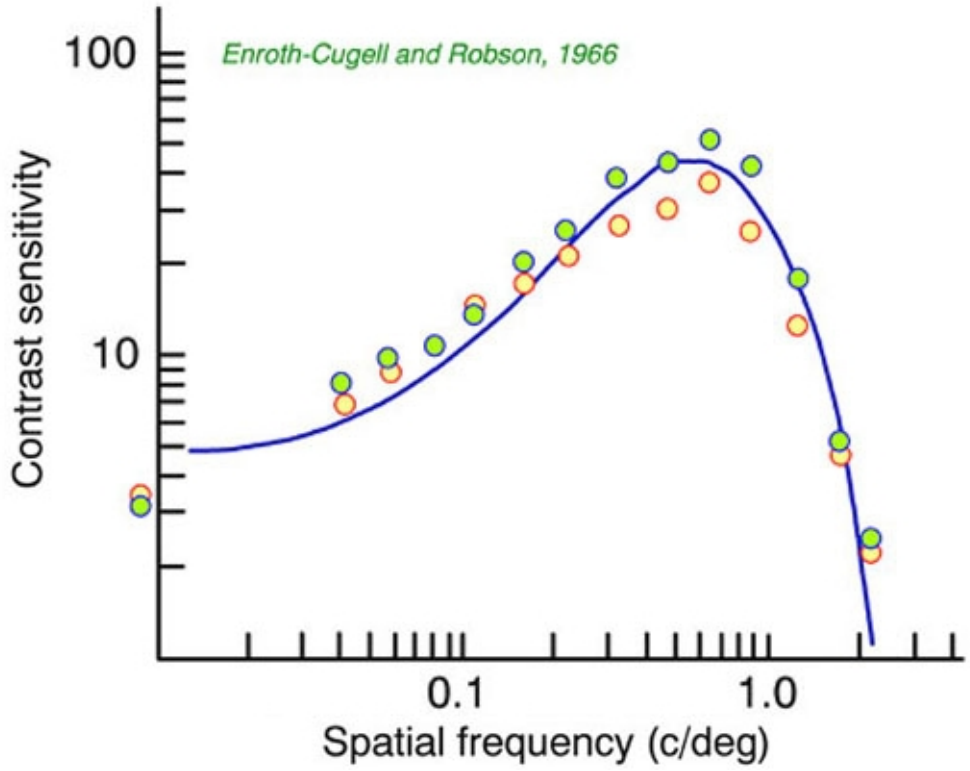

Figure 8. Contrast sensitivity function of cat retinal ganglion cell. Green and yellow symbols are the data generated with vertical and horizontal patterns, respectively, showing a symmetry of size sensitivity (18).

but evidently increment and decrement wave forms are not sufficiently symmetric for signals to cancel. This failure of linearity in Y-cells is thought to be attributable to inputs from non-linear subunits (19).

X- and Y-cells are differentiated in other ways as well. X-cells are numerous and have rather narrow receptive fields, and in cat retina are used for highest acuity vision. These are morphologically the "beta" cells of cat retina. Y-cells are rather sparsely distributed and have wide receptive fields. These are morphologically the "alpha" cells of the cat and most likely serve a visual alerting function. They are sometimes named according to the shape of the response wave form to steps of light. Y-cells are called "brisk transient" cells, and X-cells are called "brisk sustained" cells (20). Y-cells are also distinguished from X-cells by larger axon diameters and quicker conduction times from retina to the thalamic visual centers of the brain. These sets of cells initiate two separate and parallel pathways for transfer of visual information to brain visual centers (21). Morphological features and the distribution of X/beta, Y/alpha ganglion cells are discussed below.

Directionally Selective Ganglion Cells

Computing the direction of motion for a moving objector scene is the most complex information processing task performed by vertebrate retinas. Directionally selective retinal ganglion cells respond to stimuli moving in a preferred direction and are inhibited by stimuli moving in the opposite or null direction. The preferred direction is independent of the nature of the object, which can be either bright or dark, a simple object such as a small spot, or a complex object, such as a drifting grating (22). Because of center-surround inhibition, however, like other ganglion cells, directionally selective cells respond best to small spots. In addition to a preferred direction of movement these cells have preferred speeds of movement, some prefer slow movements, whereas others prefer rapid movements. They most commonly exhibit true ON-OFF receptive field centers when mapped with stationary spots, although not all cells with ON-OFF centers are directionally selective. Less frequently encountered types are ON-center when mapped with stationary spots (23) or OFF-center (24). This type of

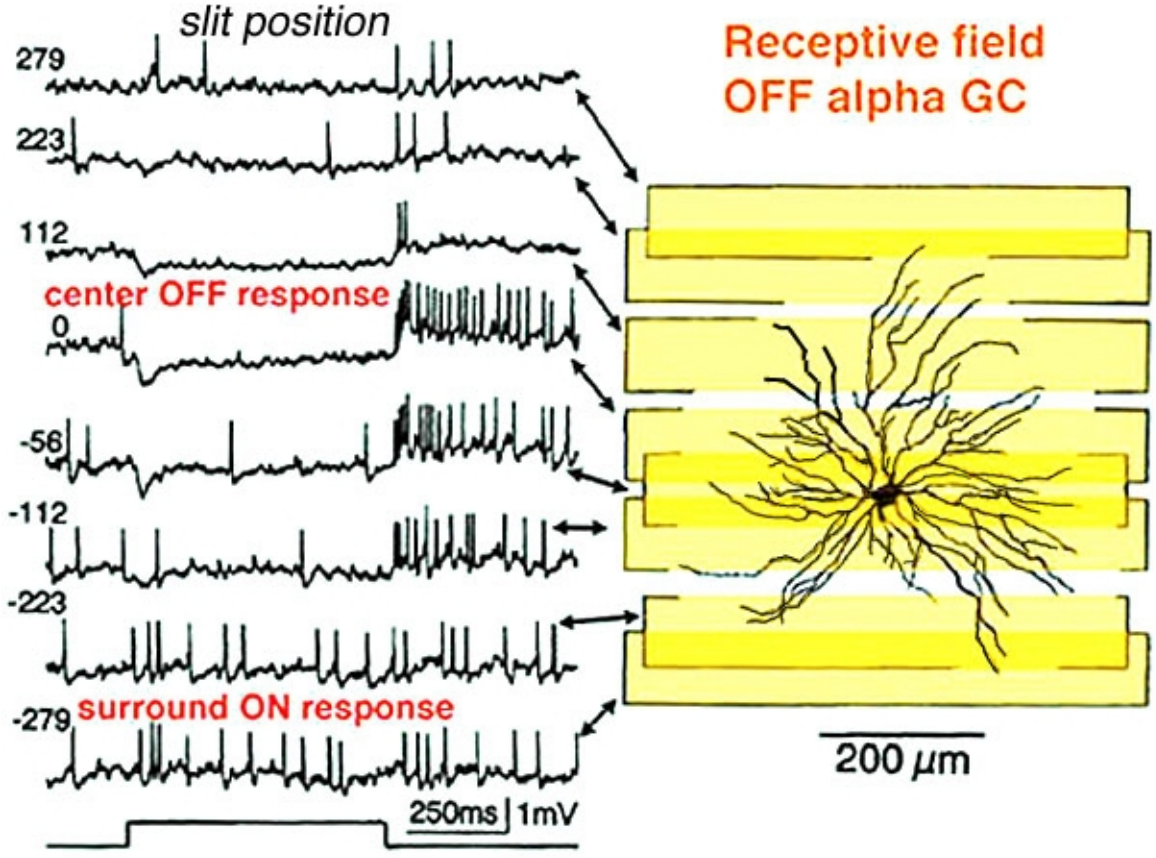

Figure 9. Relationship of dendritic and receptive field in an intracellularly stained, cat OFF-center ganglion cell (16).

response is encountered in many vertebrate retinas including birds (25, 26), reptiles (26-28), some mammals (22, 29), fish (30, 31), and amphibians (32), but is rather rare in cat (6) or primate retinas (33).

In Fig. 12, small spots of light are moved into the field of an ON-OFF type rabbit directionally selective ganglion cell from different points of the compass. When the spot is moved up from the bottom, a vigorous spike discharge occurs. When the spot is moved down from the top, no response occurs.

Modeling Directional Selectivity

The amazing feat of signal extraction found in directional selectivity, performed by a remarkably few retinal neurons, has sparked sustained interest in modeling this system, starting with the discoverers (34). Such attempts have generally met with failure (35), but here are some of the givens and some of the approaches: 1) it is generally believed that retinal interneurons are not themselves directionally selective (32), except perhaps in turtle retina (27, 36, 37); 2) models must yield the same preferred direction for both dark and bright spots. Originally, it was thought that the contrast invariance of directionally selective cells was attributable to the common ON-OFF type physiology (38) and interactions between signals of the ON and OFF pathways. The discovery of both ON-type and OFF-type directionally selective cells with contrast invariance suggests that this is not the case. The persistence of directionally selective responses under pharmacological blockade of the ON component also suggests that cooperation of both ON and OFF bipolar pathways may not be required. In ON-OFF cells, both pathways yield the same preferred directions, however (39); 3) there is evidence of preferred direction facilitation (40) as well as null direction inhibition; 4) there is little evidence that directionally selective ganglion cells themselves exhibit morphological polarization (12, 15, 24, 41, 42).

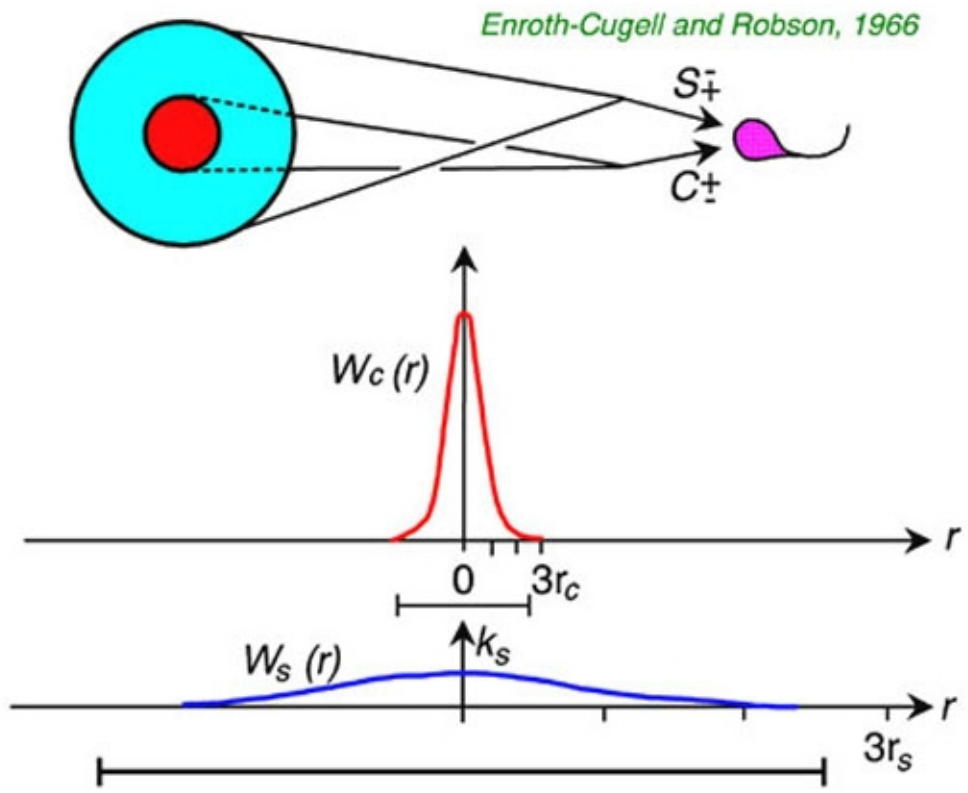

Figure 10. Difference-of-Gaussians Receptive Field Model (18).

Directionally selective ganglion cells, stained after microelectrode recordings, have a distinctive dendritic morphology with many apparently closed, or nearly closed, loops, giving the appearance of anastimosing dendrites (Fig. 13, Fig. 14). ON-OFF directionally selective ganglion cells are bistratified in the inner plexiform layer (Fig. 13), whereas ON-type directionally selective cells are monostratified, close to ganglion cell bodies (Fig. 14). None of these morphological features hints at the orientation of the null/preferred axis, however.

Some form of morphological polarization of presynaptic interneurons is a common feature of models of directionally selectivity: 1) Intrinsic neurons with axons. Originally the axon bearing horizontal cells of mammals were suggested as providing the directional arrow in the retina (29). Because ON and OFF pathways have not yet diverged at the horizontal cell level of signal processing, contrast invariance would be explained. However, bipolar cells were not found directionally selective (32). Association amacrine cells with intraretinal axons have been been found in pigeons (43). With appropriate connectivity, these might be the substrate of directional selectivity. Unfortunately, such cells do not appear to be common to most species. 2) Functional polarization of presynaptic amacrine cell dendrites. Starburst amacrine cells are cholinergic and excitatory and appear to release acetylcholine primarily at dendritic tips. An excess innervation by such amacrine cells on one side of the directionally selective cell might result in preferred direction excitation. Ablation of these cells with lasers, or pharmacological blockade of acetylcholine, have failed to abolish directional selectivity, though (35).

Pharmacology of Directional Selectivity

Some pharmacological agents abolish, or partially abolish, directional selectivity. The most classic of these is picrotoxin, a convulsant, and blocker of receptors for the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). Both $GABA_A$- and $GABA_C$-type receptors, the latter very common in the retina, are blocked by picrotoxin.

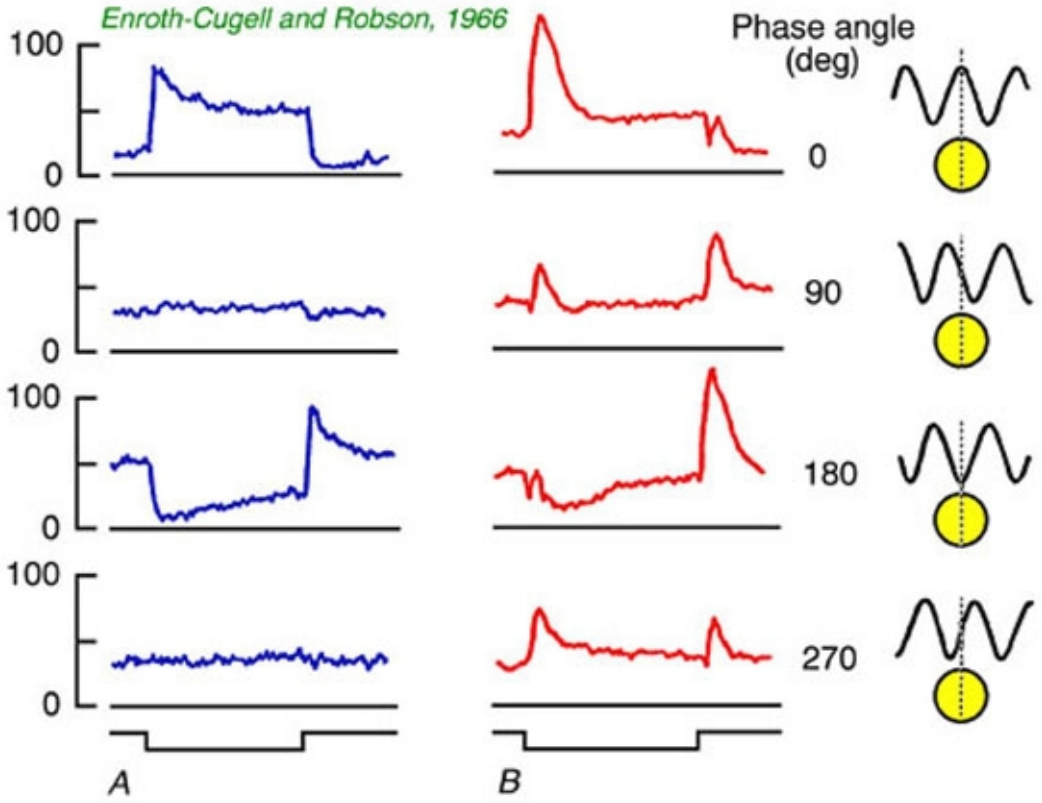

Figure 11. The null test for linear summation within X- and Y-type receptive fields (18).

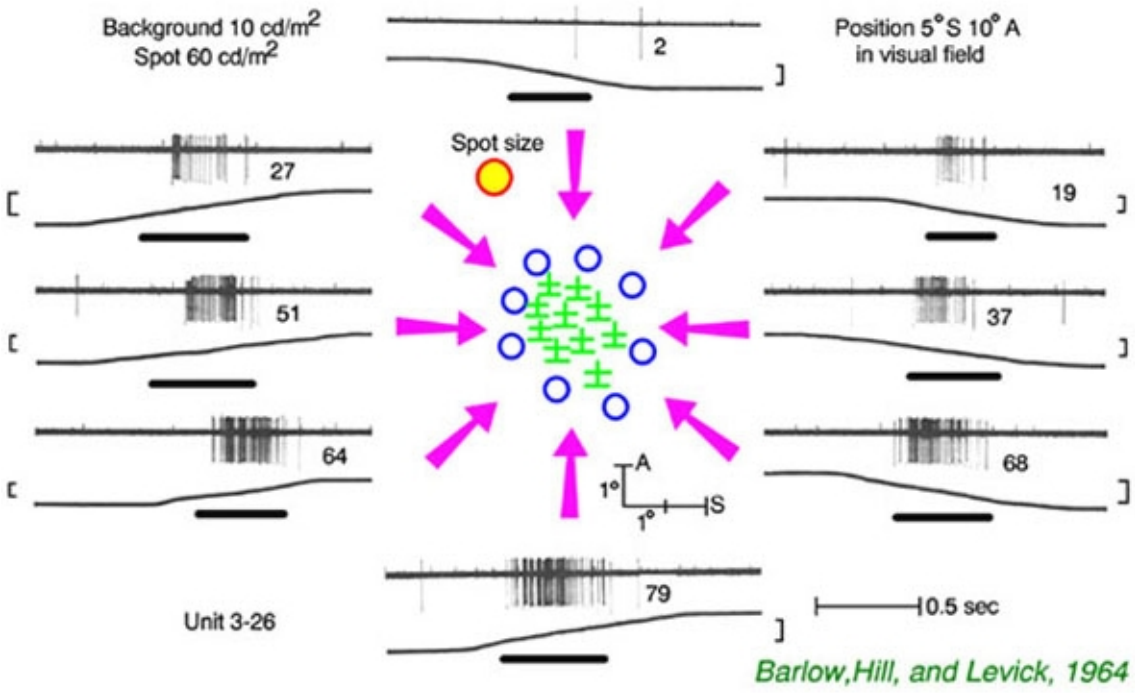

Figure 12. Responses of directionally selective ganglion cell to objects with different directions of motion (23).

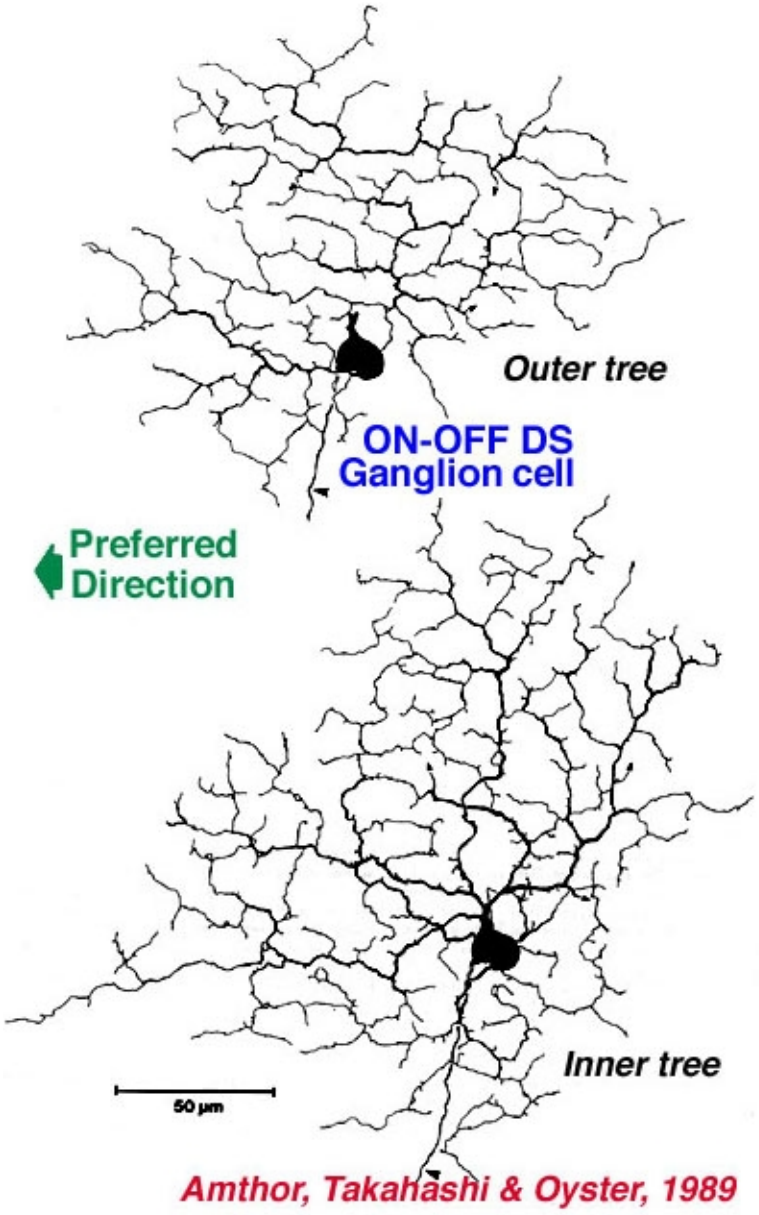

Figure 13. ON-OFF directionally selective ganglion cell of rabbit retina.

Fig. 15A illustrates the static receptive field properties of an ON directionally selective cell in rabbit retina. This cell responds to spots moving toward the lower left (Fig. 15B, P) but not the upper right (Fig. 15B, N). No responses are seen to bars of light, regardless of the direction of motion. This indicates a particularly strong surround antagonism suppressing responses to large stimuli. Picrotoxin abolishes both directional selectivity and size specificity. In these experiments (44), strychnine— another convulsant and blocker of the inhibitory neurotransmitter glycine—did not have these effects. This suggested that GABA was selectively important in neural circuitry underlying the generation of directionally selective responses. The $GABA_A$-selective antagonist SR95531 blocks directional responses, suggesting that this particular subtype of GABA receptor is critical to the process (39).

The neurotransmitter acetylcholine is a potent excitatory agent for directionally selective ganglion cells (45). It is released by presynaptic cholinergic "starburst" amacrine cells and provides excitation at both onset and offset of the stimulus. Blockade of cholinergic input (46, 47), or ablation of cholinergic amacrine cells, reduces but does not abolish directional selectivity (35). The metabotropic glutamate receptor agonist *APB* blocks the ON

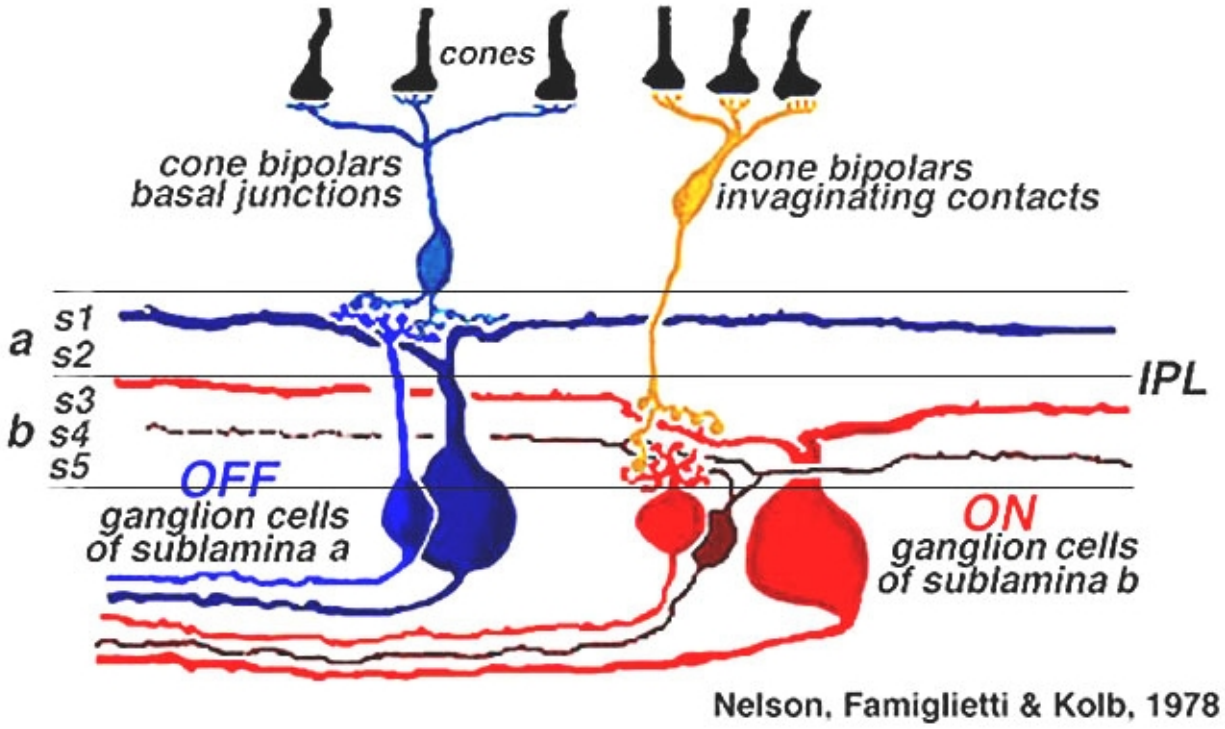

Figure 14. ON directionally selective ganglion cell of rabbit retina (12).

component of all responses in ON-OFF type directionally selective cells (39, 46). However, the OFF component of directional responses remains. *N*-Methyl-D-aspartate (NMDA) receptor agonists do not block directionally selective responses, and by implication directionally selective ganglion cells contain excitatory NMDA response components, which are non-directional (46). Interestingly, the AMPA-kainate receptor antagonist NBQX potently blocks directional selectivity in both ON-OFF and ON-type cells, leaving vigorous responses to movement in all directions (Fig. 16). Thus, a non-NMDA glutamate receptor may be selectively involved in the directionally selective mechanism, possibly as an excitatory (bipolar) input to a GABAergic interneuron (46).

Color and Spectral Responses

Ganglion cells respond to colored stimuli in one of two ways: color opponent responses and luminance responses. The patterns are similar to those of horizontal cells, which occur in chromatic and luminance types. Color opponent ganglion cells are found principally in vertebrates, which behaviorally can discriminate color. Goldfish are an animal model with color vision and have provided much information on the way in which vertebrate retinas process color. In this animal, it was first realized that individual cones express only one each of three genomically available cone photopigment types (colloquially, red, green, or blue cones; technically, long (L), mid (M), or short (S) wavelength types). This supported at least part of Thomas Young's (48) 19th century "trichromatic" theory of color vision. Neural retina does not preserve the purity of this spectral trilogy, however. Signals are both added and subtracted to form luminance and color opponent channels, respectively. Color opponency was a color vision theory of the 19th century physiologist Ewald Herring (49). Retina operationally combines both ideas from Young and Herring in processing spectral information.

In Fig. 17, white light is broken into spectral colors with a monochrometer and flashed on the retinal surface while recording ganglion cell discharges. Short-wavelength lights (400-560 nm, blue or green) excite the cell, evoking impulse discharges. Long-wavelength stimuli (570-700 nm, red) inhibit discharges during presentation but evoke discharges at offset. This is a classic color opponent pattern of the RG (red/green) type (50). There is also a symmetrical type excited by red stimuli and inhibited by green.

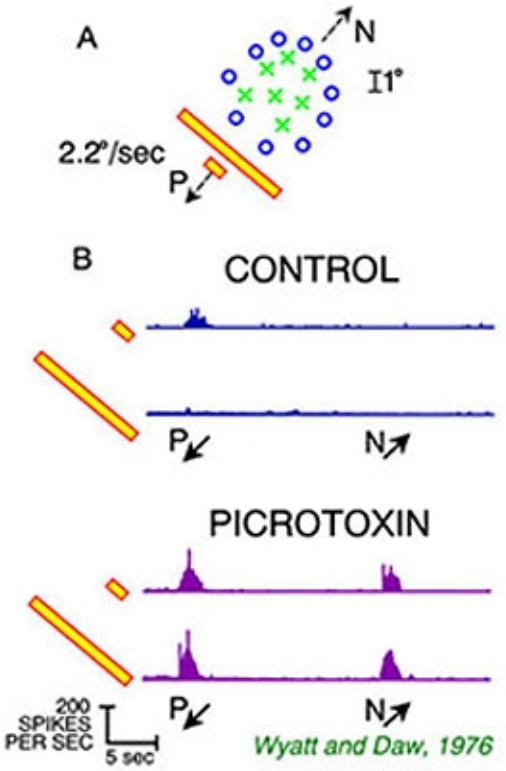

Figure 15. The GABA antagonist picrotoxin blocks directional selectivity in ON directionally selective ganglion cells. After Wyatt and Daw (44).

In cells with input pathways arising from more than one spectral class of cone, the relative strength of different cone inputs can be modified by colored backgrounds (50). This is called "selective chromatic adaptation". In the cell of Fig. 17, red backgrounds reduce the strength of OFF inhibitory responses, allowing green ON excitatory responses to be seen at long wavelengths. Conversely, green backgrounds reduce the strength of ON responses and allow red OFF responses to be seen at short wavelengths. Modification of spectral properties by colored backgrounds is often used to evaluate cone inputs, even in the absence of color opponent signals.

Cats, like many other large mammals aside from primates, are often thought to be color blind. Present evidence suggests that cats can distinguish blue from colors of longer wavelength (51), but that their color acuity is much worse than primates (52). Ganglion cells in cat retina are primarily of the luminosity type. Fig. 18 provides an example of this type of cell. Spectral curves always peak at 556 nm, characteristic of the cat's red cones, regardless of attempts to shift the sensitivity toward longer or shorter wavelengths with selective chromatic adaptation. Very rarely, color opponent cells are seen in cat. In Fig. 19 is an example of a cell excited by blue stimuli and inhibited by red. In cat retina such cells may account for only 1% of the ganglion cell population, all with blue ON excitation and red OFF inhibition (20, 51).

Color and Receptive Fields

Color opponent ganglion cells can have centers and surrounds, each with separate color opponent properties. A common type in goldfish retina is the double opponent ganglion cell. In this type, each color mechanism in the receptive field center is opposed by a mechanism of the same color type but opposite sense in the surround (53). Spectral properties of a goldfish ganglion cell with a red OFF-center, red ON-surround in combination with a

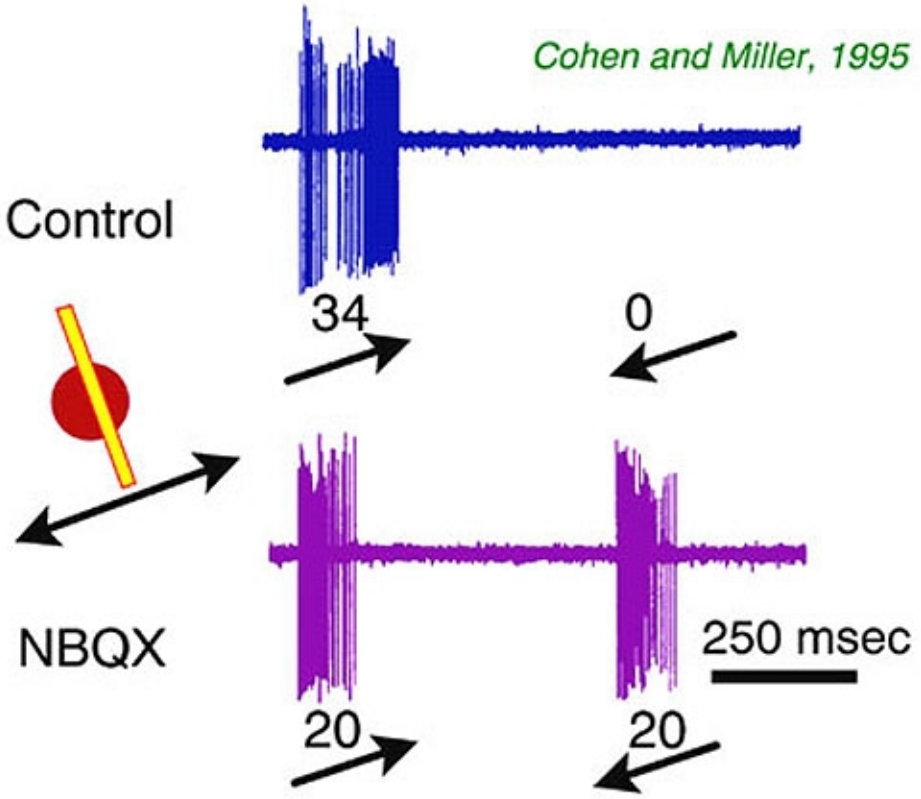

Figure 16. The AMPA-kainate antagonist NBQX (10 μM) blocks directional selectivity in ON-OFF directionally selective ganglion cell. After Cohen and Miller (46).

green ON-center, green OFF-surround appears in Fig. 20. This type of cell is thought to excel at "simultaneous color contrast"—the ability to detect color changes at borders.

Color opponency is not the only way in which cone signals are processed in the retina. In Fig. 21 is an example of synergistic addition of blue and red cone signals in the surround mechanism of a cat OFF-center ganglion cell. It is apparent then, that ganglion cells may combine cone signals in a myriad of ways. In the twilight-hunting cat, signal detection may be more important than color discrimination. Adding signals from different cone mechanisms may increase signal amplitudes across the spectrum. Multiple cone types may thus serve at least two roles, discrimination of color and increased spectral coverage.

Tonic and Phasic Ganglion Cells of Primate Retina

Primate retinal ganglion cells occur in two broad categories, "tonic" and "phasic", as described by Gouras (36). Tonic cells respond to light stimuli in a steady maintained manner. Receptive field centers are extremely small, about 15 μm on the retinal surface (~4' of arc, about 10 cm at 100-m distance). Tonic cells are often called "midgets" because they probably represent recordings of midget ganglion cells described by Polyak (54) (see below). They occur with a density distribution across the retina comparable to, anatomically, midget cells (55). The tiny receptive field centers match well the anatomical sizes of these tiny cells. The optic nerve conduction velocities of tonic fibers are slow (~2 m/s) (56). As a group, these cells are also often referred to as the "parvocellular pathway" or "P" cells. This is because the tonic fibers terminate in the parvocellular layer ofthe lateral geniculate nucleus of the thalamus.

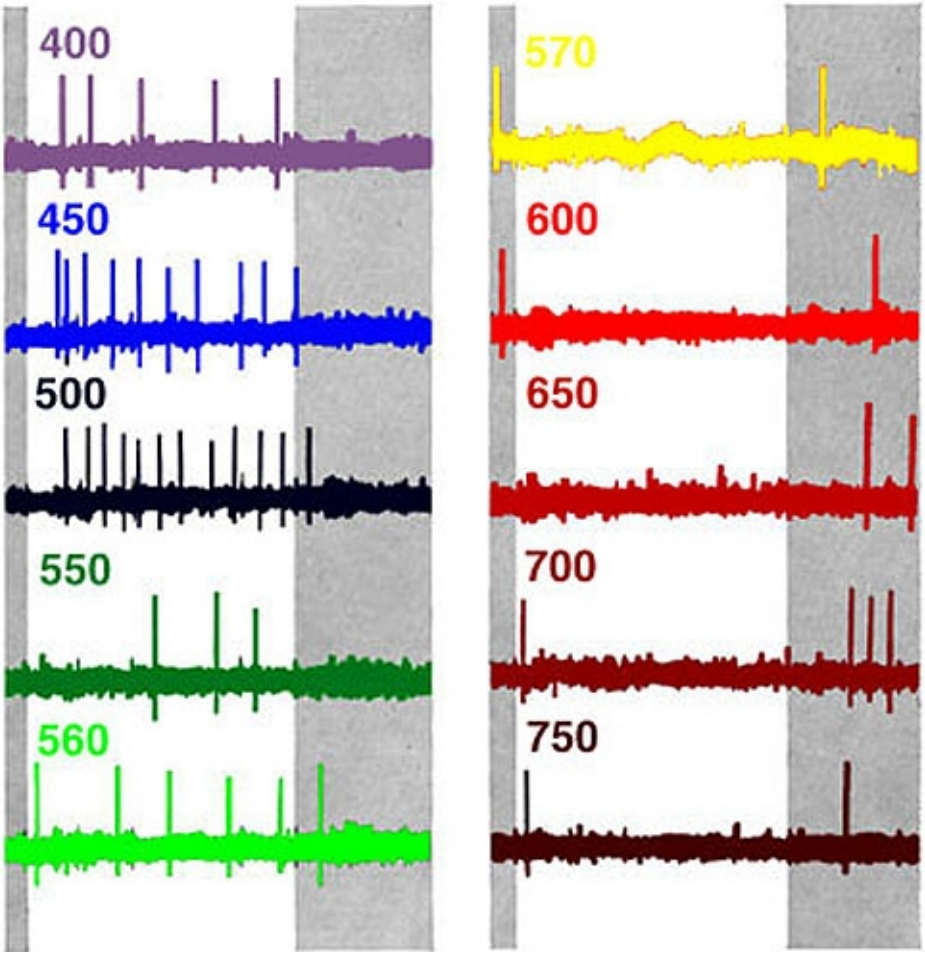

Figure 17. Impulse discharges of ganglion cells in goldfish retina. Half-second stimuli (white) are different wavelengths (left). Short wavelength (blue or green excite the cell; long wavelength stimuli (red) inhibit it). From MacNichol (94).

Phasic responses originate with morphologically larger ganglion cell types with fast optic nerve fiber conduction velocities (~4 m/s) (56). Microelectrode staining of such cells shows that they are "parasol" types (57). ON-types branch low in the inner plexiformlayer (sublamina **b**), whereas OFF-types branch high in the innerplexiform layer (sublamina **a**), following the classic branching pattern for ON- and OFF-center cells (10, 57). Phasic cells are often referred to as the "magnocellular" or "M-cell" pathway because their fibers terminate in the magnocellular layer of the lateral geniculate nucleus of the thalamus. Near the fovea, receptive fields of phasic cells are two to three times larger than those of tonic cells and may be 10 times larger in peripheral retina.

Tonic cells of the parvocellular pathway respond best to stimuli with high contrast and fine grain, whereas phasic cells respond to stimuli with very weak contrast, covering larger areas (58).

Color Properties of Primate Ganglion Cells

Tonic cells occur in three spectral types: red-center, green-center, and blue-center cells. Stimuli consisting of small spots evoke spectral responses consistent with the action of only a single spectral type of cone in each case. Surround responses are also spectrally selective and are generated only from spectral types of cone not found in the center responses (33). Tonic cells are spectrally opponent types, but the opponent signals are distributed in different regions of space.

Phasic cells combine red and green cone signals synergistically in both center- and opponent-surround mechanisms of the receptive field. These cells are luminosity types and are not generally color opponent,

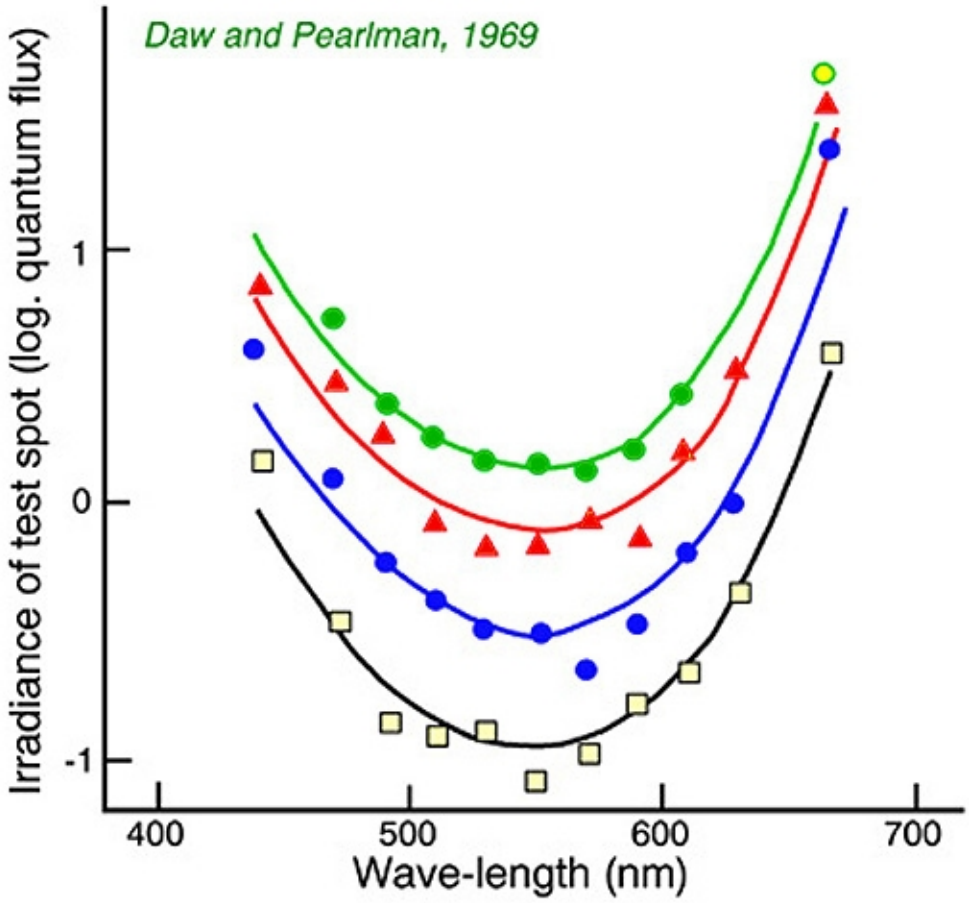

Figure 18. Spectral sensitivities of cat ganglion cell under conditions of selective chromatic adaptation. White background (squares), blue background (blue circles), red background (red triangles), and green background (green circles). After Daw and Pearlman (95).

although in some cases an imbalance of the strength of spectral mechanisms in center and surround generates some opponent characteristics (33).

A classic tonic ganglion cell with green ON-center and red OFF-surround responses appears in Fig. 22. Small green spots (540 nm, 0.02°) excite the cell, evoking a maintained discharge. Large red spots (640 nm, 2°) inhibit impulse firing, but excitation occurs when the red stimulus is turned OFF. This is a chromatically opponent receptive field surround mechanism. In Fig. 23 are spectral sensitivities of three different tonic cells for small spots. Spectral sensitivities are not altered by selective chromatic adaptation (33), indicating that each center mechanism behaves as if it were driven by a single spectral class of cone. At the top of the figure is a blue-sensitive tonic cell. The 650 Fresnel peak on the light frequency axis corresponds to about 450 nm, the peak of blue-sensitive cones. Similarly, the middle panel (Fig. 23) illustrates a green-center tonic cell, and the lower panel, a red-center tonic cell. It is important to realize that tonic cells come in OFF- as well as ON-center varieties. Thus, there are at least six different center mechanisms for this concentric color opponent class of cell. Blue OFF-center types appear to be particularly rare, however (33). Some surround mechanisms in tonic cells combine more than one cone mechanism. When the different color properties of surrounds are considered, there are a total of 12 spectral categories for this class. Reid and Shapley (59), however, found only one spectral class of cone in tonic cell surrounds.

Impulse discharges of a phasic ganglion cell (Fig. 24) exhibit an initial transient burst followed by a sustained discharge for small spots, and only a transient ON burst for large spots, as delayed antagonistic surround

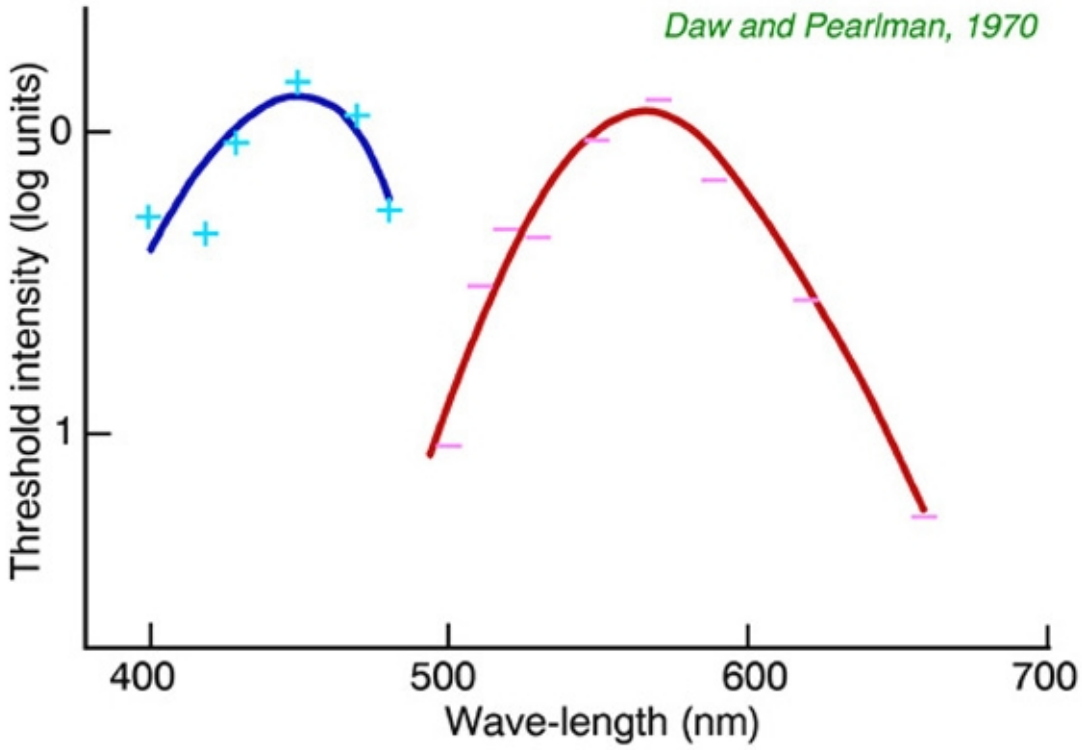

Figure 19. Blue ON, red OFF color opponent cat ganglion cell recorded on white background. (+/blue) spectral sensitivity of ON excitation, (−/red) spectral sensitivity of OFF excitation. After Daw and Pearlman (51).

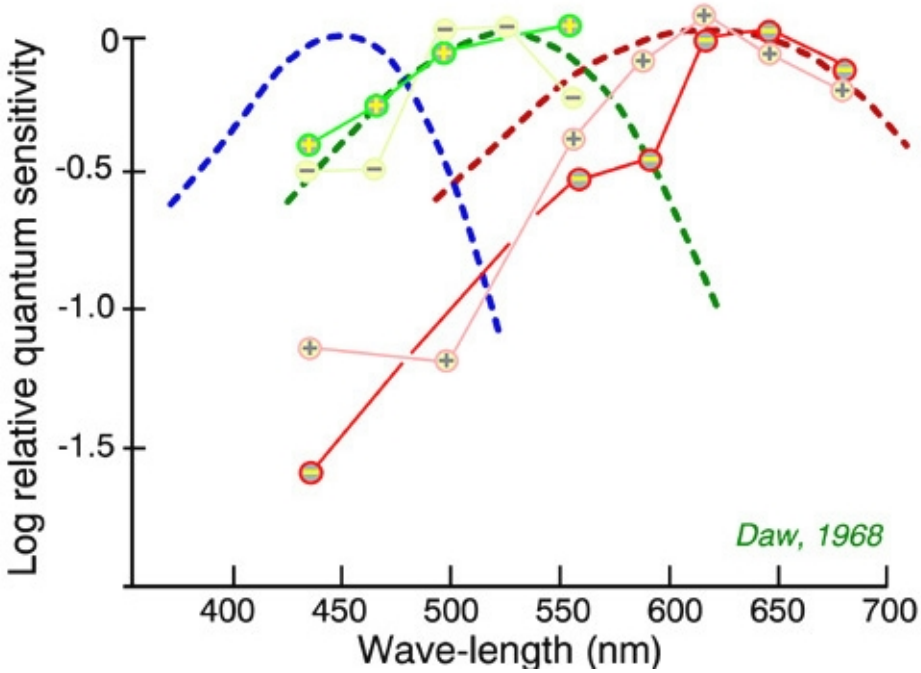

Figure 20. Red OFF center double opponent color cell of the goldfish retina. Center responses, yellow symbols; surround responses, gray symbols; excitation, +; inhibition, −. Dotted lines are red, green, and blue photopigment absorption spectra for comparison to sensitivities of receptive field mechanisms. After Daw (96).

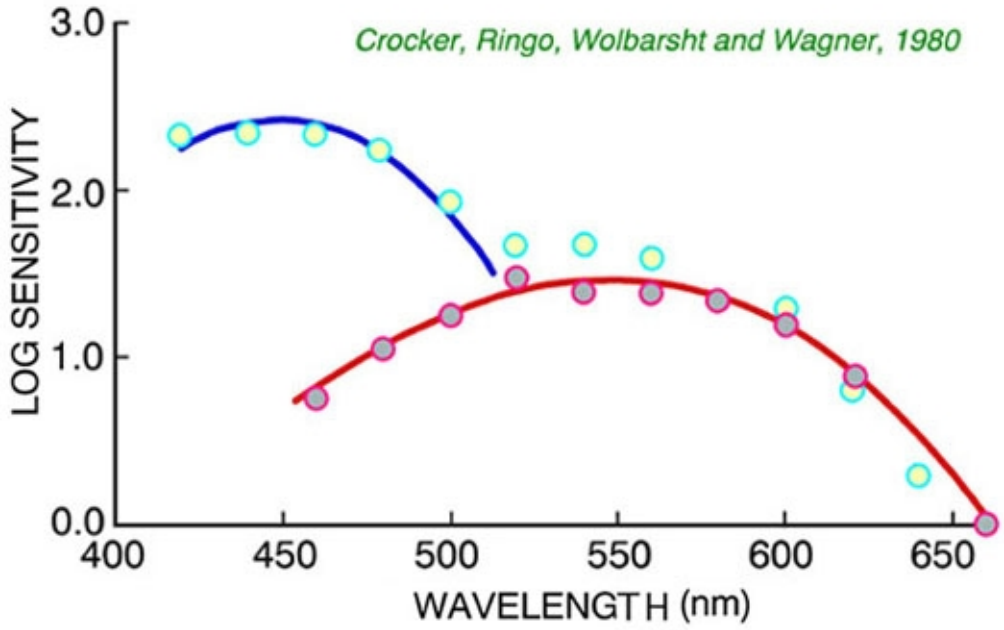

Figure 21. Synergistic action of red and blue cone signals in receptive field surround of cat OFF-center cell. Red-gray symbols, center OFF responses; blue-yellow circles, surround ON responses. Bright yellow light was required to bring out the blue mechanism. After Crocker et al. (97).

responses, induced by the large stimulus, inhibit the sustained response component. Large red spots evoke a particularly brisk OFF discharge from the receptive field surround. The cell is spectrally a luminosity type, with excitatory center responses to all wavelengths of stimulation. Both red and green cone signals sum synergistically to produce the center responses of primate phasic ganglion cells (Fig. 25). Red background lights will selectively desensitize the red cone signal components, revealing the green cone component of the center response; likewise, blue background lights selectively desensitize the green cone signal component, revealing red cone contributions to the center response.

Intracellular recordings from phasic ganglion cells in isolated monkey retina (Fig. 26) confirm that these responses originate in parasol-type ganglion cells (Fig. 27). The phasic, parasol response is chromatically a luminosity type. Vigorous responses are evoked by alternating bright and dark periods (Fig. 26a) but not by alternating blue and yellow colors (Fig. 26b), or magenta and green colors (Fig. 26c) balanced for brightness. Phasic cells sense luminance changes but not color changes (57).

There are also color opponent ganglion cells in primate retina with color opponent centers but no surround (class 2: color opponent, non-concentric) (33). These occur in both blue-yellow and red-green opponent types. The receptive fields are rather large, similar to phasic cells. Opposed spectral mechanisms fully overlap within this large receptive field center (33). No antagonistic surround mechanisms is found. Dacey and Lee (57) have recorded and stained a candidate for one of these types, a blue-yellow opponent cell. Morphologically, it is a small, bistratified ganglion cell.

Unlike the phasic cell (Fig. 26), this blue-excited cell is able to respond to color changes, being excited by a change from yellow-to-blue stimuli of equal luminance (Fig. 28c). As a bistratified type, it is clearly not a midget ganglion cell. Dacey and Lee (57) plausibly argue that the cell receives OFF-type red and green bipolar cell input onto its outer, OFF-layer dendritic tree and ON-type blue bipolar cell input onto its inner, ON-layer dendritic tree. Dacey and Lee (57) also describe a small, peripheral, monostratified ganglion cell responding to red-green

color changes but not to the magenta-green color changes designed to excite blue-sensitive ganglion cells. As yet, foveal and para foveal midget cells have not been marked by microelectrode staining techniques.

Rod Signals in Retinal Ganglion Cells

In addition to information about color, ganglion cells also transmit to the brain a monochromatic, non-color-containing signal from rods. Rods detect visual stimuli at very low light levels, including visual threshold. Their true sensitivity is rarely tested in a typical urban environment, but imagine a moonless rural night without street lights. Shapes and forms are fuzzy, colorless, and slowly perceived. This is rod vision. Such visual environments are often termed "scotopic", in contrast to brighter "photopic" environments where shape, color, and movement are readily seen. In photopic environments, cones are active. Amazingly, individual ganglion cells transmit both sorts of information, a sort of multiplexing of signals with very different characteristics, although it is only with a "mesopic" visual environment, with intermediate levels of ambient illumination, that both signals may be simultaneously present.

Rod and cone signals are found mixed in the major X- and Y-type ganglion cells (beta and alpha morphological types) in cat retina (60), and such signals are always found to be of the same polarity as the center mechanism for cone signals. Rod and cone signals are clearly mixed in the phasic type ganglion cells of the primate magnocellular pathway (61, 62). Whether tonic cells of the parvocellular pathway contain significant rod input remains controversial. Recent studies suggest that such input is either weak or absent (63) and may be absent entirely in blue-center cells. The M-cell/magnocellular pathway appears likely to be the principal conduit for transferring visual information to the primate brain under conditions of dim illumination (64). This point, however remains controversial (65). In goldfish retina, only ganglion cells with red cone-dominated center mechanisms contain rod signals (66). However, no such selective cone association has been reported in primate (62).

Rod Signals Are Delayed

Rod signals develop more slowly than cone signals. Reaction times driving automobiles or playing sports out of doors is slower at night. This is because rod signals are characteristically slow, and it is this photoreceptor system that is active at night or with dim illumination.

In Fig. 29, extracellular spikes from a primate ON-center retinal ganglion cell can be seen composed of two distinct clusters with different delays. With yellow backgrounds, only short latency spikes are generated in response to a brief flash, regardless of wavelength or stimulus brightness. These are cone signals. Under dark-adapted conditions and threshold stimulation, only long latency spikes occur. These are rod signals. Under dark adaptation and with somewhat brighter red stimuli, which begin to stimulate cones, a mixed response can be seen composed of both short latency cone components (arrow) and long latency rod components. In Fig. 30, rod and cone responses are seen in intracellular recordings of a cat OFF-center ganglion cell. Responses to flickering red (647 nm) stimuli arise mainly from red cones, whereas those from blue (441 nm) stimuli arise only from rods. Superposition of responses allows easy comparison of the timing of rod and cone signals with each flicker cycle. Rod ON hyperpolarizations evoked by the blue stimulus are distinctly delayed as compared with cone ON hyperpolarizations evoked by the red stimulus. The different delay is also apparent with the excitatory impulses evoked at the offset phase of each cycle.

In a series of flicker responses evoked by different brightnesses of blue-light stimuli, there is a characteristic shortening of phase delay with brighter stimuli. This reflects a shift from rod to cone activation in the ganglion cell signal. In Fig. 31, bright stimulus, cone-dominated flicker appears in the left column of flicker responses, whereas dim stimulus, rod-dominated flicker appears in the right column. The change in delay of ON-inhibition in this OFF alpha ganglion cell is readily apparent when the two columns are compared. In fact, on the right, rod flicker response is so slow that the excitatory OFF response of the preceding flicker cycle appears in the very

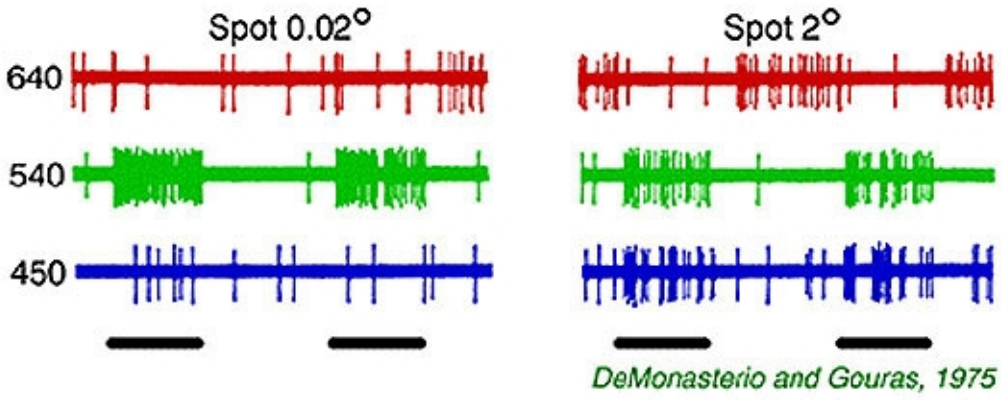

Figure 22. Spectral responses of tonic ganglion cell in rhesus monkey retina. Stimulus wavelength in nm is given to the left of impulse discharge responses. The light stimulus is ON during the black bars at the bottom of the figures. This cell is a green ON-center ref OFF-surround unit. After De Monasterio and Gouras (33).

middle of the current ON stimulation cycle. Response contradicts stimulus, an example of how perception might be at variance with reality. A superimposed horizontal cell response behaves similarly in this brightness series, although overall, it responds a little more slowly than the ganglion cell. Flicker cycles from an AII amacrine cell for dim stimuli are also shown. Many AII amacrines lack significant cone system signals, so that only very slow

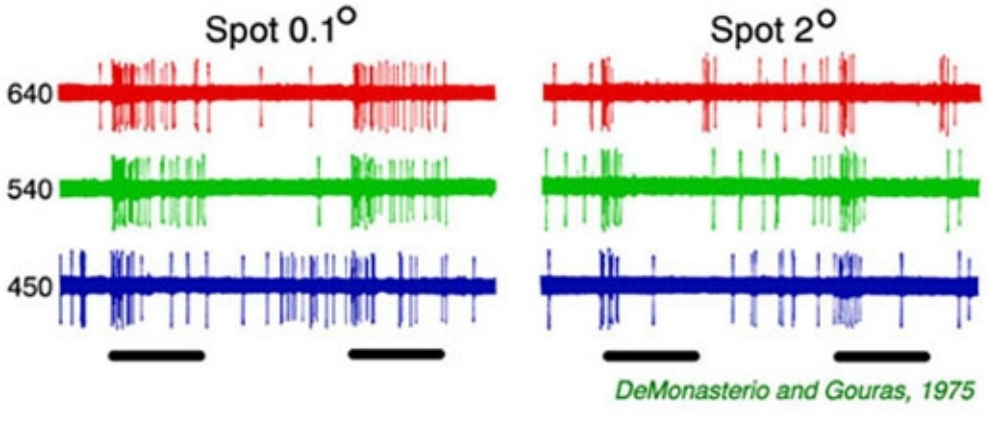

Figure 24. Spectral responses of phasic ganglion cell in rhesus monkey retina. Stimulus wavelength in nm given to left of impulse records. The light stimulus is ON during the black bars at the bottom of the figure. This cell is spectrally a luminosity type with ON-center and OFF-surround responses. After De Monasterio and Gouras (33).

rod flicker can be observed. The rod responses of this AII cell are delayed 65-70 msec compared with bright-light cone responses seen in ganglion cells or horizontal cells.

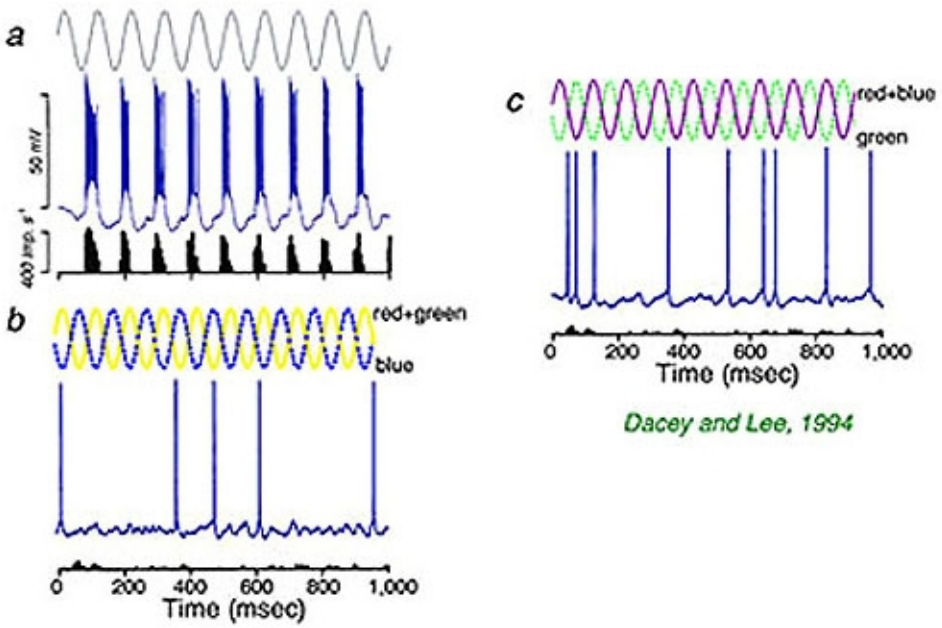

Figure 26. Intracellular recording of OFF-center phasic ganglion cell from monkey retina. The cell responds vigorously to alternating light and dark stimuli (a) but not to alternating colored stimuli with brightness of colors matched (b and c). After Dacey and Lee (57).

There is often a minimum amplitude in such flicker *versus* stimulus intensity series. This occurs because at brightness levels where rod and cone signals are both present, they are far enough out of phase with each other to mutually cancel. An example is seen in the 4.33 horizontal cell trace (Fig. 31). Flicker amplitudes for both dimmer and brighter stimuli are actually larger. The OFF-alpha ganglion cell appears also to have minimal, if not absent, flicker, near this stimulus brightness. This counterintuitive effect can be subjectively perceived. Certain flicker stimuli can be seen if they are bright or dim, but not if of intermediate intensity (67).

Rod system delays occur in specialized retinal circuitry devoted to rods. The retina has developed a set of neurons and synapses especially tuned for processing visual signals under dim lighting conditions. These may include specialized synapses between rods and bipolar cells, as well as specialized sets of rod amacrine cells. These cells are tuned to the longer integration times of rods.

In Fig. 32, turtle ganglion cell impulses are evoked by electric current injection directly into the rods and cones themselves. The delay to onset of the first impulse discharge in underlying ganglion cells is measured. This technique separates circuitry delays from delays in photoreceptor transductive machinery. OFF discharge latency (the time between cessation of hyperpolarizing current injection into a photoreceptor and the first ganglion cell impulse) was found to be about 100 msec when electrically stimulating red cones, but longer (150 msec) when stimulating rods. Interestingly, ON-discharges evoked by red cone stimulation (time from hyperpolarizing current onset to first spike) were also slow (170 msec), suggesting a slower pathway for ON cone information as well, possibly through a metabotropic glutamate pathway in such cone bipolar cells.

Detection of Light Quanta by Retinal Ganglion Cells

Retinal ganglion cells have no true threshold for detection of dim stimuli (68). When many responses are averaged, signals can be seen for light stimuli as dim as desired, and this includes stimuli so dim that only a few physical quanta of light are delivered to the surface of the eye at the cornea. Of course, in total darkness, retinal ganglion cells still exhibit a maintained but variable spontaneous firing rate, and it is against this background noise that quantal responses must be detected.

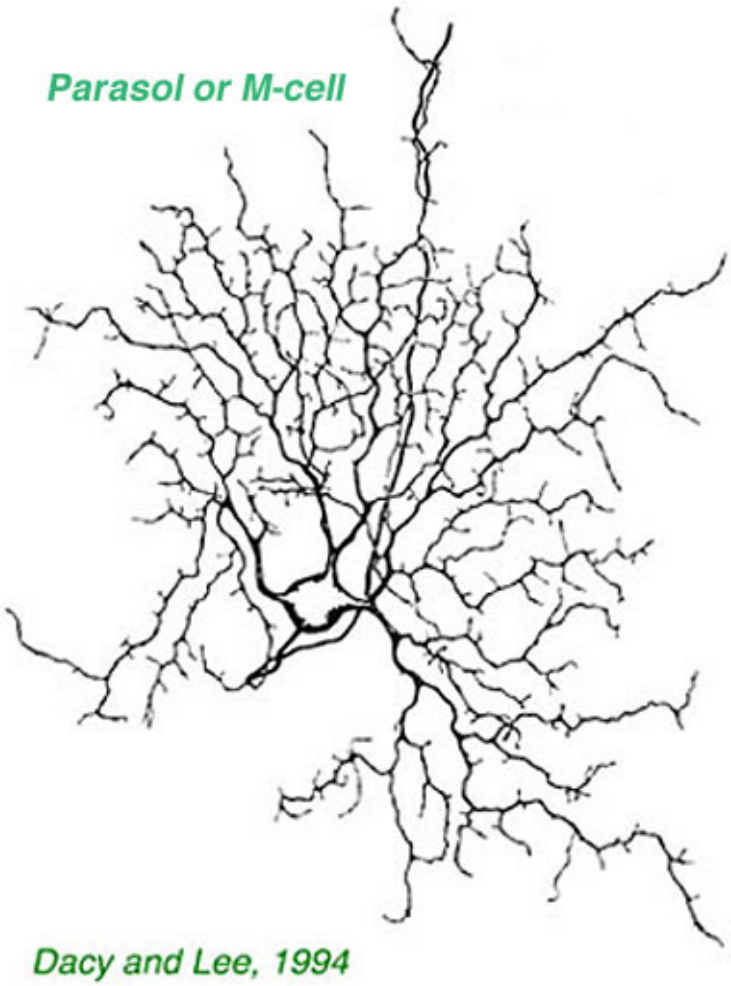

Figure 27. Drawing of a stained parasol cell in the monkey retina. Cells like this produce phasic, luminosity-type responses. The cell is 210 x 270-μm in width. After Dacey and Lee (57).

A post-stimulus time histogram (PHST) averages the number of nerve spikes fired over time for many repetitions of a stimulus. It is a useful tool for detecting small signals. This is seen in Fig. 33 for a brief, dim stimulus, which delivers on average only five quanta to the cornea each flash. Owing to optical losses, perhaps only one of these quanta is effectively absorbed in a rod and transduced into neural activity. Even so, on average, a substantial burst in mean firing rate occurs. Through analysis of data such as these, Barlow et al. (68) concluded that a single quantum absorption resulted in the firing of two to three extra ganglion cell nerve impulses. Cross-correlations in firing patterns of adjacent cells under conditions of dim illumination agree with this estimate and suggest that the time course of increased firing probability for a single quantum absorption may last about 50 msec or more, and that several adjacent ganglion cells detect the event (69).

Because of fluctuations in spontaneous background firing, single quantal events might not be readily detected in a single cell. However, three to four quantal absorptions within the cell's receptive field would be easily noticed in the discharge pattern.

Receptive Field Alterations with Rod Vision

In retinal ganglion cells, separate rod and cone pathways converge. One might expect then, during dark adaptation, as input signals to ganglion cells shift from cone-related to rod-related pathways, that receptive field properties of ganglion cells might change. The changes are, in fact, rather subtle and require careful probing with

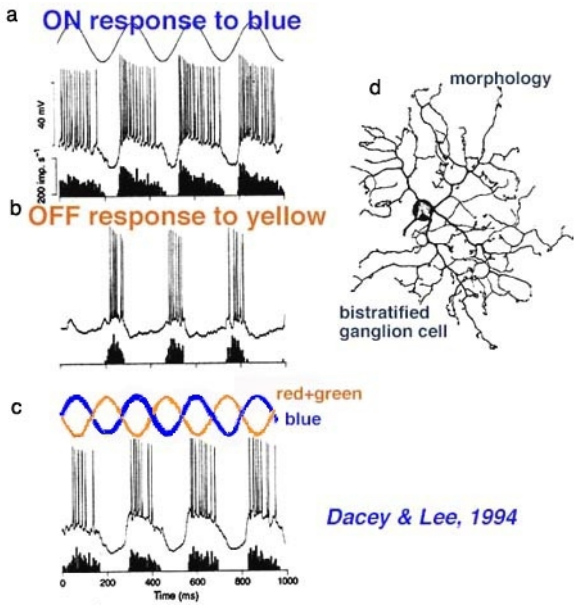

Figure 28. Blue-ON, yellow-OFF chromatic ganglion cell in monkey retina. a. Alternating blue and dark stimuli evoke ON responses. b. Alternating yellow and dark stimuli evoke OFF responses. c. Alternating blue and yellow colors matched in brightness evoke blue-ON, yellow OFF responses. d, e, f. Figure 29. Threshold and near-threshold responses of primate ON-center ganglion cells with rod-favoring blue (419 nm) and cone-favoring red (610 nm) stimuli under dark-adapted and bright-background conditions. Extracellular records, from Gouras (61).

physiological stimuli and pharmacological tools. The size of receptive field center mechanisms frequently increases. Receptive field surround responses are often less vigorous. The pharmacology of light responses

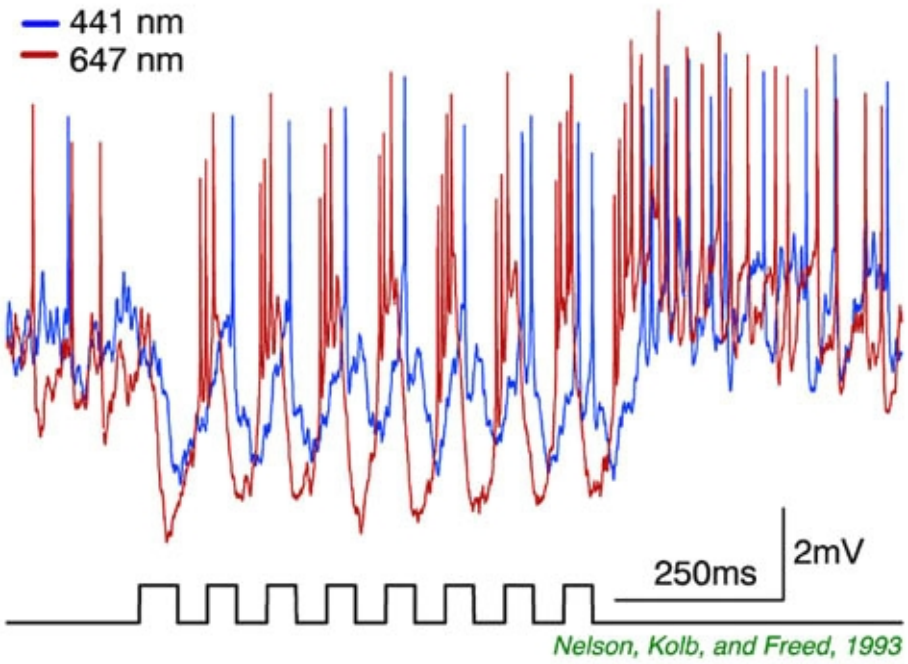

Figure 30. Near-threshold intracellular responses of cat ganglion cell to cone-favoring red (647 nm) and rod-favoring blue (441 nm) flickering stimuli. After Nelson et al. (16).

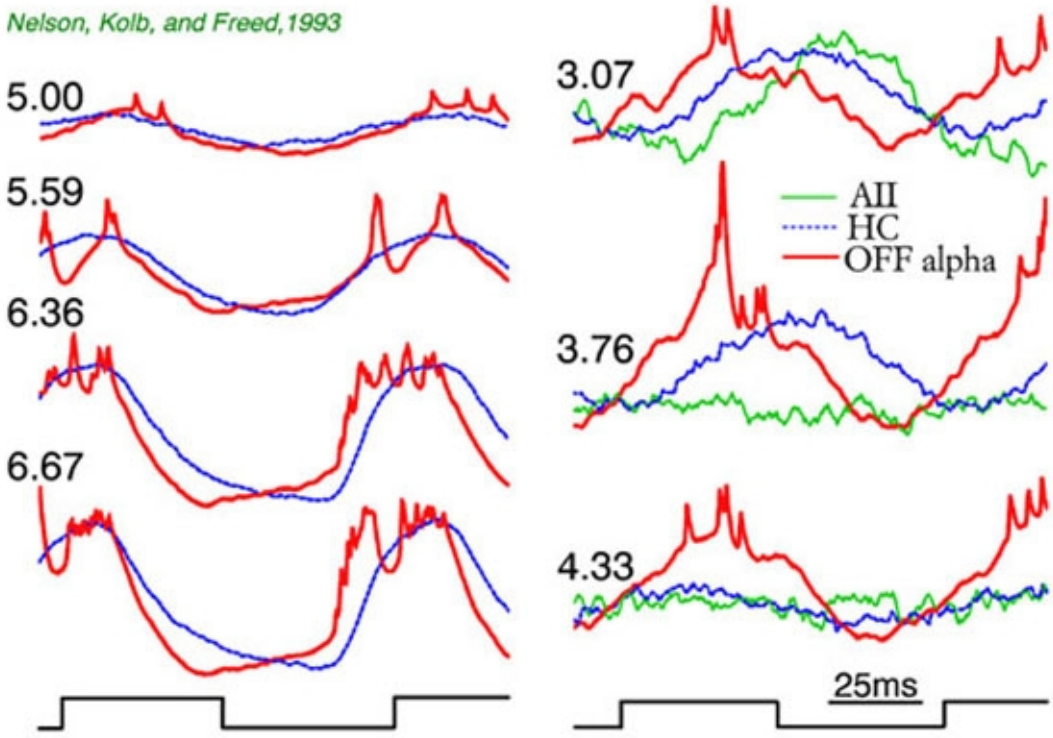

Figure 31. Phase differences in rod and cone flicker responses. Intensity response series for blue (441 nm) flickering stimuli in an OFF-center ganglion cell (OFF-alpha), a horizontal cell (HC), and an AII amacrine cell (AII). The ON-center AII amacrine response is inverted for comparison with the other OFF-center cells. In the right column, gain has been increased to better display the lower amplitude rod signals. Stimulus brightness is given in log quanta μm-2 sec-1 next to each trace. Reproduced from Nelson et al. (16).

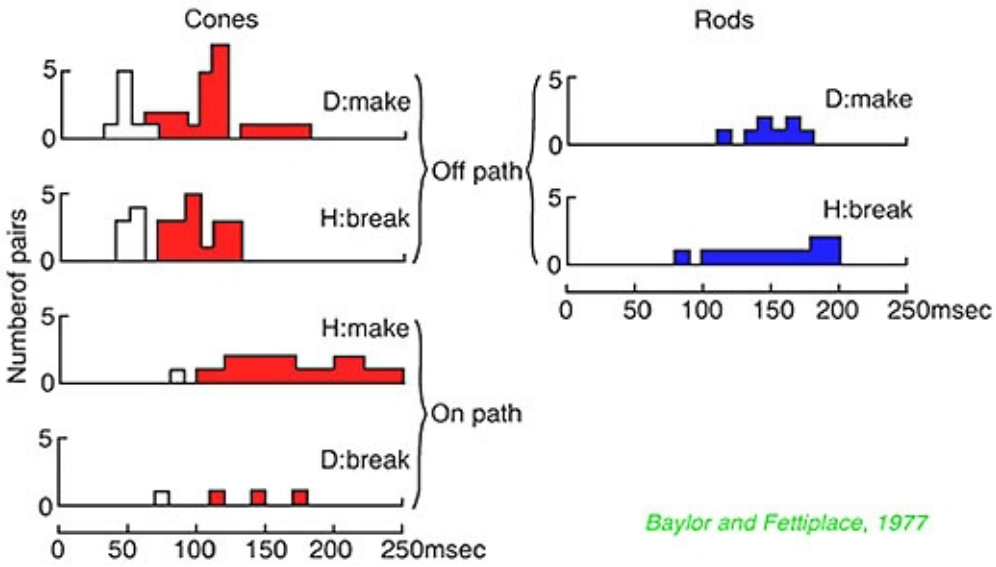

Figure 32. Turtle ganglion-cell mean impulse latencies for three synaptic pathways from photoreceptors to ganglion cells: OFF responses from red cones (red), OFF responses from rods (blue), and ON responses from red cones. Electrical currents injected directly into rods or cones generated responses. OFF responses were measured from the offset of hyperpolarizing steps (break) or the onset of depolarizing steps (make), and conversely for ON responses. Hatched cells could not be driven antidromically, fired only one impulse, and may be amacrine cells. Current pulses were 400-900 msec long. Reproduced from Baylor and Fettiplace (99).

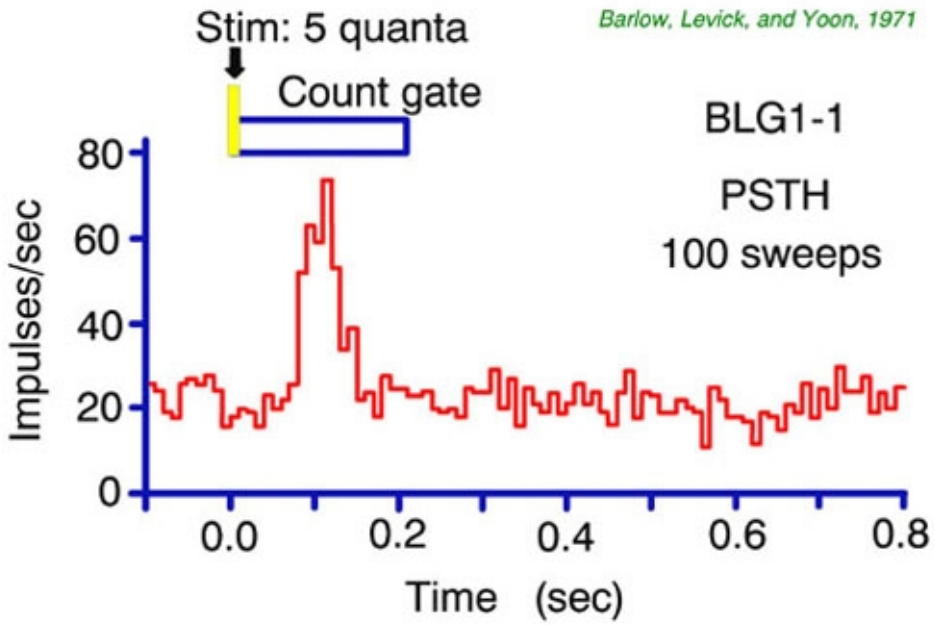

Figure 33. Post Stimulus Time Histogram (PSTH) of a cat ON-center ganglion cell response to a very dim stimulus, delivering only five quanta of light to the cornea in a 10-msec flash. The "Count Gate" is a 200-msec long interval in which impulse responses were counted, either in the dark or after the dim flash. Reproduced from Barlow et al. (68).

changes. All of these effects result from changes in the dominant retinal circuitry pattern driving ganglion cells as the retina adjusts to dim lighting conditions.

Changes in cat OFF-type ganglion cell center size during light and dark adaptation appear in Fig. 34, where response discharge rates for small-spot probes are mapped across the receptive field center. Under conditions of moderate light adaptation (mesopic, red), a narrowly peaked profile is observed, signifying a localized receptive field center. With dark adaptation, the profile spreads out (scotopic, blue) as the center becomes larger and more diffuse. Along with changes in center size, there is a change in response waveform. Under mesopic conditions, OFF excitation is brisk, transient, and of short latency. Under scotopic conditions, a more protracted, longer latency response occurs (similar to delays described above). In rabbit retina (7), dark-adapted ganglion cell center mechanisms shrunk as much as 30% during light adaptation (mean, 12%).

Surround strength diminishes during dark adaptation. In Fig. 35, responses of an OFF-center rabbit retinal ganglion cell are followed through a prolonged period in the dark. After a brief (10-min) interval, a large-spot stimulus evokes a weak ON discharge from the surround mechanism and a strong OFF discharge from the center mechanism. An annular stimulus, more selective for the surround mechanism, evokes a strong ON discharge from the surround and a relatively weak OFF discharge from the center (red). Following an extensive 30-min period of dark adaptation, the ON-surround discharges disappear from responses evoked by either stimulus (blue).

Loss of surround response can be reversed by pharmacological intervention (Fig. 35). Introduction of a cyclic AMP analogue (CPT-cAMP) into the perfusion media of this dark adapted ganglion cell restores surround responses (magenta). In additional experiments (70), strychnine, an antagonist of the inhibitory neurotransmitter glycine, was also found to restore surround responses to dark-adapted ganglion cells. It appears that surround responses are actively inhibited in dark-adapted retina by activation of glycinergic circuitry, probably from rod-dominated amacrine cells. This glycinergic amacrine release appears modulated by the intracellular messenger cAMP.

A shift in the pharmacological sensitivities of ganglion cell center mechanisms also occurs during dark adaptation, particularly for OFF-center cells in cat retina. These responses become sensitive to agents active at metabotropic glutamate receptors, normally associated with ON-type bipolar cells, and to agents selective for receptors to the inhibitory neurotransmitter glycine. Such sensitivities are not seen in the light-adapted state.

OFF discharges of a cat Y-type ganglion cell appear unaffected by the metabotropic glutamate agonist APB in the light-adapted state (Fig. 36), an expected result as cone signals (and perhaps mesopic rod signals) are transferred to such cells primarily through OFF cone bipolar cells. These use ionotropic glutamate receptors (kainate or AMPA) in synaptic transmission, which are unaffected by APB. APB does effectively block ON inhibition in the dark-adapted state. Rod bipolars are ON-type bipolars sensitive to APB. So this result likely means that ON-type rod bipolar cells are the primary signal pathway for transferring visual signals from rods to these OFF-center ganglion cells during dark adaptation. Rod bipolars do not contact OFF-center ganglion cells directly, but through inhibitory amacrine cells, such as the glycinergic AII amacrine cell. In agreement with this circuit for dark-adapted signaling, strychnine blocks ON inhibition in an OFF-center X-type ganglion cell (Fig. 37), but only in the dark-adapted state. Light responses of ON-center cells are effectively blocked by APB in both light- and dark-adapted states.

APB may not effectively block rod signals in **all** ganglion cell types however. DeVries and Baylor (71) showed, in rabbit retina, that rod responses in "brisk" ganglion cells were eliminated by APB, but rod responses of "directionally selective" or "sluggish" ganglion cell types were not. Rod signals that could not be blocked in these ganglion cells may use a pathway through rod-cone photoreceptor gap junctions into the APB-resistant OFF cone bipolar pathway.

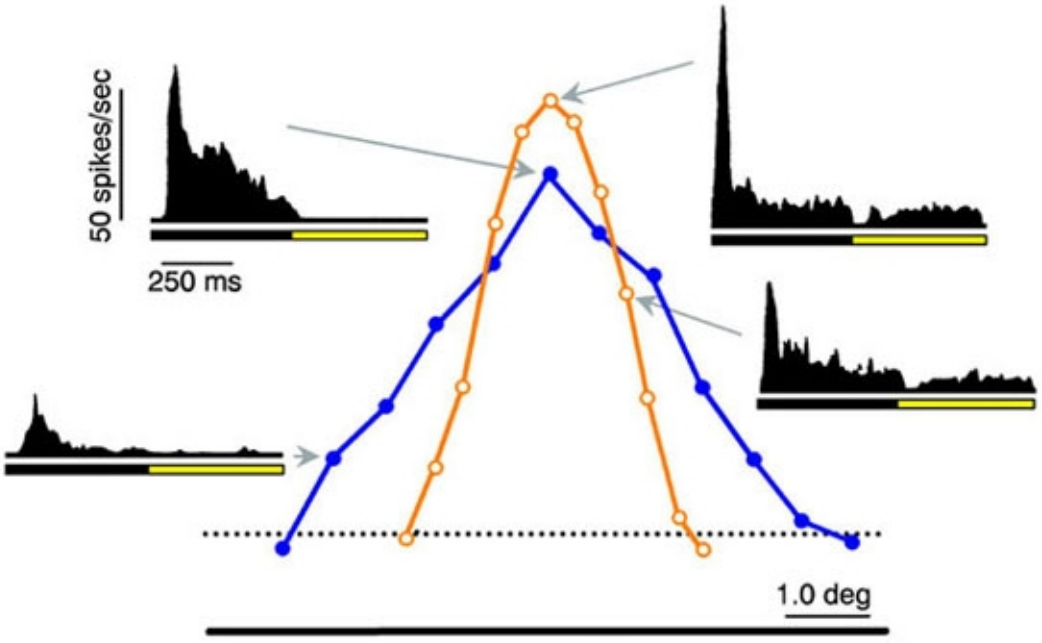

Figure 34. Ganglion cell receptive field centers increase in size during dark adaptation. Responses are more sustained. The profiles are small-spot response amplitudes from different positions within the OFF-center receptive field. Open symbols (red) recorded on mesopic (intermediate intensity) backgrounds. Closed symbols (blue), recorded in fully dark-adapted state. Post stimulus time histograms shown for indicated points (arrows). Repetitive stimulus was OFF for 500 msec (black bar, shown first) then ON for 500 msec (yellow bar, shown last). After Peichl and Wässle (100).

Spatial Distribution of Ganglion Cell Fields

Ganglion cells transmit visual information to the brain as a concert of individual signals arising from multiple cells representing different points in space. Information about visual objects is thus shared in parallel pathways from many ganglion cells. The arrangement of ganglion cells on the retinal surface is not spatially random. Each cell type is distributed in an ordered mosaic. Within each mosaic, cells tend to be spaced apart so as not to occupy a neighboring cell's territory (72). Characteristically, the "nearest neighbor distances" are greater than would be expected of a random distribution. Cells of different types may be closely spaced, however. The mosaics of different cell types are said to be independent. Receptive and dendritic fields of cells within a mosaic partially overlap (Fig. 39).

Neighboring ON- and OFF-center alpha cells position themselves in space in characteristic ways (Fig. 38). In the mosaic of ON-center cells, neighbors do not approach each other closely, maintaining an "arms length" spacing, close enough to "shake hands" with the distal dendrites of neighboring ON cells, but rarely closer. A similar spacing occurs among OFF-center cells. ON- and OFF-center cells appear mutually indifferent to each other's presence and may approach closely without an exclusionary zone. These cell types are said to occupy independent lattices (72). ON and OFF Y-cells are thought to illustrate general relationships within and among lattices.

Receptive fields and dendritic fields are similarly spaced. Multielectrode arrays allow simultaneous recording of all ganglion cell light responses in a patch of retina, characterization of trigger features, and mapping of receptive fields (7). Such studies show that receptive fields of ganglion cell types having common trigger features approach each other only at the edges. When spatial profiles are fit with two-dimensional Gaussian functions, receptive

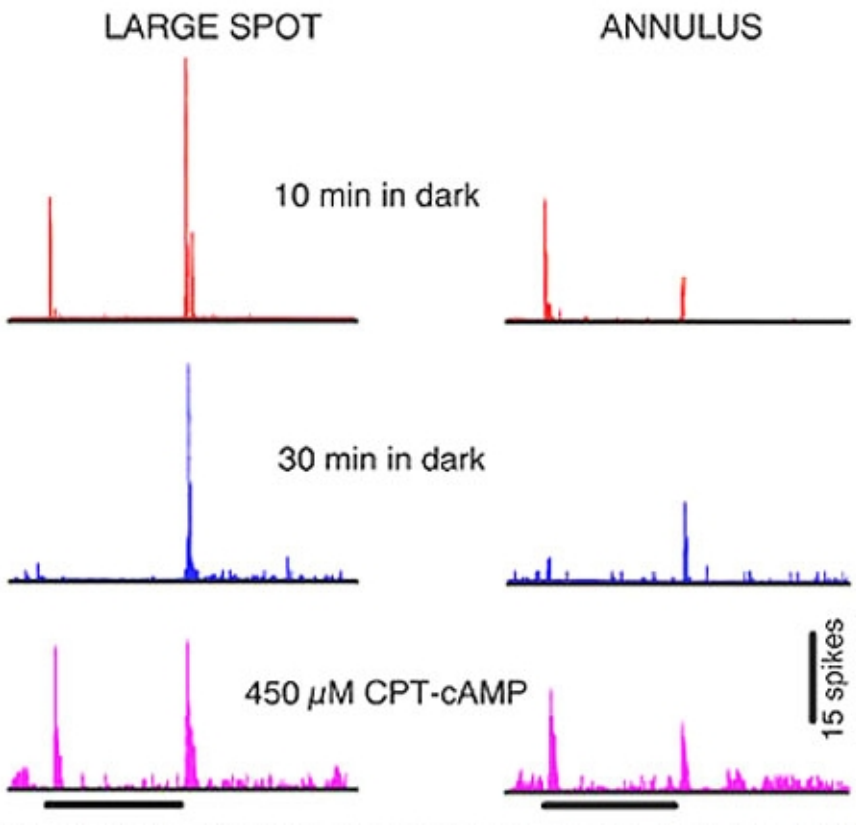

Figure 35. Ganglion cell receptive field centers increase in size during dark adaptation. Responses are more sustained. The profiles are small-spot response amplitudes from different positions within the OFF-center receptive field. Open symbols (red), recorded on mesopic (intermediate intensity) backgrounds. Closed symbols (blue), recorded in fully dark-adapted state. Post stimulus time histograms shown for indicated points (arrows). Repetitive stimulus was OFF for 500 msec (black bar, shown first) then ON for 500 msec (yellow bar, shown last). After Peichl and Wässle (100).

field centers are typically 2 Gaussian radii apart. In this arrangement, summation of sensitivities from all cells of a given type leads to a flat sensory surface (7).

Ganglion Cell Mosaics and Spatial Resolution

The lattice spacing of ganglion cell receptive field centers may limit certain forms of visual acuity, according to the Nyquist limit (7, 73). To unambiguously define the spatial grain of a periodic pattern, grating, or spatial sine wave, at least two cellular detectors are required, spaced closely enough that if one is at the peak of brightness of a repeating pattern, the other is at the trough. If multiple peaks and troughs occur in the space intervening between the two closest cells, signals will, of course, be detected in both but cannot unambiguously be associated with any single spatial periodicity. In fact, excitation patterns similar to those produced by low frequency patterns (wide spacing of peaks and troughs) may be produced by high spatial frequency patterns. This is called spatial aliasing. DeVries and Baylor (7) argue that spatial integration within the ganglion cell receptive field acts as a spatial low-pass filter to attenuate signals from very high spatial frequencies, preventing detection, so that such ambiguities do not arise.

Spatial resolution of ganglion cells and the spacing of receptive field centers appears approximately equal (7, 73). Given this observed relationship, the spatial low-pass filtering action of ganglion cell receptive fields would appear to attenuate periodic patterns at or above the Nyquist limit by about a factor of five or more (Fig. 40B), thus reducing the likelihood of detecting potentially confusing higher spatial frequencies with potential for aliasing. The ability to resolve regularly repeating spatial patterns, such as spatial sine waves, is a good proxy for

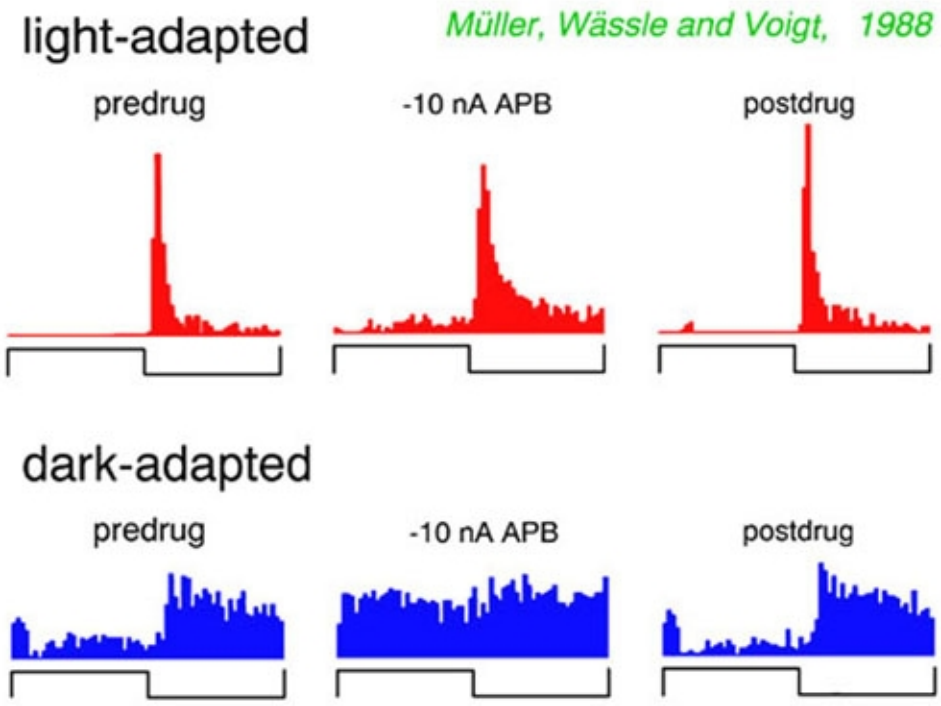

Figure 36. An excitatory metabotropic glutamate agonist selective for ON-center bipolar cells (2-amino-4-phosphonobutyrate, APB) blocks light responses of an OFF-center Y-type cat ganglion cell in the dark-adapted, but not the light-adapted, state. APB was applied electrophoretically from a nearby micropipette filled with the substance. Spot stimulus is congruent with the center mechanism. Upward deflection of the stimulus trace indicates light ON. The stimulus is repetitive, 512 msec ON, followed by 512 msec OFF. After Müller et al. (85).

spatial resolution in general, because all spatial patterns can be represented, in Fourier fashion, by sums of orthogonal spatial sine waves.

Arguments concerning ganglion cell spacing and visual system spatial performance are constrained by several caveats. First visual space is covered by many cell mosaics. One must carefully consider which mosaic might be limiting for the task at hand, or if any one mosaic need be. Second, as discussed previously, stimulus movements much finer than any retinal cell mosaic spacing can be detected by ganglion cells, if not precisely localized (14). This is referred to as visual hyperacuity (74). Finally, it is well to recall that older style video cameras achieved high spatial resolution without any mosaic of discrete detectors. "Newvicon" tubes used a single photosensitive surface, scanned by a single electron beam. Spatial resolution was excellent. If the visual system were supplied data about the velocity of image motion, even a single cell might, in principle, attain spatial resolution unconstrained by Nyquist mosaic limits.

Correlated Firing of Neighboring Ganglion Cells

Ganglion cell fields partially overlap in visual space. Ganglion cells, moreover, share an overlapping neural substrate composed of retinal interneurons and circuitry. Synchronous chemical synaptic signals from individual amacrine and bipolar cells are distributed onto multiple ganglion cells. Such signals may spread among these presynaptic elements through mutual interconnections by electrical junctions. Finally, ganglion cells themselves intercommunicate through electrical junctions. So although ganglion cells eagerly stake out their own individual turf in a spatial anatomical sense, the physiological signals they transmit are often plagiarized from common sources, resulting in highly correlated firing patterns among neighboring cells.

Such cross-correlations in firing pattern may be significant centrally, where signals converge on common neurons in the brain centers. Synapses that are simultaneously activated tend to be mutually strengthened. Such

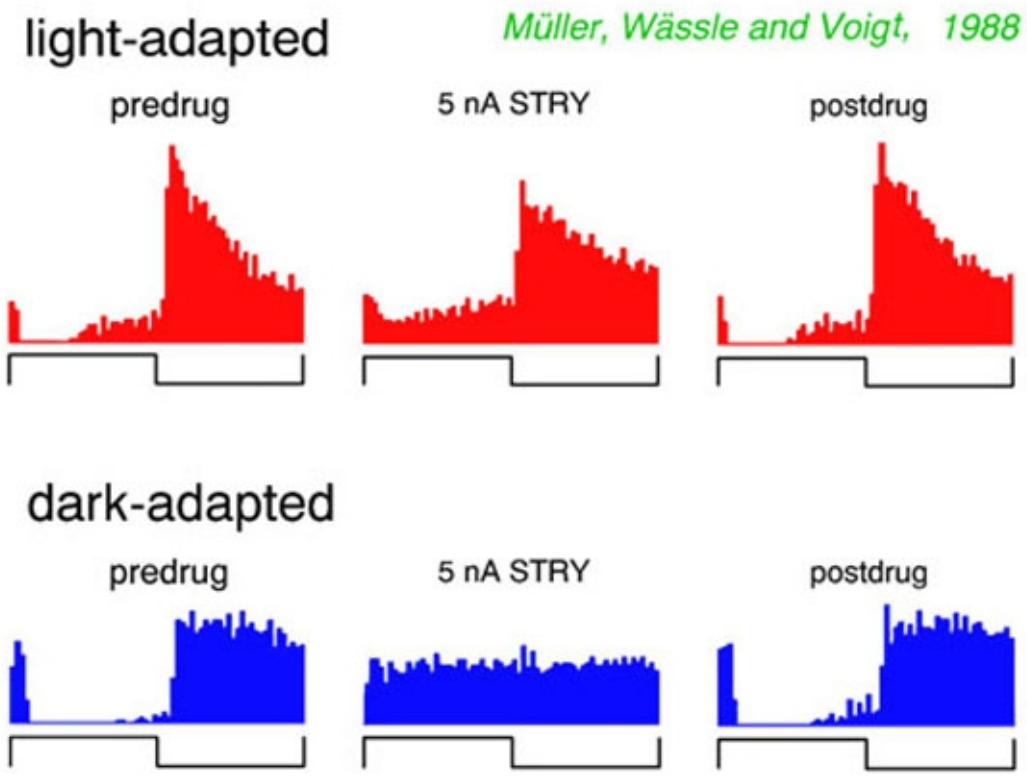

Figure 37. An agonist of the inhibitory neurotransmitter glycine (strychnine, STRY) blocks OFF-center light responses of an X-type ganglion cell in the cat retina, but only in the dark-adapted state. Strychnine was applied electrophoretically from a nearby micropipette filled with the antagonist. Small-spot stimuli are selective for the center mechanism. Upward deflection of the stimulus trace indicates light ON. The stimulus is repetitive, 512 msec ON, followed by 512 msec OFF. After Müller et al. (85).

synapses are often called "Hebian" and are thought to be reinforced by calcium entry through simultaneously active synapses. Calcium enters through synapses containing the glutamatergic NMDA receptor. The physiological effect is referred to as long term potentiation (LTP), wherein synaptic currents become larger with repeated stimulation.

Cross-correlations are generated from simultaneous recording of two ganglion cell spike trains. Impulses from the first cell set the zero time around which impulse firing rate histograms for the second cell are generated. The histogram is accumulated for every impulse fired by the first cell. When two neighboring ON-center cells are so paired, a large central peak in firing rate for the second ON cell is seen (Fig. 41, red, left). A similar pattern is seen when two OFF cells are recorded (Fig. 41, blue right). In both cases, increased firing rate represents an increased likelihood that if one cell fires, the other will also. Impulse generation in the two cells is not independent. The cells share common excitatory inputs sources and are likely to be simultaneously excited. There is symmetry about the zero time axis. This is consistent with the idea that the cells share one or more common excitatory inputs, and that either one may respond first.

When an OFF cell and an ON cell are simultaneously recorded, the situation is different. There is a large central trough in the firing rate from the second cell (Fig. 14, center, magenta). When one cell fires a spike, the other is inhibited from firing, regardless of whether it is the ON cell that fires or the OFF. There appear to be common, spontaneously active inputs for both cells, inhibitory for one while excitatory for the other. Symmetry about the time zero axis suggests that in fact two symmetric inputs are required: one inhibiting the ON cell while exciting the OFF cell, and the other exciting the ON cell while inhibiting the OFF cell. Physiologically, ON and OFF ganglion cell mosaics are not independent then. Mutual inputs are found. Such inputs occur, however, only for

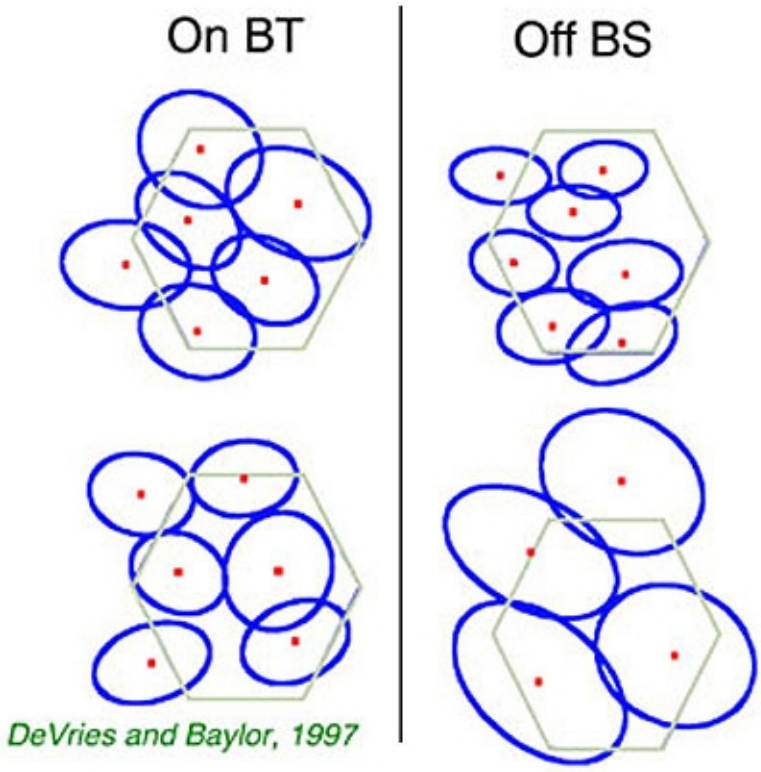

Figure 39. Gaussian receptive field borders of neighboring, simultaneously recorded, rabbit retinal ganglion cells. Mosaics of ON brisk transient cells (On BT) or OFF brisk sustained cells (Off BS) are spaced about 2 Gaussian radii apart. Elliptical profiles (blue) are at 1 Gaussian radius from receptive-field centers (red squares). The gray hexagon outlines the borders of the multi-electrode recording array. After DeVries and Baylor (7).

cells with overlapping, or partially overlapping, receptive fields, as is also the case for paired ON or paired OFF cells (75).

In the illustration (Fig. 41), the events induced the altered firing probability to last 10 msec or less. These were described as arising from spontaneously active inputs, best observed in moderately light-adapted preparations (75). As progressively dimmer backgrounds were used, other cross-correlations with longer durations (50 msec or longer) were observed. These were associated with quantum detection by rods (69). Finally, shorter duration events were also observed and appeared associated with direct electrical interconnections between neighboring cells of the same center response polarity (76). There appear to be multiple mechanisms of different temporal duration leading to synchronization of firing among neighboring cells.

Among the multiple mechanisms of different temporal duration leading to synchronization of firing among neighboring cells, even some of the longer duration cross-correlations between neighboring ganglion cells appear also to be mediated by electrical junctions.

Three cross-correlation patterns of different durations were identified among salamander ganglion cells, narrow (0-1 msec), medium (10-50 msec), and broad (50-100 msec). Broad correlations were blocked by cadmium chloride-containing medium, but narrow and medium correlations were not (Fig. 42). Cadmium chloride blocks calcium-dependent synaptic transmission, making it very likely that both narrow and medium time correlations were mediated by other means, such as electrical junctions. Direct electrical connections among ganglion cells may mediate narrow correlations, similar to cat retina, whereas medium correlations may result from electrical coupling between amacrine and ganglion cells. Waves of slow potentials passing through the amacrine layer may stimulate multiple ganglion cells by this mechanism. The cadmium-sensitive broad correlations appear to result, at least in part, from photoreceptor photon noise (77), as in the cat.

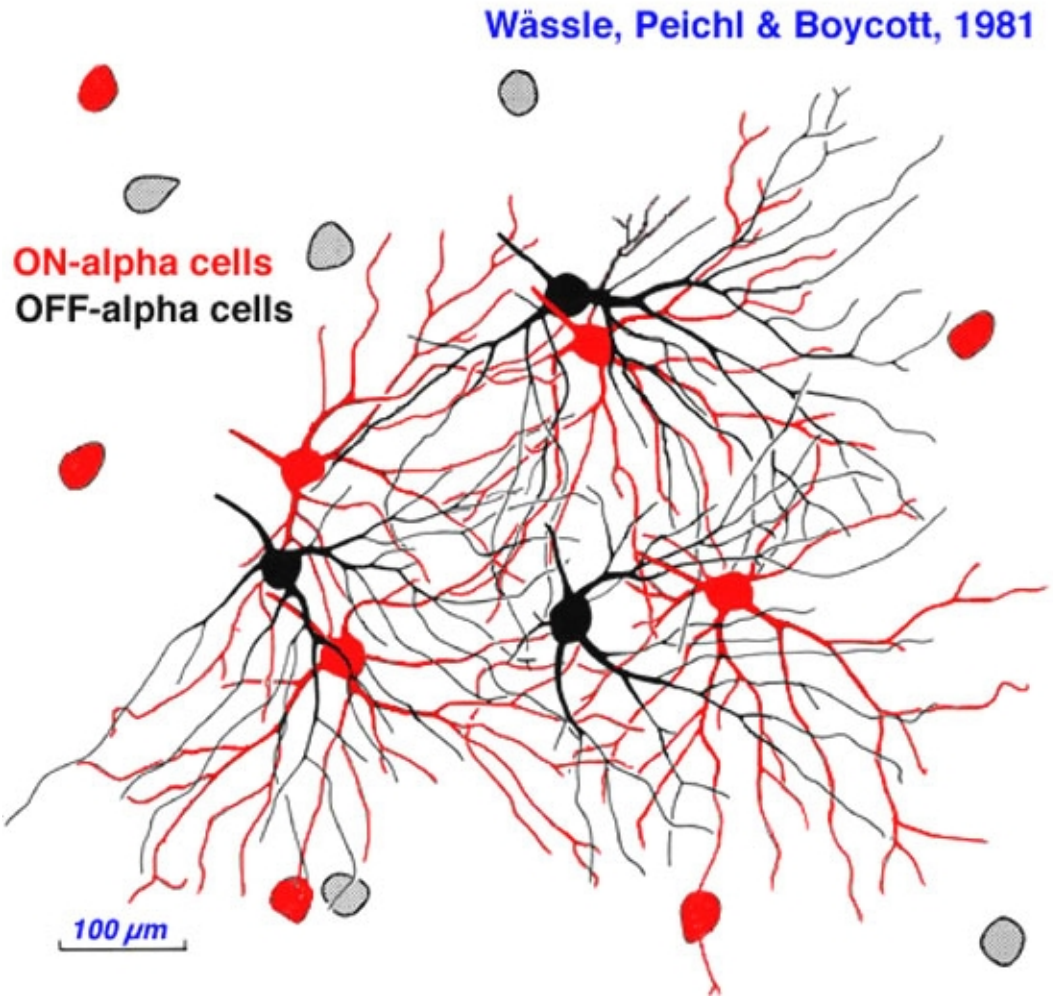

Figure 38. HRP-filled ON- and OFF-center alpha cell mosaics in cat retina.

Only time-invariant background stimulation was used in the previous two studies. When localized flashing stimuli are used, a further cross-correlation pattern emerges. Oscillatory firing patterns become entrained among cells responding to a contiguous stimulus.

Ganglion cells develop a high frequency (~100 Hz) oscillatory firing pattern when presented with localized bright stimuli. This is seen in autocorrelation functions (black, Fig. 43). These functions show that the probability of a second ganglion cell impulse depends, in a periodic way, on the firing of a previous impulse in the same cell. If stimuli are spatially separate (left, Fig. 43), the oscillatory firing patterns in the two cells are independent. However, if the stimulus covers the area between the two cells, oscillatory patterns in each cell become entrained with each other. This is seen in an oscillatory cross-correlation function in the two cells firing patterns for this stimulus (right, Fig. 43). This is a long-range effect. The two ganglion cells need not have overlapping receptive fields. It is a longer distance phenomenon than reported for other cross-correlation patterns in ganglion cell firing. It likely involves gap junctions among ganglion or amacrine cells (78).

Neurotransmitter Receptors and Synaptic Currents

Ganglion cells are tiny, information processing, neural machines. They extract features of the visual world, encode them in frequency-modulated spike trains, and send them coursing along optic nerve axons to various visual brain centers. The first step in this process is the binding of amacrine and bipolar cell neurotransmitters onto specialized receptor proteins embedded in ganglion cell dendritic membrane. These receptor molecules are

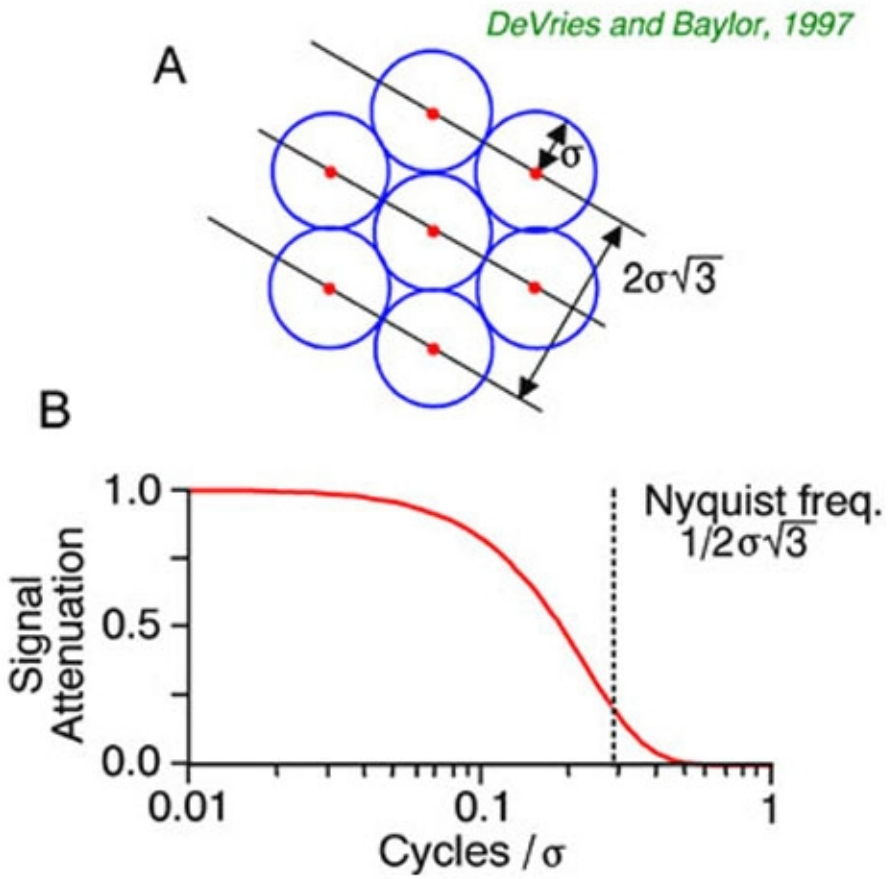

Figure 40. Spatial resolution of a ganglion cell mosaic. A. Receptive field centers are found spaced approximately one Gaussian radius (Greek sigma) apart. Presumptive hexagonal packing of receptive fields on the surface leads to to the indicated Nyquist frequency limit. B. Spatial integration within the receptive field attenuates high spatial frequencies and limits aliasing. After DeVries and Baylor (7).

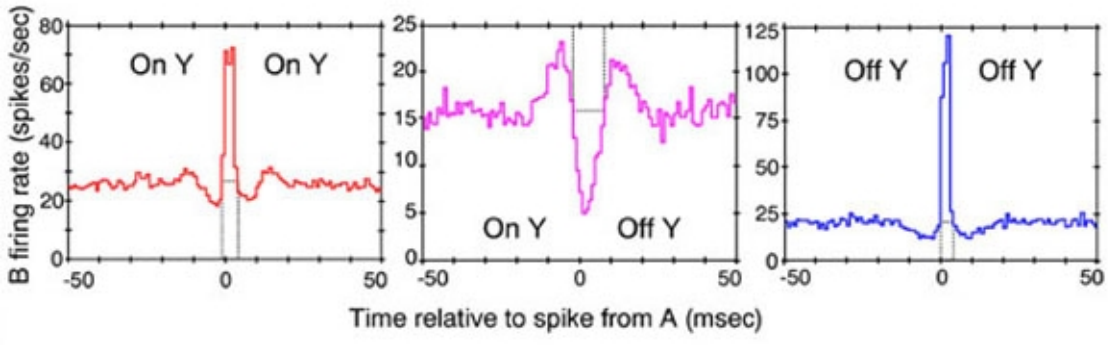

Figure 41. Correlations in the firing pattern of simultaneously recorded, neighboring Y-cells in cat retina. Firing rate histograms are generated for cell B, referenced to the points in time (0 msec) when cell A fires an impulse. Patterns are generated from spontaneous activity in the presence of a steady mesopic background. After Mastronarde (75).

concentrated at sites of synapses with amacrine and bipolar cells. Once the neurotransmitter is bound, ion-selective channels, a kind of micropore in the subsynaptic membrane, open. Charged ionic species rush through these channels, driven by electrochemical gradients. As a consequence, current flows into the cell, altering

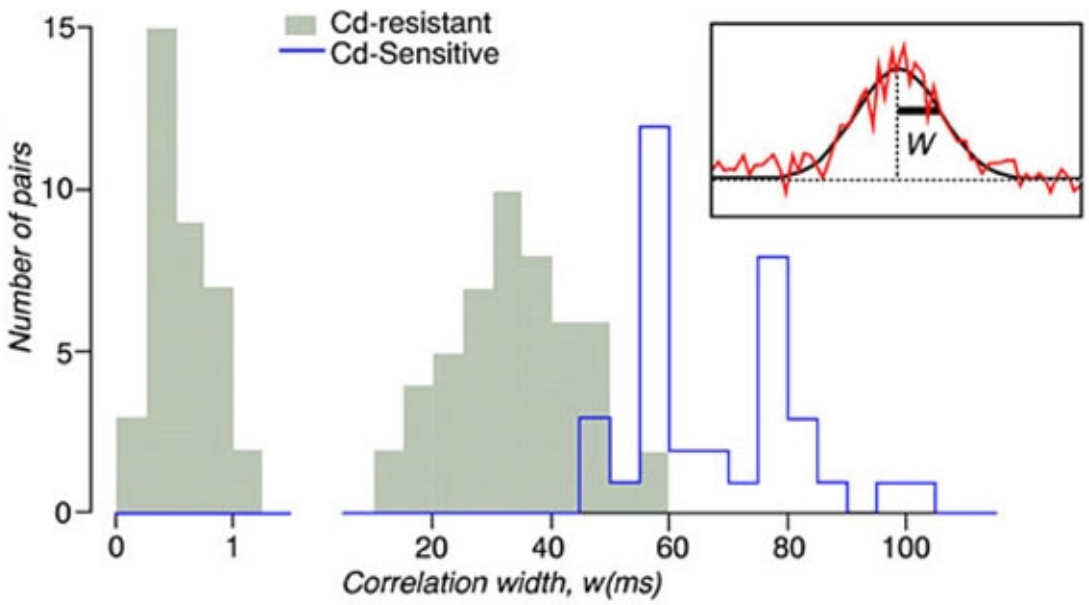

Figure 42. Both chemical and long time scale electrical interactions contribute to cross-correlations among retinal ganglion cells. Cross-correlations generated from recordings with multielectrode arrays in salamander, fit by Gaussians of standard deviation W (inset), are categorized as to the time scale of the correlation (W) and as to cadmium sensitivity. After Brivanlou et al. (77).

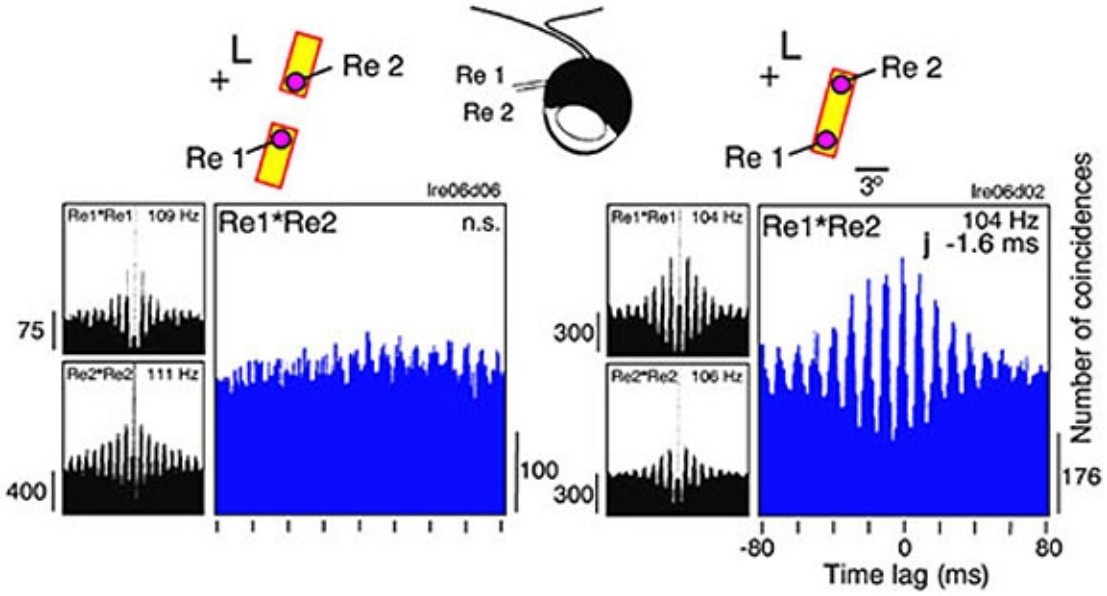

Figure 43. When stimuli cover the area between ganglion cells, oscillatory patterns become entrained. Re1 and Re2 denote two ON-type retinal ganglion cells with receptive fields separated by 6 degrees. Autocorrelation functions (black) and cross-correlation functions (blue) are shown for spatially separate (left) and spatially contiguous (right) stimuli in cat retina. After Neuenschwander and Singer (78).

membrane potential. These synaptic currents, through a complex interplay of dendritic structure and other potential-sensitive ion channels (79), alter ganglion cell firing rates and convey visual signals to the brain.

There are eight synaptic ion channel associated retinal neurotransmitter receptors. Such receptors are referred to as "ionotropic". Glutamate, the most common excitatory neurotransmitter, activates three distinct channels: AMPA-type channels, kainate-type channels, and NMDA-type channels. Acetylcholine is another excitatory neurotransmitter active at nicotinic receptors. Excitatory receptors are associated with channels selective for positively charged ionic species, monovalent or divalent cations. When open, they allow positive charges to enter neurons, depolarizing them and exciting impulse firing. GABA and glycine are inhibitory ionotropic neurotransmitters. GABA activates two distinct ionotropic receptor types: the bicuculline-sensitive $GABA_A$ receptor and the bicuculline-insensitive $GABA_C$ receptor. Bicuculline is a convulsant, and a common blocker of GABA inhibitory action. GABA and glycine open channels selective for the negatively charged chloride anion, which hyperpolarizes neurons and inhibits impulse firing. In teleost fish retinas, a further inhibitory, chloride-selective channel present in bipolar cells has been found activated by glutamate. All of these ionotropic receptors are heteropolymers composed typically of five subunits. There are multiple alleles of these subunits, allowing for considerable heterogeneity in receptor composition and details of function.

Retinal ganglion cells respond to all common excitatory or inhibitory retinal neurotransmitters. When neurotransmitters are applied to the solution that bathes ganglion cells, membrane currents are induced. AMPA, kainate (Fig. 44) or NMDA evoke excitatory currents in both ON- and OFF-type cat beta cells (80). NMDA currents are of the typical "conditional" sort, dominant only if cells are depolarized first by other excitatory neurotransmitters, or in the absence of extracellular magnesium (Fig. 45). Extracellular acetylcholine also excites retinal ganglion cells (80-84).

When the bath is applied, inhibitory retinal neurotransmitters GABA and glycine potently evoke inhibitory currents in ganglion cells. GABA receptors in cat beta cells are of the "A" type. These responses can be largely blocked by the GABA-antagonist bicuculline. Strychnine effectively blocks glycine-evoked currents (80).

Ganglion cell membranes appear to be broadly tuned to receive signals from many neurotransmitter systems. Rather than being neurotransmitter selective, they limit input of information from amacrine and bipolar cells by selective synaptic connections. Thus, it is important to study the properties of responses evoked by natural photic stimulation to determine which of the available transmitter systems in the retinal inner plexiform layer are actually used. In extracellular impulse recordings, metabotropic glutamate receptors were shown important for the ON-center circuit in cat alpha and beta ganglion cells, whereas both these receptors and glycine receptors were found important for OFF alpha and beta cells (85). To determine whether either of these systems operates directly on the ganglion cell itself, it is necessary to measure light-evoked conductance changes in intracellular ganglion cell recordings.

Central illumination of an ON-center ganglion cell depolarizes the cell membrane. Much of the normally inside-negative resting potential is lost. The action excites nerve impulse activity. There is an increase in membrane conductance with a reversal potential near 0 mV, typical of an open ion channel selectively permeable to cations. This synaptic mechanism causes light responses to increase in amplitude as the cell is hyperpolarized by extrinsic current. The picture is consistent with the activation of ionotropic glutamate receptors permeable to sodium, potassium, and perhaps calcium ions (86, 87). In the cat ON-beta ganglion cell (Fig. 46), reversal potentials were found to shift to more negative values over the time course of the response. This appears to result from delayed activation of inhibitory synaptic currents with negative reversal potentials. Such inhibition arises in part from the receptive field surround but also may be intrinsic to the center mechanism. A simple circuit involving excitatory ionotropic glutamate impingement from narrow field bipolar cells, and a more protracted GABAergic and/or glycinergic input from broader field amacrine cells, serves to model such results. ON-center ganglion cells may receive tonic inhibitory input in the dark as well (86) (Fig. 47).

Central illumination of OFF-center ganglion cells hyperpolarizes the cell membrane. The normally inside-negative cell potential increases in magnitude. This action reduces nerve impulse activity and causes the cell to become quiet. Concomitantly, there is an increase in membrane conductance with a reversal potential more

negative than the resting potential. This is typical of the opening of channels selectively permeable to the chloride anion (86). A simple circuit involving narrow-field GABA- or glycine-releasing amacrine cells, which are themselves excited by light, serves to model the OFF-center response.

The neural circuits of ON- and OFF-center ganglion cells appear asymmetric. One might have expected the activity of OFF-center cells to be diminished in the light principally through loss of excitatory input from OFF-center bipolar cells. Yet, it is amacrine inhibition that appears key to the physiology of these cells. There is evidence of excitatory input from bipolar cells at stimulus offset. At this point in time, there is a burst of action potentials driven by excitatory, depolarizing synaptic input. This appears to be the role for glutamate released from OFF bipolar cells onto OFF-center ganglion cells. There may also be a low level of dark excitation of these cells contributed by OFF-center bipolar cell input (86). There is, as yet, little evidence concerning synaptic mechanisms involved in the excitatory surround responses of these cells.

Ganglion Cells That Are Involved in the Circadian Clock

Certain large-field, sparsely-branching ganglion cell types are known to project to the hypothalamic suprachiasmatic nucleus (SCN) in the brain (Fig. 49). The latter nucleus is the primary circadian oscillator in mammals and is essentially the biological clock, allowing reseting of bodily functions to local time. The ganglion cells involved in entraining the circadian clock project from the eye to the SCN via the retinohypothalamic tract (RHT) (Fig. 48). They apparently contain the neuropeptide pituitary adenylate cyclase activating polypeptide (PCAP), as well as glutamate. They receive input in the inner plexiform layer from amacrine cells and cone bipolar cell axons (88). These ganglion cells are now known to contain a photoreceptive pigment—melanopsin—in their dendrites, proximal axons, and cell membranes and are thus intrinsically photreceptive. In other words, they do not need the input of rods and cones to activate them to light; they can signal, luminance levels at least, independently of the photoreceptor bipolar chain of input (89, 90). The responses of these melanopsin ganglion cells are slow, sluggish depolarizations in contrast to the faster hyperpolarizing responses of rods and cones (Fig. 50). They are probably the equivalent ganglion cells to those described by Barlow and Levick (91) as luminance units in 1969 and described by Pu (92) in 1999, both in cat retina. The action spectrum of the melanopsin ganglion cells appears to be attributable to an opsin-like pigment, but it is most sensitive at 484 nm compared with rods at 500 nm and cones at 510 (green cones) and 359 nm (UV cones) in the mouse (89) (Fig. 50).

The melanopsin ganglion cels are also thought to be involved in the pupillary light reflex for they also project to the lateral geniculate nucleus through the olivary pretectal nucleus (OPN) and on to the Edinger Westaphal nucleus (EW) for control of the pupillary light reflex (Fig. 48, light blue pathway).

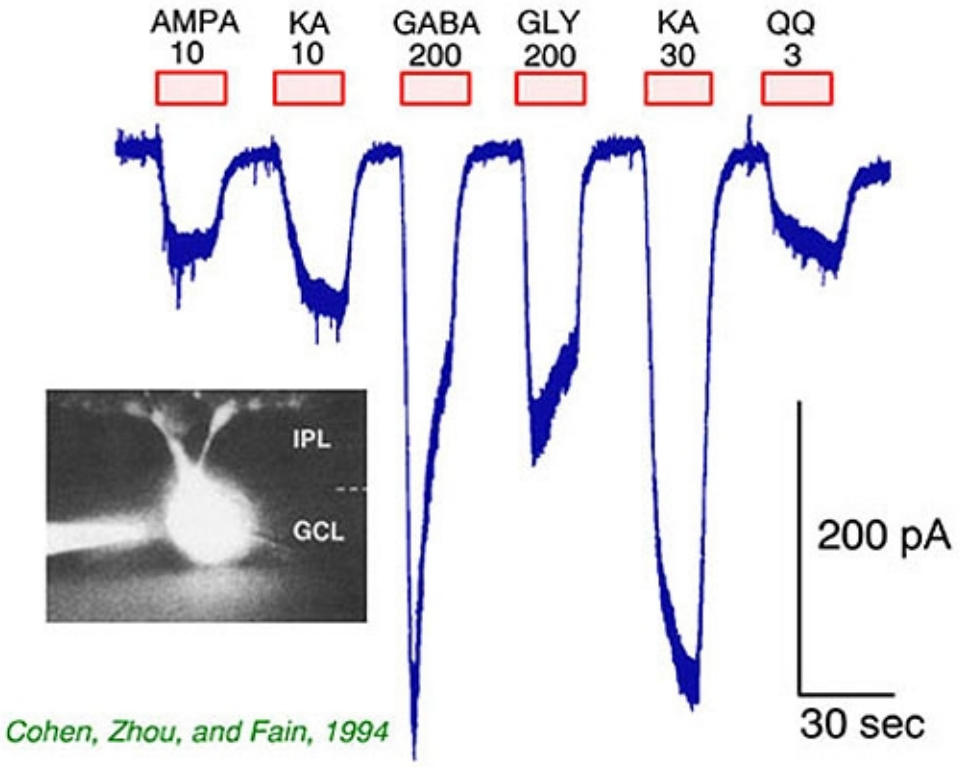

Figure 44. Membrane currents evoked by excitatory or inhibitory neurotransmitters applied to a cat OFF beta type ganglion cell. The cell (seen in the inset together with recording electrode) was studied in a retinal slice. GABA and glycine (GLY) activate inhibitory neurotransmitter receptors. AMPA (alpha-amino-3-hydroxy-5-methylisoazole-4-propionic acid), kainic acid (KA), and quisqualic acid (QQ) activate glutamatergic excitatory receptors. Numbers give doses in mM. Release of endogenous neurotransmitter has been blocked by cobalt. After Cohen et al. (80).

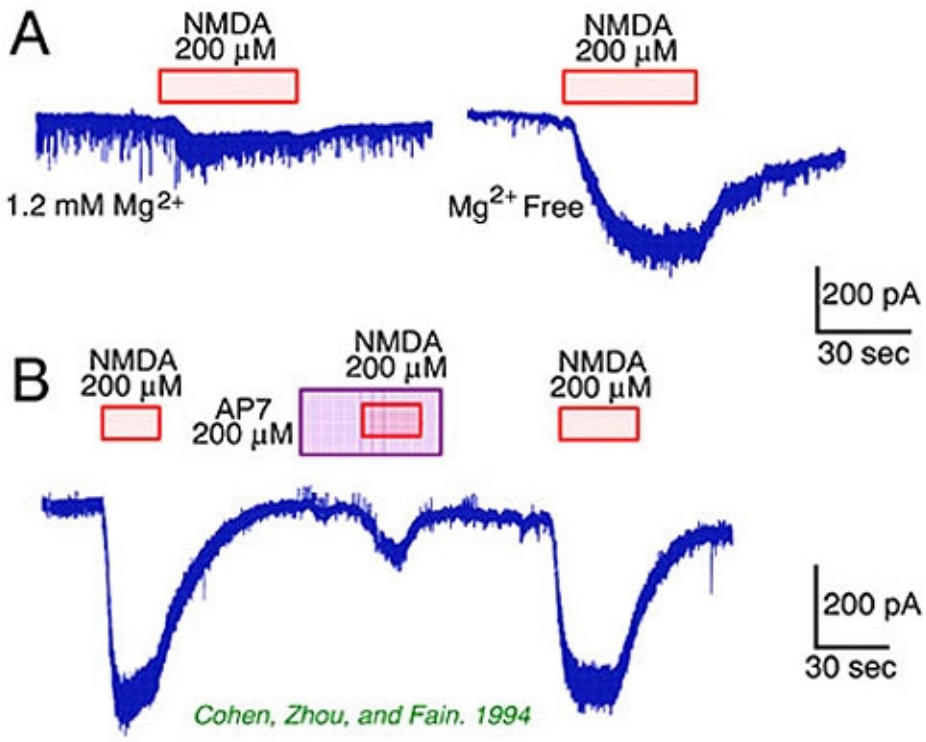

Figure 45. N-methyl-D-Aspartate (NMDA) activates an excitatory glutamate receptor in a cat ON beta ganglion cell (A) or OFF beta ganglion cell (B). Responses are conditional on either the absence of magnesium ions in the medium (A) or depolarized membrane potentials. They can be reversibly blocked (B) by the NMDA receptor antagonist 2-amino-7-phosphonoheptanoic acid (AP7). After Cohen et al. (80).

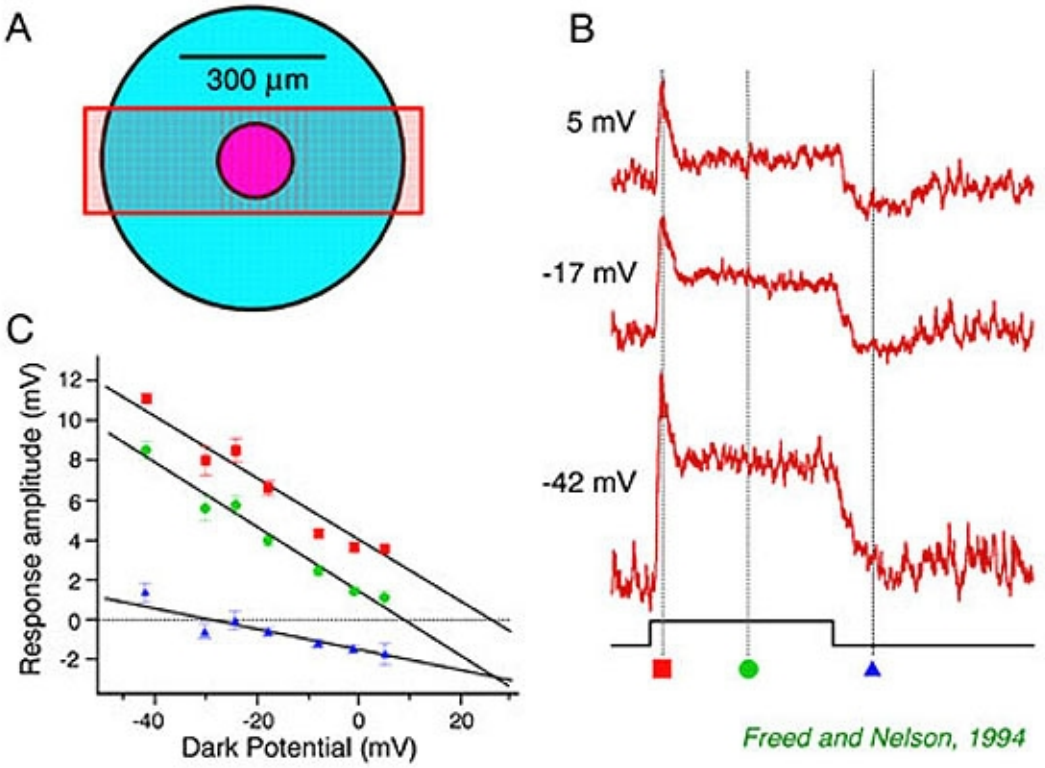

Figure 46. Properties of light-evoked synaptic voltages in ON-center cat beta ganglion cell. A. Slit stimulus covers the center (inner circle) and part of the surround (outer circle) of the receptive field. B. Depolarizing, excitatory responses become larger and more sustained as the ganglion cell is hyperpolarized by extrinsic current. C. Reversal potential of the light responses becomes progressively more negative over time but always exceeds the dark potential. After Freed and Nelson (87).

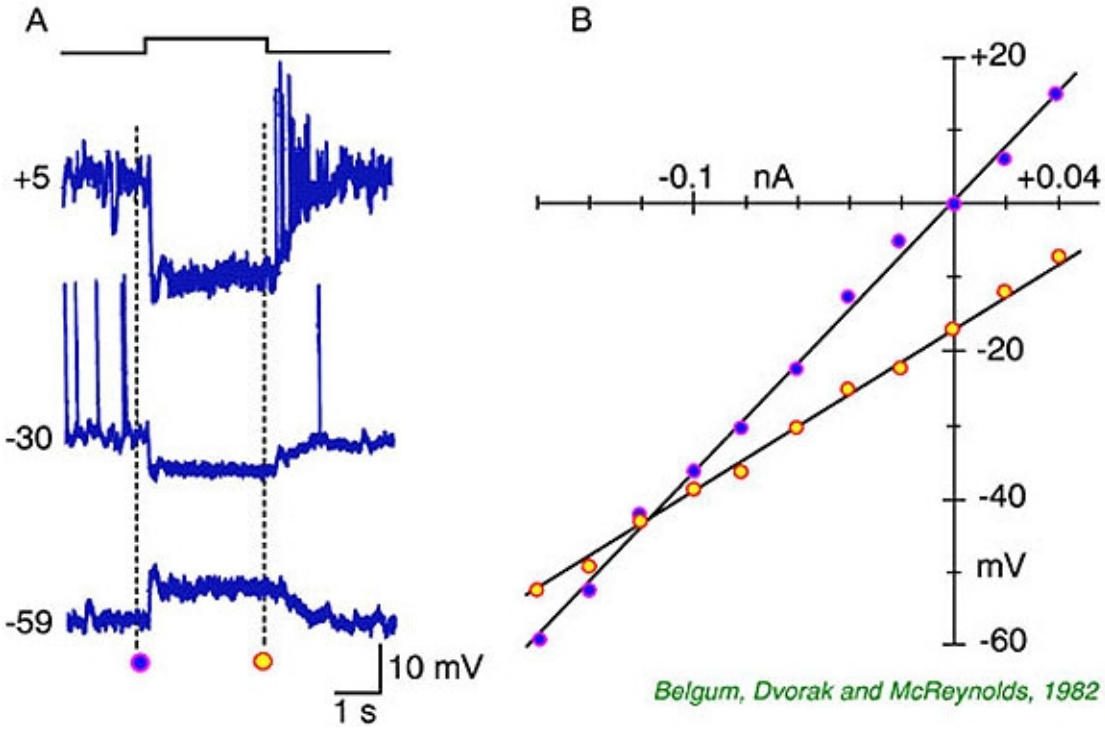

Figure 47. Properties of light-evoked synaptic voltages in OFF-center mudpuppy ganglion cell. A. Hyperpolarizing, inhibitory responses become larger as the cell is depolarized by extrinsic current. B. Reversal of the light response occurs at voltages more negative than the dark potential. After Belgum et al. (86).

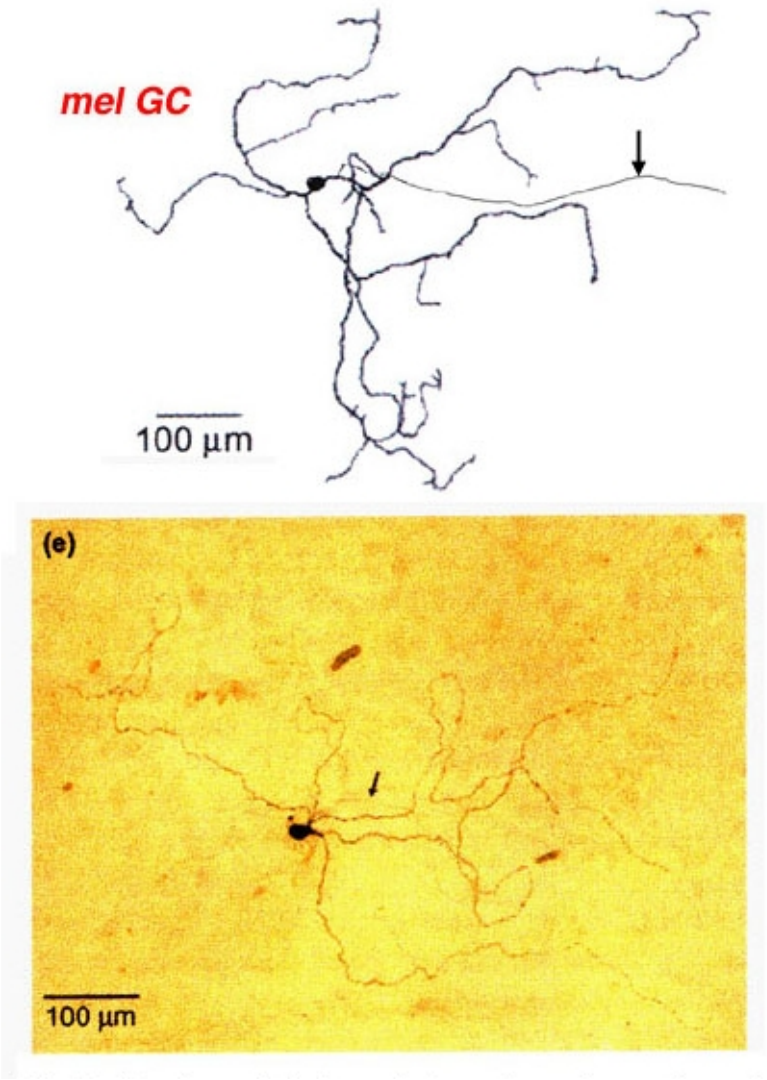

Figure 49. Drawing and photograph of a melanopsin ganglion cell in whole-mount mouse retina. The axon is indicated by an arrow. After Berson (89).

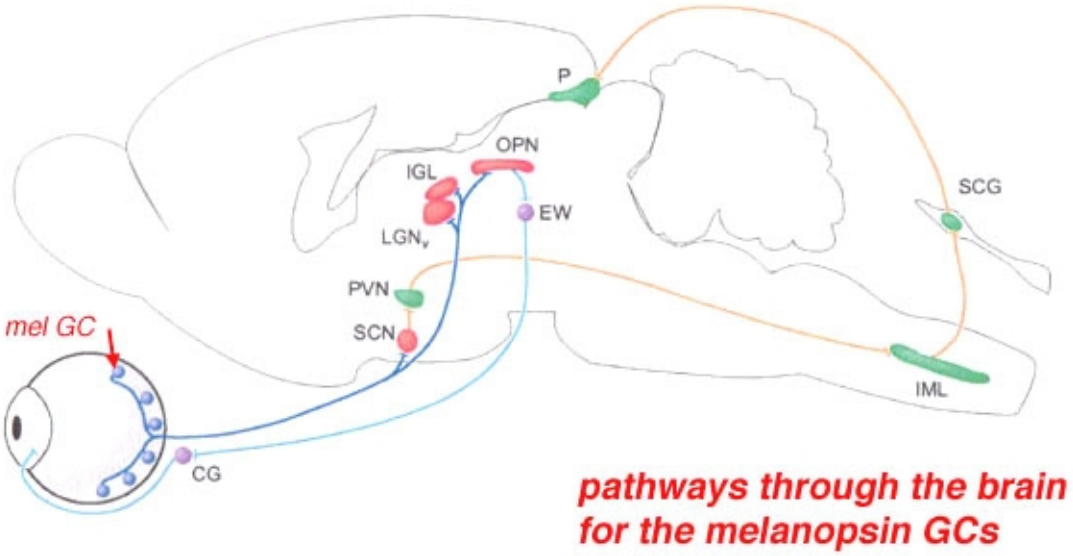

Figure 48. Diagram of the pathways taken by melanopsin ganglion cells to the brain. The pathway is to the suprachiasmatic nucleus (SCN) via the retinohypothalamic tract (blue) and on to the pituitary to regulate melatonin release. This circuit drives the circadian oscillator. A second pathway is through the lateral geniculate nucleus to the olivary pretectal nucleus (OPN) and to the Edinger Westaphal nucleus (EW) for control of the pupillary light reflex (light blue). After Berson (89).

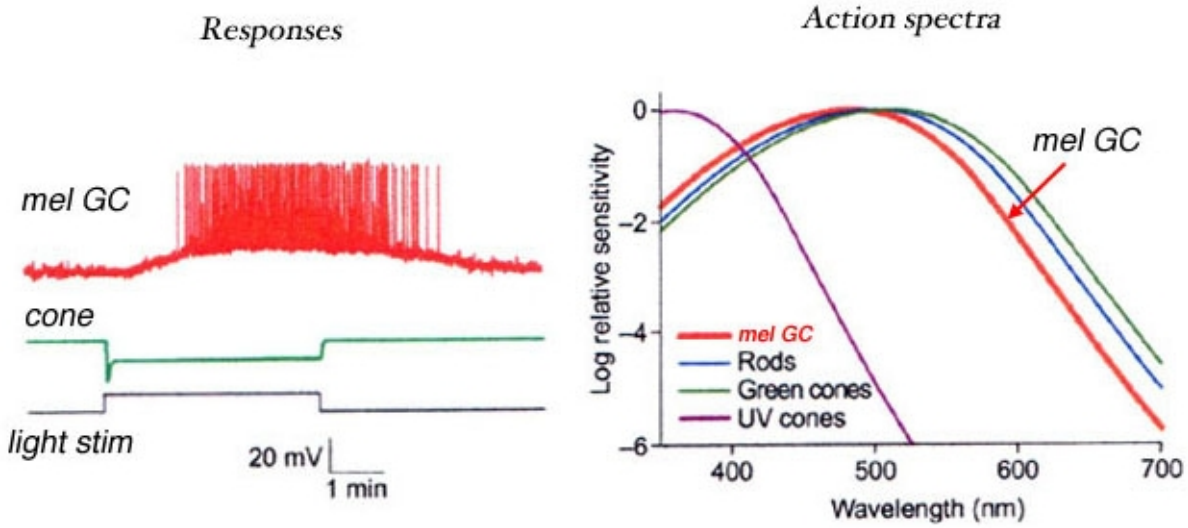

Figure 50. The physiological responses of melanopsin ganglion cells to light. The response on the left shows the melanopsin cell's slow onset, steady-state depolarizing spiking that occurs to a light flash as compared with the slow but faster onset hyperpolarization of the green cones in the mouse retina. The action spectra to the right show the melanopsin ganglion cell to have a peak sensitivity to light of 484 nm, compared with the rods and other cone types in the mouse. After Berson (89).

Melanopsin-expressing, Intrinsically Photosensitive Retinal Ganglion Cells (ipRGCs)

Dustin M. Graham, Ph.D.[1,*] and Kwoon Y. Wong, Ph.D.[2,†]

Created: August 1, 2008; Updated: November 2, 2016.

1. Introduction

For the greater part of 150 years it was assumed that the mammalian retina contained only two classes of photoreceptors, rods and cones. However, a flurry of studies in the late 1990s and early 2000s demonstrated the existence of a third class of mammalian photoreceptors that differs greatly from rods and cones. It utilizes a different photopigment, is much less sensitive to light, responds to light far more slowly, and has far lower spatial resolution, characteristics that fit with its primary function of signaling ambient light levels (irradiance) to the brain. Most surprisingly, these photoreceptors are retinal ganglion cells (RGCs), and thus, have the unique ability to communicate directly with higher visual centers of the brain. These intrinsically photosensitive retinal ganglion cells (ipRGCs) are a rare subpopulation of ganglion cells (<5%) whose primary role is to signal light for largely subconscious, non-image-forming visual reflexes, such as pupillary constriction, neuroendocrine regulation, and synchronizing daily ("circadian") physiological rhythms to the light/dark cycle ("circadian photoentrainment"). Recent research has revealed additional roles for ipRGCs in conscious visual perception, including brightness discrimination and contrast detection. Many visual behaviors under ipRGC control are remarkably tonic, and require prolonged integration of ambient light levels. The unique properties of ipRGCs make them well suited for regulating such behaviors.

2. History and discovery

As a graduate student in 1923, Clyde Keeler made a number of interesting observations from mice that had severe outer retinal degeneration (1, 2). Though they lacked most of their rod and cone photoreceptors, and were considered functionally blind, these mice were still able to constrict their pupils in response to light (3), leading Keeler to deduce that some other photoreceptive cells must be lurking in the retina. But an alternative, more parsimonious explanation for these pupil reflexes was that they were driven by the small number of surviving cone photoreceptors, and so the existence of non-rod non-cone photoreceptors remained uncertain. Seven decades later, Russell Foster and colleagues engineered mice that lacked all rods and cones, which displayed not only robust pupillary light reflexes, but also maintained the ability to shift their circadian rhythms in accordance with shifting light cycles, and to suppress nocturnal pineal melatonin secretion in response to light pulses (4, 5). [Recent work detected a very small number of ultraviolet cones in these mice (6), but they were unlikely to be stimulated by the 509 nm stimuli used in the Foster studies.] These processes disappeared, however, when animals had their eyes removed, strongly supporting Keeler's prediction of a novel ocular photoreceptor (7). But it wasn't until the discovery of a new light-sensitive molecule (or opsin), from an unlikely source, that Keeler's prediction would prove true.

Iggy Provencio and colleagues, studying the photosensitive skin cells ("dermal melanophores") of frogs, cloned a novel opsin-like molecule which they proposed was responsible for the redistribution of skin pigment in response to light (8). Orthologues of this putative opsin, which Provencio et al. called melanopsin, were also found to be expressed in a small subset of RGCs in mouse (Figure 1A) and human retinas (8-10), and additional work found that melanopsin-containing cells send their axons to the suprachiasmatic nucleus (SCN), the site of the mammalian central circadian clock (11, 12).

These findings suggested that these RGCs could be the mysterious third photoreceptor type Keeler had predicted almost 80 years earlier. They express a putative opsin, potentially allowing them to directly respond to light, and they send axon projections to a brain target known to be involved in two of the visual reflexes observable in rodless/coneless mice, i.e. circadian photoentrainment and photic suppression of pineal melatonin release. However, definitive proof that these melanopsin-containing, SCN-projecting RGCs could directly sense light was still lacking. Combining tracer injections into the SCN with electrophysiology, David Berson and colleagues tested the hypothesis that SCN-projecting RGCs are photoreceptive. They made whole-cell recordings from RGCs retrogradely labeled by the tracers (Figure 1B), and found that these cells were indeed able to respond to light in the presence of a cocktail of drugs that eliminated all rod and cone signaling in the retina (Figure 1C, *top*) (13). Even after mechanical isolation from the rest of the retina, these cells were still photosensitive (Figure 1C, *bottom*), leaving to rest all doubts that the labeled RGCs were true photoreceptors (13). Immunohistochemistry performed after whole-cell recording confirmed the presence of melanopsin in these SCN-projecting cells (14). The morphology and distribution of these SCN-projecting ipRGCs are illustrated in Figure 2.

3. Melanopsin

We now know that the ability of ipRGCs to respond directly to light is indeed due to expression of melanopsin. The melanopsin gene (opn4) has been found in many mammalian species, e.g. mice, monkeys, and humans (9). Hydrophobicity analysis of melanospin's amino-acid sequence predicted a 7-transmembrane structure, common to all G protein-coupled receptors (Figure 3A, B) (8). Interestingly, melanopsin shares higher homology with the rhabdomeric opsins (r-opsins) of invertebrate photoreceptors than with the ciliary opsins (c-opsins) of vertebrate photoreceptors, suggesting that melanopsin could signal light through a different phototransduction mechanism than that used in vertebrate rods and cones (Figure 3C) (8) (see "Phototransduction" below).

Although the first studies of ipRGCs implicated melanopsin as the photopigment in these cells, a role for a group of blue-light-absorbing flavoproteins known as cryptochromes could not be initially ruled out (15). Cryptochromes function as photopigments in plants and invertebrate animals, and early studies favored their functioning as retinal photopigments in the mammalian circadian system (16, 17). However, subsequent work provided overwhelming evidence that melanopsin is the photopigment in ipRGCs. When the melanopsin gene was deleted via transgenic techniques in mice ("melanopsin-knockout mice"), RGCs retrogradely labeled from the SCN no longer could respond directly to light (18). In addition, animals missing the melanopsin gene showed deficiencies in multiple visual reflexes such as pupillary constriction and photoentrainment (18-22). Despite this evidence, there were still controversies regarding melanopsin's ability to function as a photopigment. For example, it remained possible that melanopsin is not the ipRGC photopigment, but is instead an isomerase essential for the proper functioning of the ipRGC photopigment. These doubts were firmly extinguished with a series of experiments whereby the melanopsin gene was heterologously expressed in multiple cell types that are normally insensitive to light. When made to express melanopsin, these cells were able to robustly respond to light, indicating melanopsin's ability to function as a bona fide photopigment (23-25).

4. Phototransduction

As seen in Figure 4, the intrinsic light response of ipRGCs differs dramatically from those of rods and cones. Most notable, is the difference in response polarity: the direct photoresponse of ipRGCs is depolarizing, whereas rods and cones hyperpolarize to light. In addition, ipRGCs are much less sensitive to light than the classical photoreceptors, and signal with far slower kinetics (Figure 4A) (13, 26). IpRGCs are also capable of very long-lasting light responses, faithfully encoding stimulus energy over relatively long periods of time (Figure 4C). This feature sets ipRGCs apart from all other mammalian RGCs, which cannot stably represent ambient light levels in this fashion (27-29). Another remarkable feature of ipRGC physiology is the ability of their dendrites (which contain melanopsin) to respond directly to light (13). Combined with their large overlapping dendritic fields, the entire ipRGC population creates what Provencio and colleagues called a “photoreceptive net” (10). These

characteristics of ipRGCs are no doubt tailored to their role in signaling diffuse ambient light levels over many hours for tonic, non-image-forming visual behaviors such as photoentrainment and pupillary reflex. A further distinction of ipRGCs is their action spectrum (i.e. wavelength-sensitivity function), due to the utilization of melanopsin as their photopigment. IpRGC photoreception is most sensitive to light at around 480 nm (13, 30, 31), significantly different (≥20 nm) from the best wavelengths for stimulating rods and cones (Figure 4B).

As noted earlier, animal photoreceptors come in two basic flavors: rhabdomeric (found mainly in invertebrates), and ciliary (vertebrate rods and cones being most notable). A defining feature of rhabdomeric and ciliary photoreceptors is the distinct biochemical cascades both cell classes use to transduce light energy into an electrical signal the brain can interpret. Rods and cones use a cascade involving cyclic guanosine monophosphate (cGMP) as a second messenger (Figure 5B) (32, 33). The response to light is a decrease in cGMP levels which closes cGMP-gated cation channels, causing the plasma membrane to hyperpolarize. This is in stark contrast to rhabdomeric photoreceptors which use a phosphoinositide signaling cascade involving the

enzyme phospholipase C (PLC) and breakdown of the membrane lipid phosphatidylinositol bisphosphate (PIP2) (Figure 5A), leading to the opening of cation channels and membrane depolarization (34, 35). In addition, although both phototransduction cascades are G protein-mediated, the specific G proteins required are different. Ciliary photoreceptors require transducin, a member of the Gi/o family of G proteins, whereas rhabdomeric photoreceptors use a G protein of the Gq/11 family (Figure 5).

Just like rod and cone photopigments, melanopsin uses *11-cis*-retinal as the light-absorbing chromophore, and light-induced isomerization of *11-cis*-retinal to *all-trans*-retinal is the first step in the phototransduction process (36, 37). However, melanopsin's relatively high homology with invertebrate opsins, and the depolarizing intrinsic light response of ipRGCs, suggest these neurons may use a rhabdomeric phototransduction cascade distinct from the rod and cone ciliary cascade. Early pharmacological studies of ipRGCs could not confirm this hypothesis, most likely due to the whole-mount retina preparation employed. The combination of photosensitive ipRGC dendrites buried deep within the inner plexiform layer (IPL, where synapses are formed among bipolar, amacrine and ganglion cells) and a glial membrane sheath covering the retinal surface, created a significant diffusion barrier for pharmacological agents, especially hydrophobic drugs commonly used to study transduction mechanisms. To overcome this hurdle, David Berson and colleagues recorded from mechanically dissociated ipRGC somas to facilitate pharmacological manipulation. Isolated ipRGCs survive remarkably well in culture, generating robust light responses for up to 6 days. Using this system, Berson et al. showed that ipRGC

phototransduction utilizes a rhabdomeric-like phosphoinositide cascade, requiring a member (or possibly members) of the Gq/11 family of G proteins and the effector enzyme phospholipase C (PLC) (Figure 6) (38) (but see(39)). In addition, the presence of specific Gq/11 and PLC isoforms was confirmed in ipRGCs using single-cell RT-PCR and immunocytochemistry, consistent with the pharmacological findings (38). Genetically knocking out the β4 isoform of PLC nearly eliminated the intrinsic light response of ipRGCs (40).

In rhabdomeric photoreceptors, breakdown of PIP2 by PLC generates two by-products: a membrane-bound component called diacylglycerol (DAG), and inositol-triphosphate (IP3), which is free to move about the cytosol (34). DAG can be broken down within the membrane into polyunsaturated fatty acids (PUFAs), which have been shown to directly open Drosophila photoreceptors' Transient Receptor Potential (TRP) channels (41). IP3, on the other hand, can cause release of Ca^{2+} from intracellular stores, which can lead to the opening of so-called "store-operated channels" in the plasma membrane. In Drosophila photoreceptors the downstream mechanism linking PIP2 breakdown to TRP channel opening is still unclear, although a membrane-associated pathway is likely (42). In ipRGCs, the light-gated cation channels are also TRP channels, specifically, TRPM6 and TRPM7 (40), and data strongly suggest that the cytosolic IP3 pathway is not required for phototransduction, similar to Drosophila photoreceptors (Figure 7) (38). Intracellular application of high concentrations of IP3 neither induced a current, nor did it occlude light responses in ipRGCs (Figure 7A), although it did modulate certain response properties, suggesting a non-essential secondary role for IP3 and intracellular Ca^{2+}. Likewise, ipRGC phototransduction survived blockade of IP3 receptors with intracellular heparin, or intracellular Ca^{2+} store depletion using thapsigargin (Figure 7A). Only after extended exposure to very high (10mM) concentrations of the general Ca^{2+} chelator BAPTA, does one see significant attenuation of phototransduction (38), although this is probably a side effect of clamping resting intracellular Ca^{2+} levels so low that enzymes such as PLC are no longer able to function (43). The most compelling evidence that ipRGC phototransduction does not require the cytosolic IP3 branch is that excised patches of ipRGC membrane (both outside-out and inside-out) remained autonomously photosensitive (Figure 7B), ruling out a vital role for highly diffusible cytosolic components (38). Based on these findings, all the necessary components for ipRGC phototransduction appear to be within, or tightly coupled to, the plasma membrane.

The exact channel-gating mechanism downstream of PLC activation is still not clear. Application of DAG or PUFAs, either to isolated ipRGC somas or to excised patches of ipRGC membrane, failed to evoke a current or to block light responses (Figure 8A-D). An alternative hypothesis, and one in line with a membrane-associated transduction cascade, is that the breakdown of PIP2 itself (as opposed to production of DAG or PUFAs) is the critical signal that opens the light-gated TRP channels in ipRGCs. There is evidence that PIP2 can either open or close a variety of ion channels, including the light-gated channels in Drosophila photoreceptors (44, 45). As a preliminary test of this hypothesis, Berson et al. pharmacologically interfered with PIP2 synthesis using wortmannin. This drug inhibits phosphoinositide 4-kinase (PI4-K), the synthetic enzyme for phosphatidylinositol 4-phosphate (PIP), which is an essential precursor of PIP2. According to the hypothesis, wortmannin should slow the termination of the photocurrent at light offset by delaying the restoration of resting levels of PIP2 and, hence, the closure of the light-gated channels. Indeed, when wortmannin was included in the recording pipette solution, response shutoff was dramatically delayed (Figure 8E). Further and more direct evidence, however, is needed to resolve the gating mechanism of the light-modulated channels in ipRGCs.

Following light exposure, *all-trans*-retinal in a rod, cone or ipRGC photopigment must be isomerized back to *11-cis*-retinal to make the photopigment photoexcitable again (46). For rhodopsin, this re-isomerization requires the adjacent retinal pigment epithelium (RPE), while cone pigments rely on Müller glial cells in addition to the RPE (47). In contrast, photoexcited melanopsin appears to retain *all-trans*-retinal and isomerize it to *11-cis*-retinal upon subsequent photon absorption, in a process called photoreversal (48-52). Thus, melanopsin can function as both photopigment and photoisomerase, similar to some invertebrate photopigments, and ipRGCs remain directly light-sensitive when RPE enzymes that synthesize *11-cis*-retinal are genetically or

pharmacologically inhibited (53, 54). Nevertheless, without these enzymes, the melanopsin-based light response of ipRGCs is attenuated, suggesting that melanopsin function depends on the RPE to some extent (37, 55).

5. Synaptic input

Although ipRGCs can function as photoreceptors, they nevertheless receive intraretinal synaptic input from rod/cone-driven circuits. Electron microscopy revealed synaptic contacts made by amacrine and bipolar cells onto melanopsin-immunopositive processes in the IPL (56). Thus, ipRGCs respond to light not only directly through melanopsin, but also indirectly through synaptically mediated input from rods and cones (27, 30, 57-59). Both the intrinsic light response and the extrinsic, rod/cone-driven light response are remarkably tonic and can signal light continuously for at least 10 hours (28). Moreover, the receptive fields for both response components are coextensive with each ipRGC's dendritic field (27). However, these components are drastically different in two important ways. Firstly, whereas the intrinsic photoresponse is very sluggish, the extrinsic response is as rapid as the light responses of conventional RGCs (Figure 9) (27). The intrinsic response integrates photons over many seconds, while the extrinsic response enables ipRGCs to track rapid changes in light intensity (26, 27, 60). Secondly, the intensity thresholds for rod input, cone input and melanopsin phototransduction are vastly different, roughly 7 log photons cm^{-2} s^{-1}, 9 log photons cm^{-2} s^{-1} and 11 log photons cm^{-2} s^{-1}, respectively (30, 58). The different dynamic ranges of synaptic input and intrinsic photoreception enable ipRGCs to encode light intensities spanning at least 9 orders of magnitude (30).

Using whole-cell voltage-clamp recordings combined with pharmacology, investigators demonstrated that SCN-projecting ipRGCs have spontaneous inhibitory and excitatory synaptic inputs in the dark, and that they express receptors for glutamate, GABA and glycine (27, 57). Light stimulation increases both excitatory glutamatergic input and inhibitory GABA/glycinergic input, which are presumably mediated by bipolar and amacrine cells, respectively (27). Both inputs evoke primarily ON light responses, although comparatively weak OFF responses can also be seen under some conditions (27, 58, 61). This predominating ON-channel input was surprising because SCN-projecting ipRGC dendrites are found mainly in the distal half of the IPL, which had been assumed for decades to be the "OFF" sublamina where RGCs receive input only from OFF bipolar cells but not ON bipolars (62, 63). ON bipolar cells use two unconventional strategies to release glutamate onto the dendrites of SCN-projecting mouse ipRGCs in the "OFF" sublamina. Some ON bipolar cells' axons extend lateral protrusions that contain synaptic vesicles (Figure 10A), whereas others possess *en passant* (in passing) synaptic vesicles within their axonal shafts (64). Distally stratifying ipRGCs are also present in rabbit, marmoset and macaque retinas, and they likewise receive unconventional ON bipolar input in the "OFF" sublamina (Figure 10C) (65, 66).

The mammalian retina contains about a dozen types of bipolar cells and over 30 types of amacrine cells (67, 68). In mice, the ON bipolar cells that use axonal side branches to contact "OFF"-sublamina ipRGC dendrites appear to be type-6 cone bipolar cells (Figure 10A) (64). Trans synaptic viral tracing has shown that these "OFF"-sublamina ipRGC dendrites are also directly postsynaptic from dopaminergic amacrine cells which costratify with these ipRGC dendrites (69). As will be discussed in detail in "Adaptation, neuromodulation, and circadian control", ipRGCs receive modulatory input from dopaminergic amacrine cells (70, 71). Trans synaptic viral tracing also revealed that proximally stratifying mouse ipRGCs with dendrites in the "ON" sublamina (see "Morphological and physiological diversity") are directly postsynaptic from type-8 ON cone bipolar cells and another type of monostratified amacrine cell (Figure 10B) (69). In rabbits and primates, distally stratifying ipRGCs are contacted by a type of calbindin-positive ON cone bipolar cell (Figure 10C) (65) and DB6 ON cone bipolars (Figure 10D) (66), respectively. Besides receiving direct ON cone bipolar input, ipRGCs also receive ON rod bipolar input, albeit polysynaptically just like for all other mammalian RGCs (59, 66). Specifically, ipRGCs receive ON rod bipolar input through AII amacrine cells making gap junctions onto ON cone bipolar cells, which then synapse on ipRGCs. Another putative pathway that affects ipRGCs may be added by centrifugal fibers entering the retina. These centrifugal fibers are known to be histaminergic (72) and they have an effect on

dopaminergic amacrine cells in mouse retina through H1 receptors (73). The synaptic input to "OFF"-stratifying ipRGCs is summarized in Figure 11.

6. Intraretinal synaptic output

Besides receiving intraretinal synaptic input, ipRGCs mediate intraretinal synaptic output. For many decades, RGCs were thought to function strictly as retinal output neurons, signaling only to higher visual centers of the brain. But there is electron microscopy evidence that RGC dendrites are presynaptic in catfish (74), and more recent work by Douglas McMahon and coauthors yielded evidence that ipRGCs signal to a subpopulation of dopaminergic amacrine cells (DA cells). Dopamine released by DA cells diffuses throughout the retina and reshapes the functional properties of retinal circuits according to current lighting conditions and time of day, and thus allows the retina to be a more dynamic system (75). DA cells come in three flavors showing transient, sustained and null responses to light (76). The light responses of the transient DA cells were eliminated by L-AP4, which blocks rod/cone signaling to ON bipolar cells (Figure 12A). By contrast, the sustained DA cells remained light-responsive in the presence of L-AP4 (Figure 12B), or in rod/cone degenerate retinas (77). In the presence of L-AP4, the sustained DA cells' light responses peaked at a wavelength near 480nm (Figure 12C),

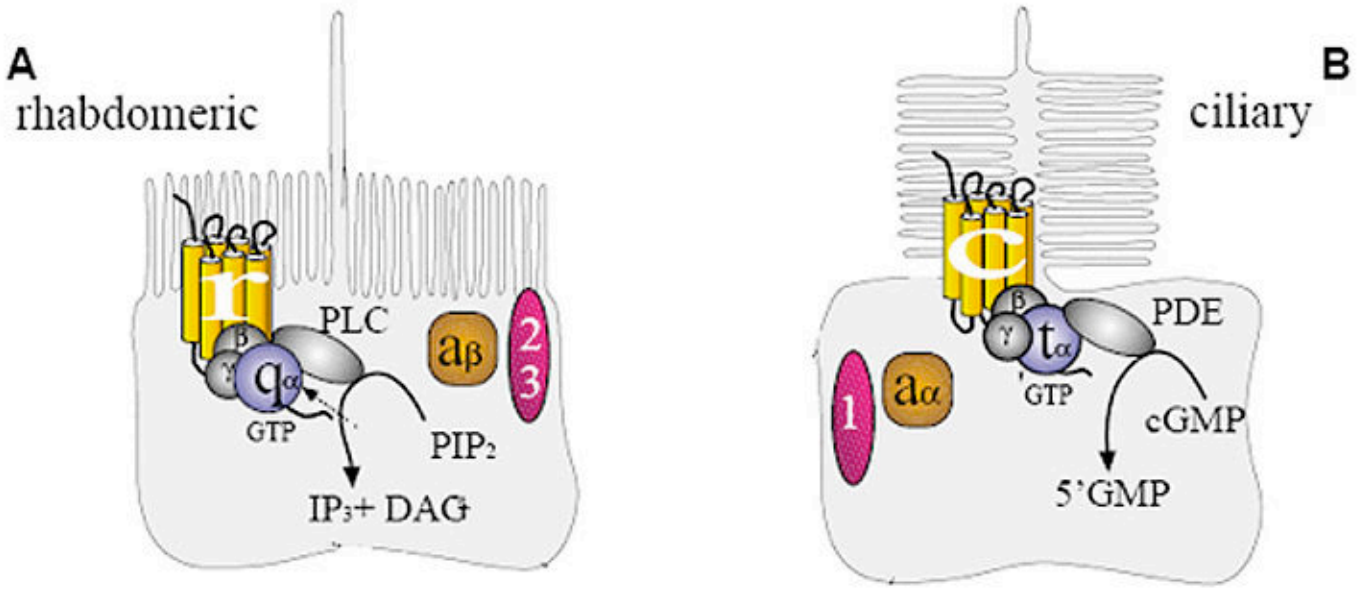

Figure 5. Schematic representation of the phototransduction cascades in (A) rhabdomeric photoreceptors and (B) ciliary photoreceptors. Adapted from Arendt 2003 (32).

matching very well with a melanopsin-based input (76, 77). In melanopsin-knockout mice, blocking ON bipolar input with L-AP4 abolished all DA cells' light responses, confirming that the L-AP4-resistant photoresponse originates from ipRGCs (78).

In addition, staining for cFos, an immediate early gene used to mark activated neurons, showed that roughly the same percentage of DA cells were activated by sustained light in rod/cone degenerate retinas as retinas injected with L-AP4 (Figure 13) (77). Knocking out melanopsin suppressed light-induced dopamine release (79). These observations strongly suggest that sustained DA cells receive input from ipRGCs. Both DA cells and SCN-projecting ipRGCs have dendrites stratifying in the outermost sublayer of the IPL, raising the possibility that these ipRGC dendrites signal directly to the DA dendrites (69, 70). Another plausible transmission route has been suggested by the observation that some ipRGCs extend axon collaterals toward the IPL (Figure 14) (80). In support of the latter possibility, blocking voltage-gated Na^+ channels (which are present in RGC axons) with tetrodotoxin suppressed ipRGC signaling to DA cells (81). Antagonizing AMPA/kainate receptors also disrupted ipRGC output to DA cells (78), suggesting ipRGCs signal to DA cells by releasing glutamate in a Na^+ spike-dependent manner.

IpRGC signaling to sustained DA cells can account for the light-induced secretion of dopamine in rat retinas with severe rod/cone degeneration (82, 83) (but see(84)). Because dopamine is known to play myriad modulatory roles throughout the retina, intraretinal output from ipRGCs to DA cells could influence image-forming retinal circuits, and several studies have reinforced this possibility. Using a non-invasive field-potential recording technique called the electroretinogram, Mark Hankins and Rob Lucas found that prolonged nocturnal light exposure altered the photoresponse kinetics of ON bipolar cells in human subjects (Figure 15). This effect exhibited a remarkably long integration time and was most optimally induced by 483 nm light, implicating a melanopsin-based mechanism (85). The same researchers later observed diurnal rhythms in the amplitude and kinetics of the mouse electroretinogram, which were abolished upon knocking out melanopsin (86). Additional evidence for ipRGC regulation of retinal function came from a study by Ouria Dkhissi-Benyahya et al. examining clock gene expression in rods and cones. In wild-type mice, the expression of these clock genes

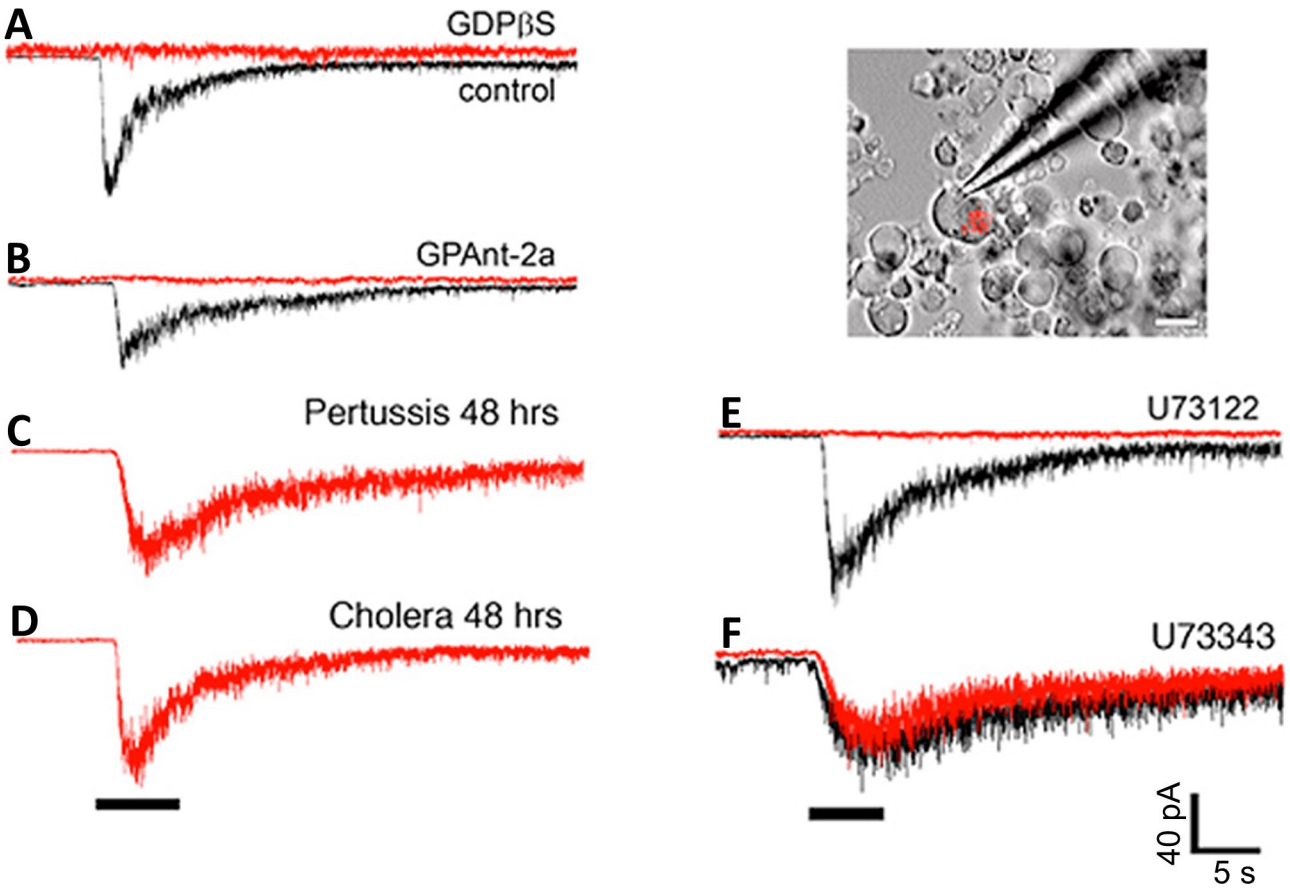

Figure 6. Invertebrate-like phosphoinositide phototransduction cascade in ipRGCs, elucidated through whole-cell recordings from dissociated rat ipRGCs. (A) GDPβS, a general G protein blocker, completely abolished the light response in ipRGCs (red trace), indicating a G protein-coupled cascade. (B) The specific Gq/11 family G protein blocker GPAnt-2a completely blocked the light response in ipRGCs (red trace), while 48-hour incubation in toxins disrupting (C) Gi/o-family G protein signaling and (D) Gs-type G protein signaling did not block the light response. (E) Consistent with a Gq/11- and PLC-mediated cascade, the PLC blocker U73122 completely blocked the light response (red trace), while the inactive analog U73343 (F) had no effect, indicating the effect of U73122 is specific. Inset is a picture of an isolated rat ipRGC in culture during a typical patch-clamp recording; red dots within the cell are due to the tracer dye retrogradely transported from the SCN. Adapted from Graham et al. 2008 (38).

(which are thought to drive circadian rhythms within the retina) exhibits a daily rhythm, but when melanopsin was knocked out, this rhythm was dampened substantially (79).

Ca^{2+} imaging suggested an additional potential pathway for intraretinal signaling by ipRGCs. Under normal physiological conditions, about 3% of ganglion cell layer (GCL) cells in rodless coneless mouse retinas showed increases in Ca^{2+} dye signals in response to light, but in the presence of the gap junction blocker carbenoxolone, this percentage dropped to ~1%, leading the authors to propose that ipRGCs propagate their light responses to amacrine cells in the GCL ("displaced amacrine cells") via gap junctions (87). But this conclusion was challenged by subsequent research showing that carbenoxolone has various non-specific effects, and can abolish light-driven increases in Ca^{2+} signals even in mechanically dissociated ipRGCs (88). Nonetheless, tracer dye coupling between ipRGCs and displaced amacrines had been observed (89), and so gap-junction-mediated intraretinal signaling by ipRGCs remained a possibility. A recent study showed that rat ipRGCs indeed transmit their melanopsin-based light responses to displaced amacrine cells (90). Whole-cell recordings were made from >2,000 randomly targeted displaced amacrine cells to search for cells exhibiting spiking, sustained ON light responses, and 154 such cells were encountered. Surprisingly, all of them were still photosensitive during bath

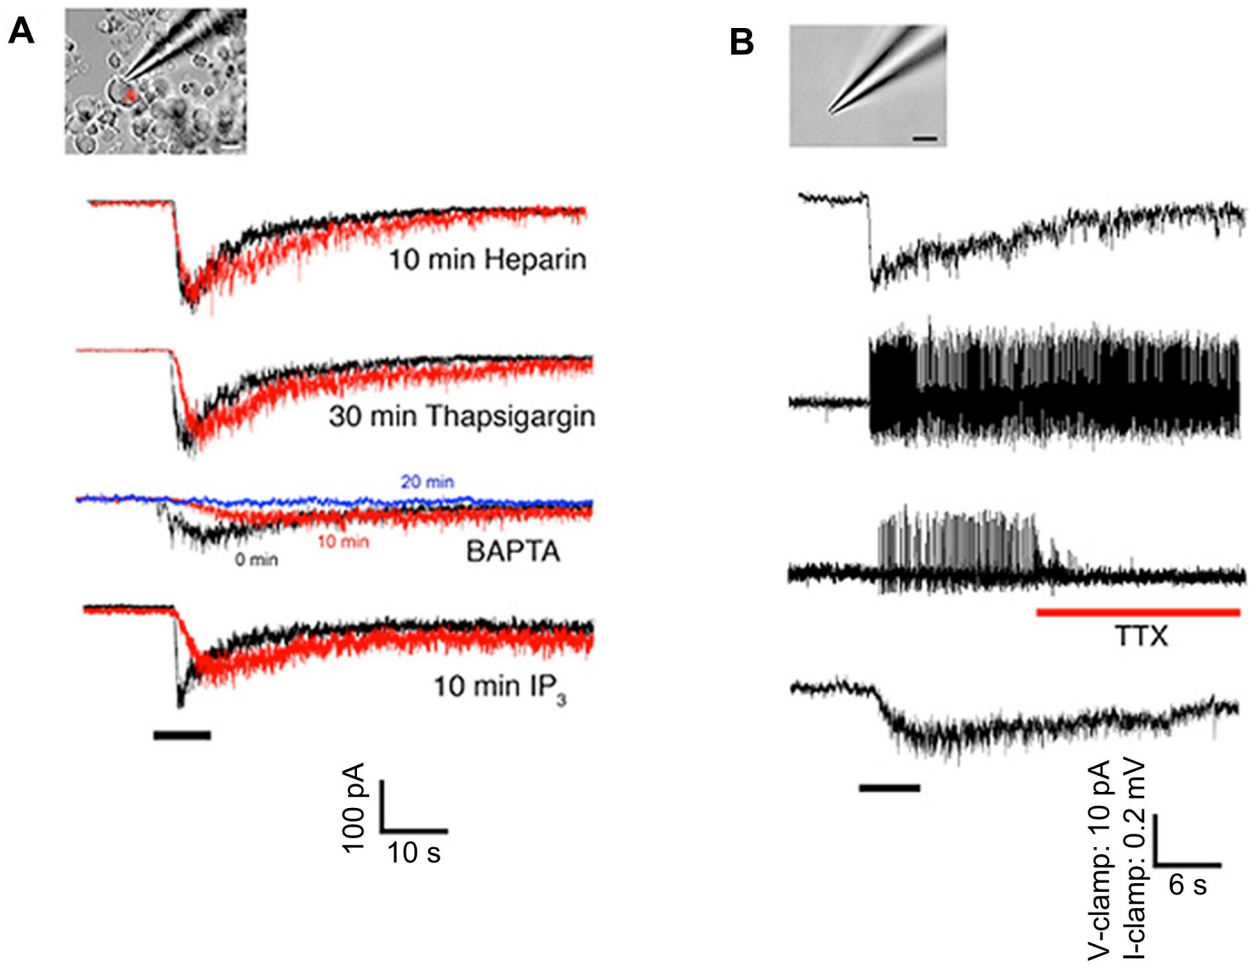

Figure 7. Evidence for a membrane-associated phototransdcution cascade in ipRGCs. (A) Whole-cell patch-clamp recordings from dissociated rat ipRGCs. Voltage-clamp traces showing control light responses (black traces) and light responses after 10-minute (red traces) and 20-minute (blue trace) application of various agents to block the cytosolic IP3-related branch of the phosphoinositide signaling cascade. (B) Light responses from excised patches of ipRGC membrane. Top two traces are voltage-clamp (top trace) and current-clamp (second from top trace) recordings from an inside-out patch of ipRGC membrane. The bottom two traces are current-clamp (second from bottom trace) and voltage-clamp (bottom trace) recordings from outside-out patches of ipRGC membrane. Note the cessation of spiking activity in response to applied TTX (second to bottom trace) indicating the spikes are due to voltage-gated Na+ channels. Stimulus light timings are indicated by the horizontal black bars. Adapted from Graham et al. 2008 (38).

application of L-AP4, DNQX and D-AP5, which fully block rod/cone signaling to the inner retina. In the presence of these drugs, all 154 amacrines gave sluggish depolarizing light responses resembling ipRGCs' intrinsic light responses, but they lost all photosensitivity after the addition of the gap junction blocker meclofenamic acid, indicating that ipRGCs signal to these amacrines via gap junctions (90).

7. Morphological and physiological diversity

The SCN-projecting rat and mouse ipRGCs appear to be morphologically homogeneous, suggesting they constitute a single cell type (but see(91)). All such cells have somas medium in size among GCL neurons and sparse dendrites terminating in the outermost sublayer ("S1") of the IPL, corresponding to the main plexus of melanopsin-immunoreactive dendrites (Figure 16A-C, G) (12-14). However, a number of studies from the early 2000s implicated the existence of multiple types of ipRGCs. For example, there is an additional plexus of melanopsin-positive dendrites in the innermost sublayer ("S5") of the IPL (10). Ca^{2+} imaging and "blind"

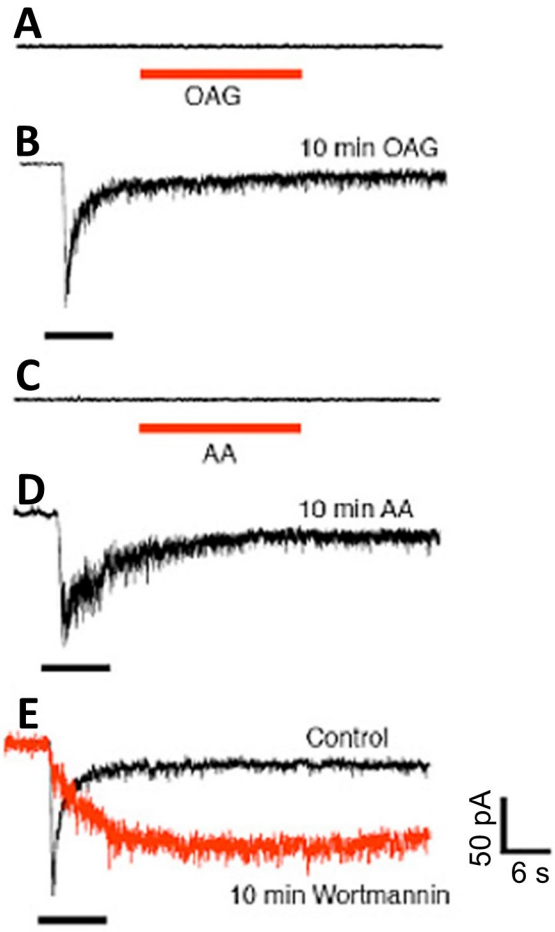

Figure 8. Possible gating mechanism for the light-modulated channels in ipRGCs. (A) The DAG analogue OAG did not induce a current in ipRGCs when applied from a puffer pipette, (B) nor did it block the light response after prolonged bath application at high concentrations. (C) The polyunsaturated fatty acid arachidonic acid (AA) did not induce a current in ipRGCs when applied via puffer pipette, (D), nor did it block the light response when bath-applied for prolonged periods. (E) Wortmannin significantly delayed post-illumination ipRGC response recovery (red trace) compared with control cells (black trace), suggesting PIP2 breakdown itself may be the gating mechanism of the light-modulated channels in ipRGCs. Adapted from Graham et al. 2008 (38).

multielectrode-array extracellular spike recording also revealed diverse melanopsin-mediated light responses in the GCL (31, 87). Using various fluorescent labeling techniques, subsequent work revealed the existence of at least at least five morphological types of melanopsin-expressing ipRGCs in the mouse retina. The SCN-projecting type originally described by David Berson is now called "M1", whereas the new types are called M2, M3, M4 and M5 (69, 92, 93). Examples of mouse M2 cells are shown in Figure 16D-F, H. By whole-cell-recording from a large sample of randomly selected RGCs, all five morphological types of ipRGCs were also found in the rat (94); representative examples are shown in Figure 17. Among these ipRGC types, M1 is the only one that stratifies exclusively in S1 of the IPL. M3 is the only bistratified type, extending dendrites toward both S1 and S5. The remaining ipRGC types are all monostratified in S5, with M2 having relatively sparse dendrites, M4 having denser and radiate dendrites similar to the previously described alpha cell (95, 96), and M5 having the densest dendrites covering the smallest fields (Figure 17).

The five types of ipRGCs exhibit diverse physiological properties, suggesting they perform different functions. In both mouse and rat, the five ipRGC types spike spontaneously at different frequencies (58, 94). The various types of mouse ipRGCs also differ significantly in various basic biophysical properties such as membrane resistance,

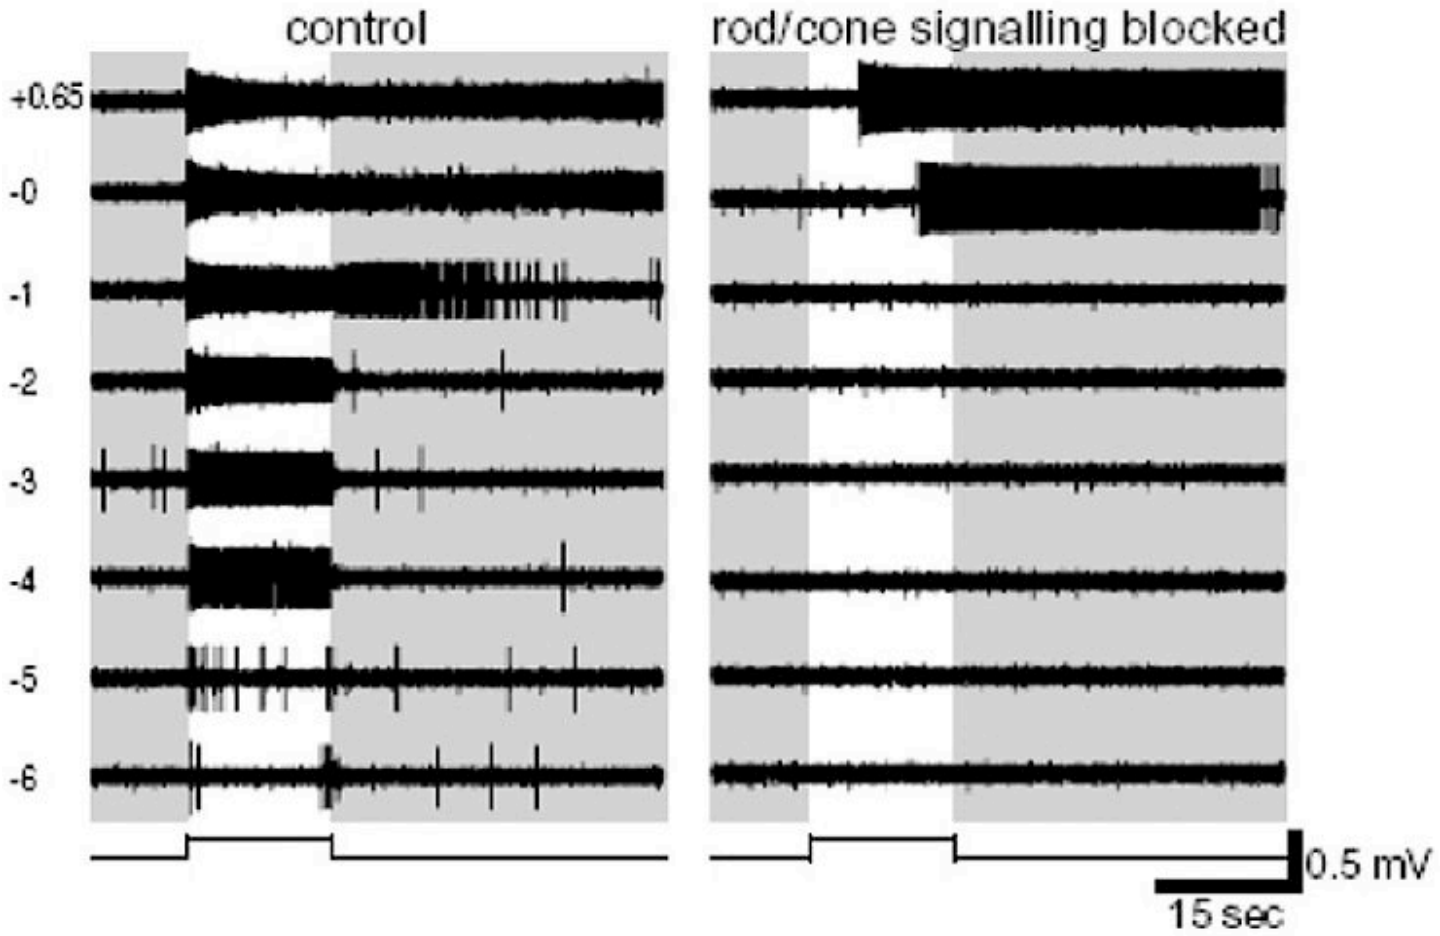

Figure 9. Extracellular spike recording of a rat ipRGC using an electrode in a multielectrode array. Note how the long-lasting and relatively insensitive intrinsic melanopsin-driven component becomes obvious at increasing illumination levels (left traces) and can easily be isolated using pharmacological blockade of rod/cone-driven input (right traces). Adapted from Wong et al. 2007(27).

membrane capacitance, Na^+ spike waveform, Na^+ spike threshold, and voltage-gated Ca^{2+} and K^+ currents (97, 98). Under dark-adapted conditions, the five mouse ipRGC types respond fairly similarly to full-field light, generating sustained depolarizing responses that last for the duration of the light (58). Under light-adapted conditions, however, M1's and M2's cone-driven full-field light responses are significantly different, with the former's responses being far more transient and much lower in amplitude (61). Diversity was also observed in the various cell types' responses to moving lights, and to light spots of different sizes, even under dark-adapted conditions. All five cell types responded more strongly to moving lights than to static lights; however, different cell types appeared tuned to different speeds of motion (Figure 18A).

Furthermore, whereas M1's receptive field consists of just an ON-center region, the non-M1 ipRGCs' receptive fields display ON-center/OFF-surround antagonism, so that a large light spot illuminating the entire receptive field induces a weaker response than a smaller spot covering just the center region (Figure 18B) (58). Under conditions blocking rod/cone signaling, the five types of rat and mouse ipRGCs generate melanopsin-based light responses that differ in kinetics, amplitude, and threshold, with M1 cells' intrinsic photoresponses being the fastest, largest, and most sensitive (Figure 19) (58, 93-95, 97).

Besides mice and rats, many other species that have been examined also possess multiple morphological and/or physiological types of ipRGCs, although it is unknown whether these other species also have five ipRGC types. In primates including humans, only two morphological types of melanopsin-expressing RGCs have been documented (Figure 20). Both cell types have giant somas and sparse, monostratifying dendrites. The outer-

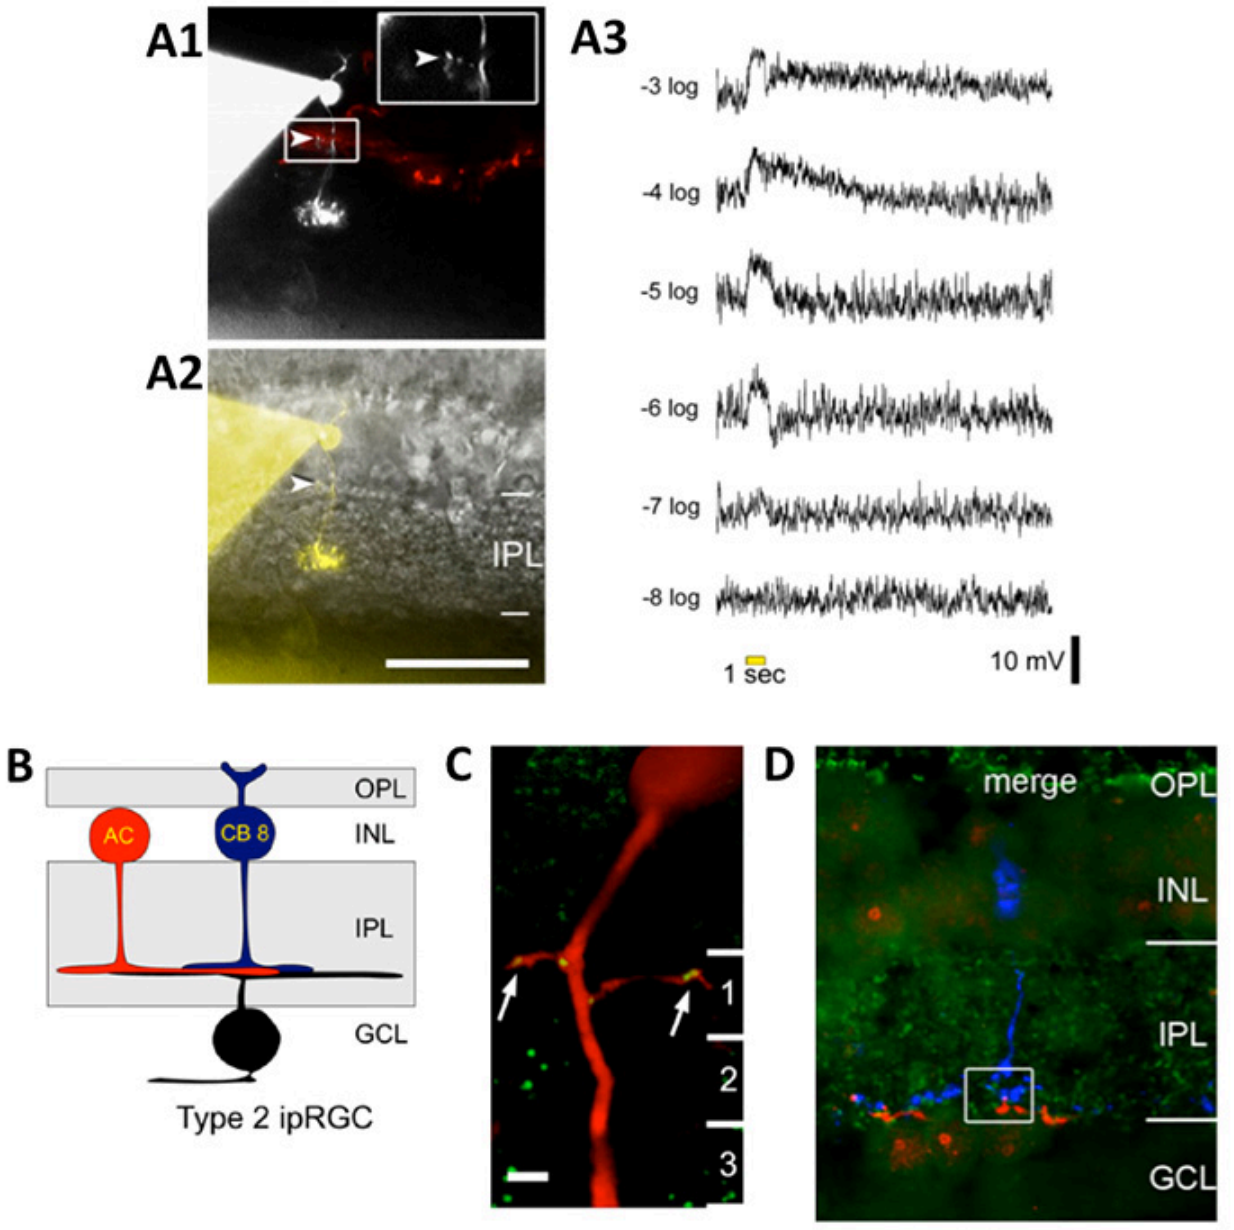

Figure 10. Examples of bipolar and amacrine cell types known to be presynaptic to ipRGCs. (A) In mice, type-6 ON cone bipolar cells extend lateral axonal branches in S1 of the IPL, where they contact the distal dendrites of ipRGCs. A1 & A2: Intracellular fill using the fluorescent dye HyLite488. A1 shows the staining in white, and the Red Fluorescent Protein (RFP)-labeled dendrites of dopaminergic amacrine cells (which serve as a marker for S1) in red. A2 shows the same bipolar cell in an infrared image of the retinal slice. The axonal protrusion (arrowhead) is near the outermost limit of the IPL. stratifying type stratifies in S1 whereas the inner-stratifying type stratifies in S5, and so they could be homologous to the M1 and M2 types found in rodents (30, 66, 99-101). The dendritic fields of the outer-

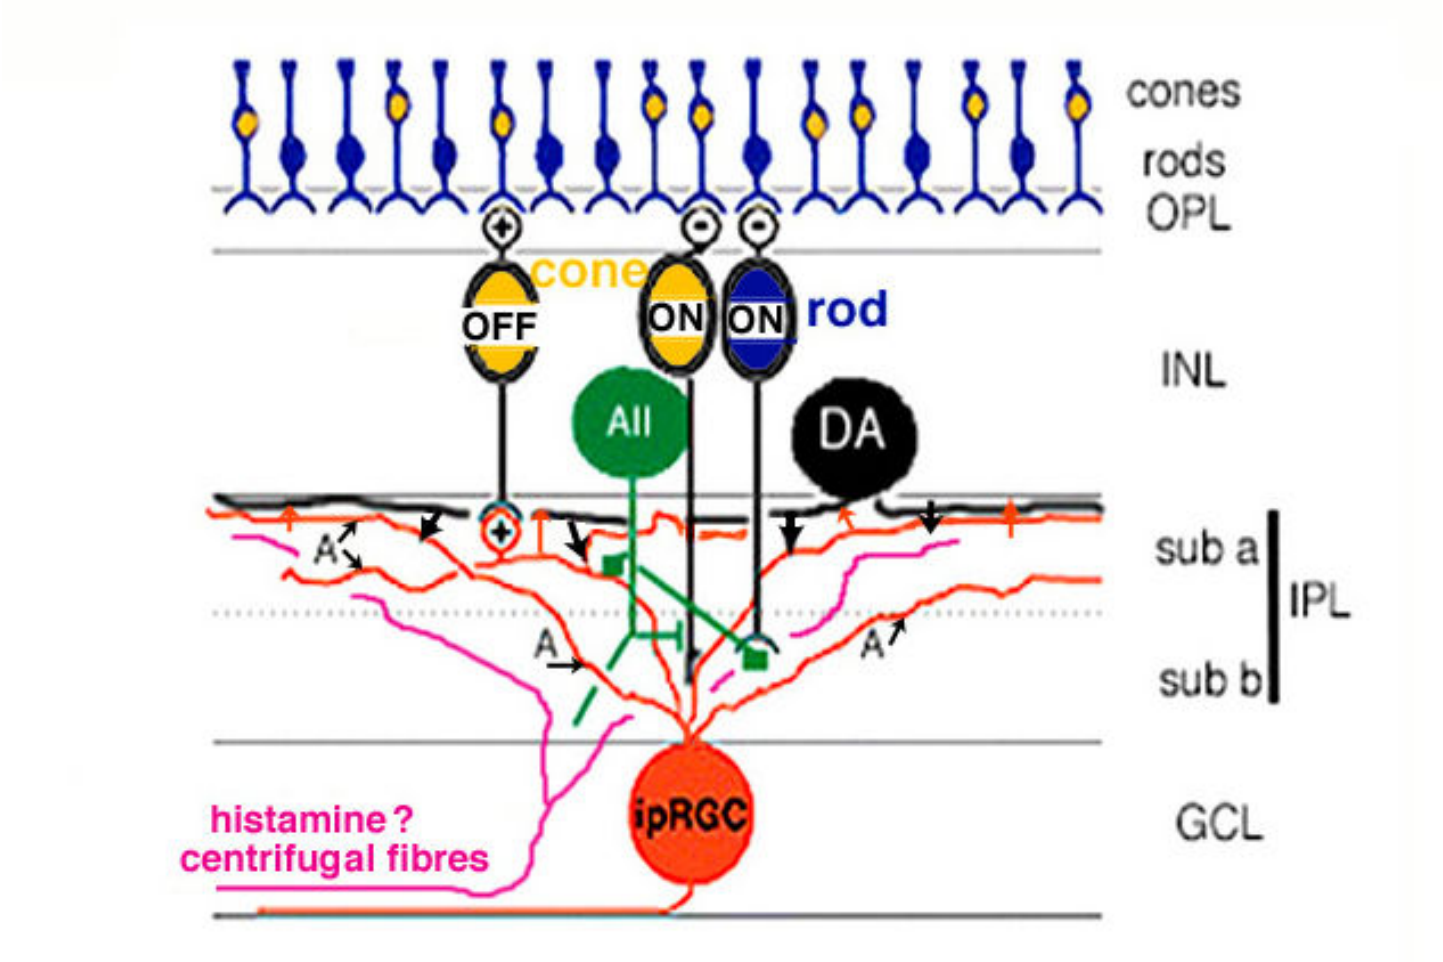

Figure 11. Presumptive synaptic connection scheme for M1-type, SCN-projecting ipRGCs. OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer; OFF, OFF cone bipolar cell (yellow); ON, ON rod (blue) and ON cone bipolar cell (yellow); A, amacrine cell input; ipRGC, intrinsically photosensitive retinal ganglion cell (orange); AII, rod amacrine cell (green); DA, dopaminergic amacrine cell (black); centrifugal fibers (pink) enter the retina and have influence on dopaminergic amacrine cells, which in turn modulate ipRGCs by releasing dopamine.

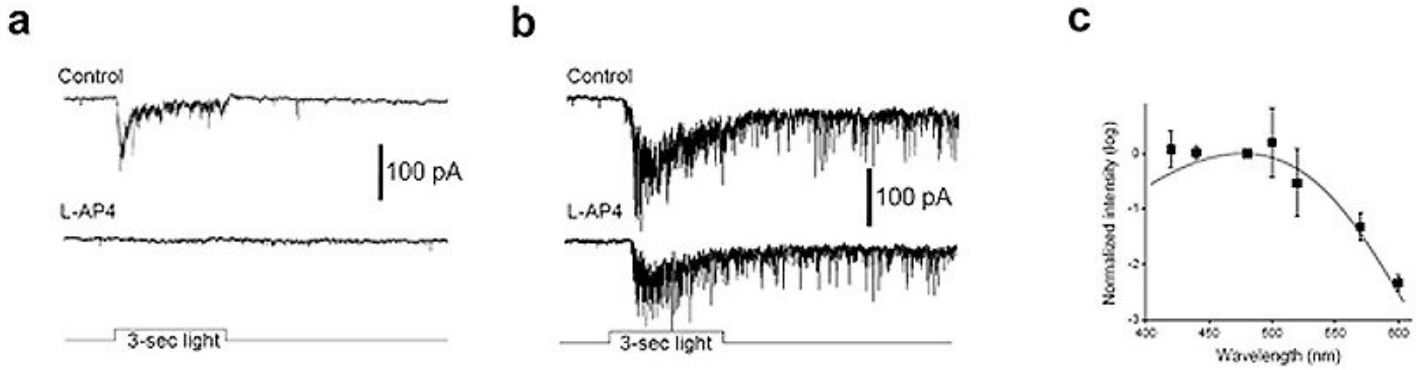

Figure 12. Physiological evidence for a melanopsin-based input to mouse dopaminergic amacrine cells (DA cells). Whole-cell voltage-clamp recordings from a transient DA cell (A) and a sustained DA cell (B). Notice how the application of L-AP4, an agent used to block rod/cone-driven photoresponses from ON bipolar cells, completely eliminated the light response of the transient DA cell (A), whereas it had little effect on the sustained DA cell (B). Panel C shows a fitted plot of L-AP4-resistant responses to varying wavelengths of light, showing a peak near 480 nm, the λ_{max} for stimulating melanopsin. Adapted from Zhang et al. 2008 (77).

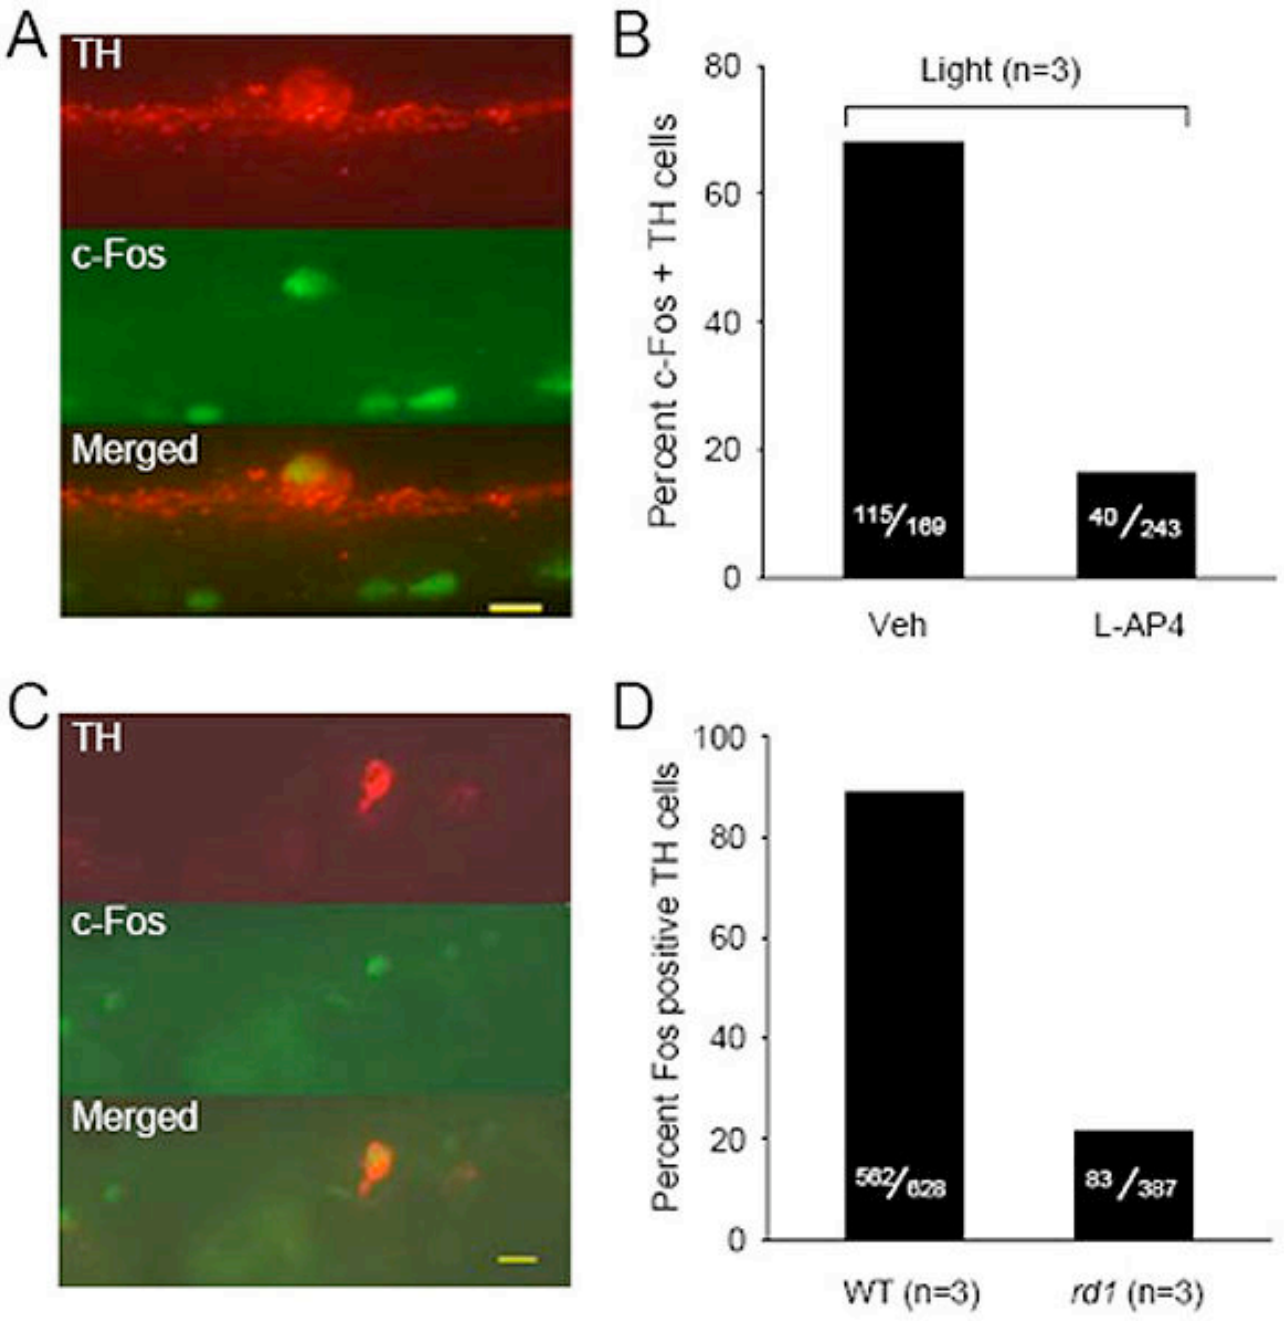

Figure 13. Light-induced cFos staining in retinas with rod/cone input blocked pharmacologically, and in retinas with no rods and virtually no cones. (A, B) Mouse retinas injected with L-AP4 or just the vehicle. A: Example staining illustrating that even with rod/cone input blocked using L-AP4, some dopaminergic amacrine cells (DA cells) showed light-driven expression of the immediate early gene cFos, an indicator of neural activity. Red: tyrosine hydrolase staining of DA cells. Green: cFos staining. B: Summary results for all DA cells examined. The vehicle-injected retinas showed ~70% of DA cells were activated by light, but with the drug L-AP4 injected, roughly 20% of the DA cells were cFos-positive, indicating only a small number of DA cells are potentially contacted by ipRGCs. (C, D) Results from uninjected wild-type and retinal degenerate (rd1) mice. C: Example staining in rd1 retinas. D: Wild-type (WT) animals had roughly 90% of DA cells with light-evoked cFos staining, whereas in rd1 mice roughly 20% of DA cells stained for cFos, matching very well with the L-AP4 experiment (panel B). Adapted from Zhang et al. 2008 (77).

stratifying cells tile the retina with little overlap, but they overlap substantially with the dendritic fields of the inner-stratifying cells, suggesting they constitute two distinct cell types (99). The receptive fields of both outer- and inner-stratifying primate ipRGCs consist only of an ON-center region, and both cell types appear to

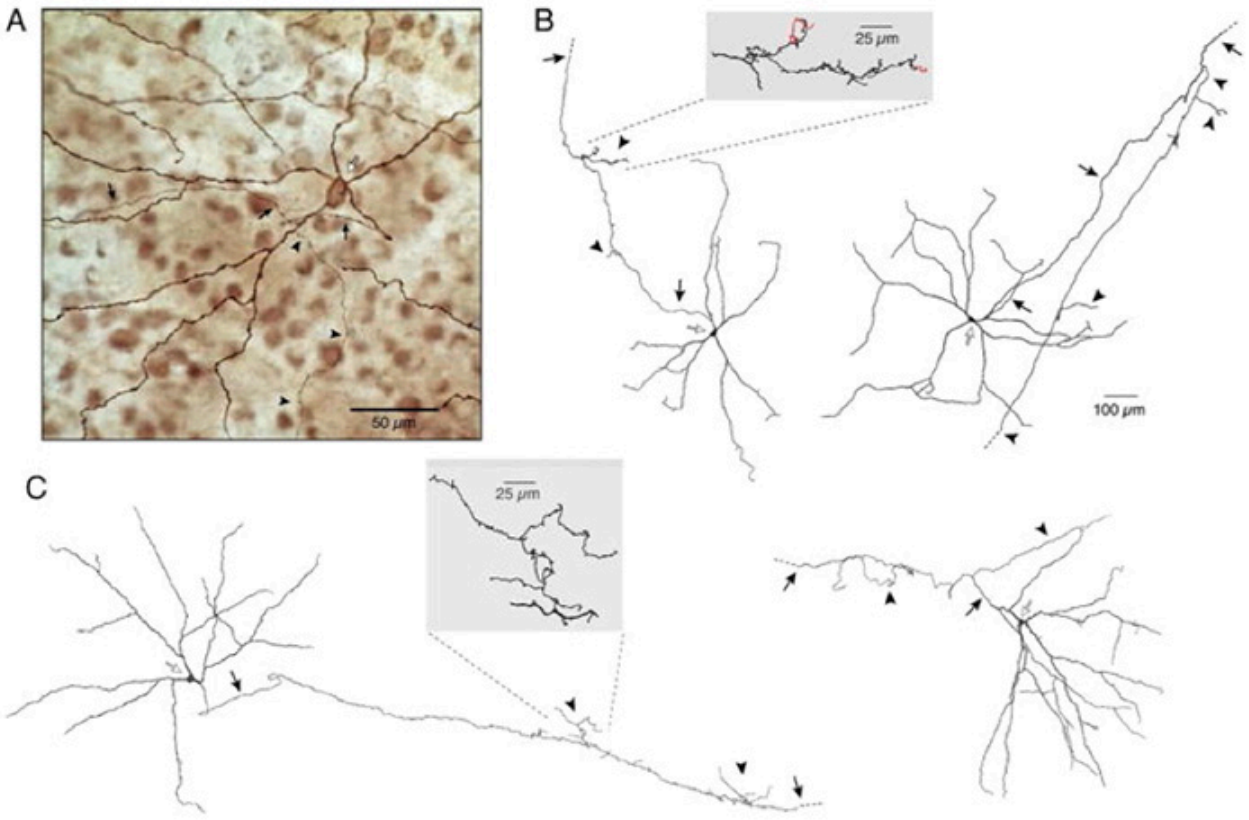

Figure 14. Primate ipRGCs possess axon collaterals. (A) An outer-stratifying melanopsin-positive cell from a macaque. The axon (*black arrows*) extends thin collaterals (*arrowheads*). (B) Tracings of two inner-stratifying macaque ipRGC. *Arrows*, axons. *Arrowheads*, axon collaterals. generate remarkably similar rod-driven, cone-driven and melanopsin-mediated light responses (Figure 21) (30). Moreover, both types project to the lateral geniculate nucleus and olivary pretectal nucleus (see "Central Projections" below for further information) (30, 102). Thus, functional differences between the outer- and inner-stratifying primate ipRGCs remain elusive, although there is anatomical evidence that they receive different synaptic inputs (99, 101).

8. Central Projections

Using a transgenic mouse line whose ipRGCs express the marker enzyme β-galactosidase, Samer Hattar et al. visualized the axons of M1-type ipRGCs and characterized their projections throughout the brain. As expected for cells that regulate non-image-forming visual behaviors, Hattar and colleagues found M1-type ipRGCs sent dense projections to the SCN, the intergeniculate leaflet (IGL), and the olivary pretectal nucleus (OPN) (Figure 22A–C) (103). The SCN and IGL are parts of the circadian system, while the OPN mediates the pupillary light reflex. In addition to these expected sites, the same study discovered a number of other central targets. Within the hypothalamus, M1 cells sent axonal fibers to the ventral portion of the subparaventricular zone, a region controlling the autonomic nervous system. Rostrolateral to the SCN, a number of scattered fibers reach the lateral and ventrolateral preoptic areas, which influence release of reproductive hormones from the pituitary

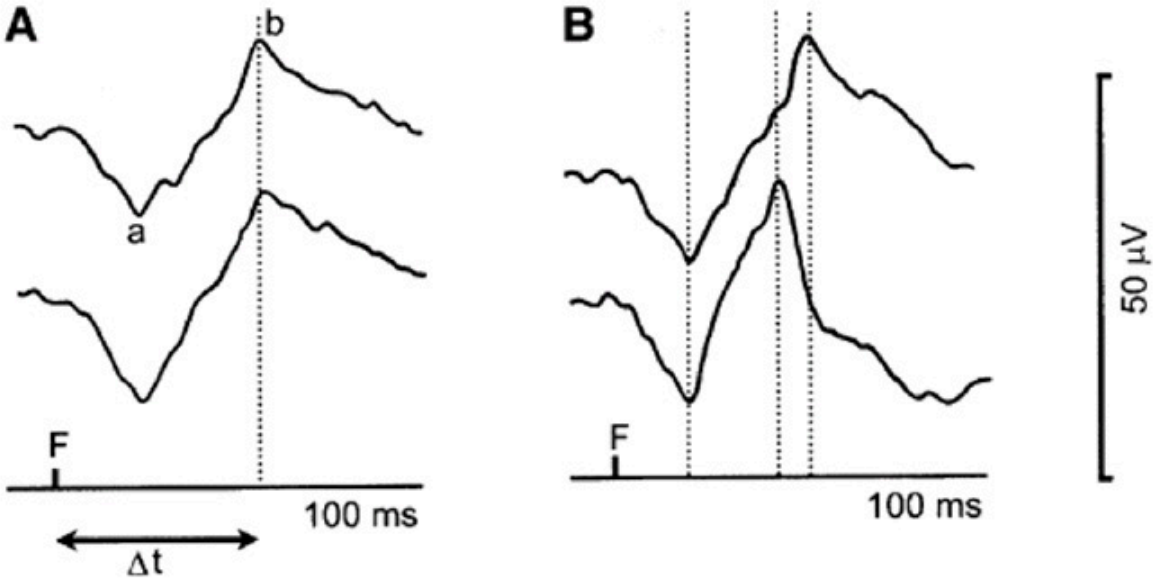

Figure 15. Electroretinograms recorded from a human subject. Each sweep lasted 100 ms, with a flash presented at "F". "a" denotes the a-wave, which arises from the hyperpolarizing light response of photoreceptors; "b" denotes the b-wave, which reflects the depolarizing light response of ON bipolar cells. (A) The upper recording was made at 9 PM, after which the subject was kept in darkness until performing the lower recording at 3 AM. The timings of the a- and b-waves were unchanged. (B) After recording the upper trace at 9 PM, a 15-min 471-nm light was presented to the subject at 11 PM and the bottom trace recorded at 3 AM. Notice that the 15-min light accelerated the b-wave. Adapted from Hankins & Lucas 2002 (85).

(103). The brain targets identified in this study are summarized in Figure 22D. These central projections suggest that M1 cells regulate a diverse array of non-image forming visual functions.

More recently, using a more sensitive Cre-based melanopsin reporter mouse line to label all five ipRGC types, Hattar and colleagues detected pronounced ipRGC projection to two additional visual nuclei: the dorsal division of the lateral geniculate nucleus (LGN), which is the primary thalamic relay site of retinal input to the visual cortex, and the superior colliculus (SC), a sensorimotor nucleus that detects novel visual stimuli (Figure 22E, F). Retrograde and anterograde labeling has shown that primate ipRGCs also project to both the LGN and SC (30, 100). These findings suggest that in addition to their well-known role in regulating subconscious visual reflexes, ipRGCs may contribute to conscious visual perception, a possibility that has received strong support from electrophysiological and behavioral studies (see "Behavioral aspects of ipRGC function" below).

9. Adaptation, neuromodulation, and circadian control

IpRGC photosensitivity displays various forms of plasticity. The gain of melanopsin phototransduction is influenced by background light level and prior lighting history. IpRGCs' light responses are also modulated by neuromodulators released endogenously within the retina. Moreover, these neurons' photoresponse amplitude depends on the time of day, suggesting it is under circadian control. All three aspects of ipRGC plasticity are considered in this section.

The image-forming visual system can operate over a wide spectrum of ambient light intensities covering more than ten orders of magnitude. While much of this range is due to the existence of two separate photoreceptor

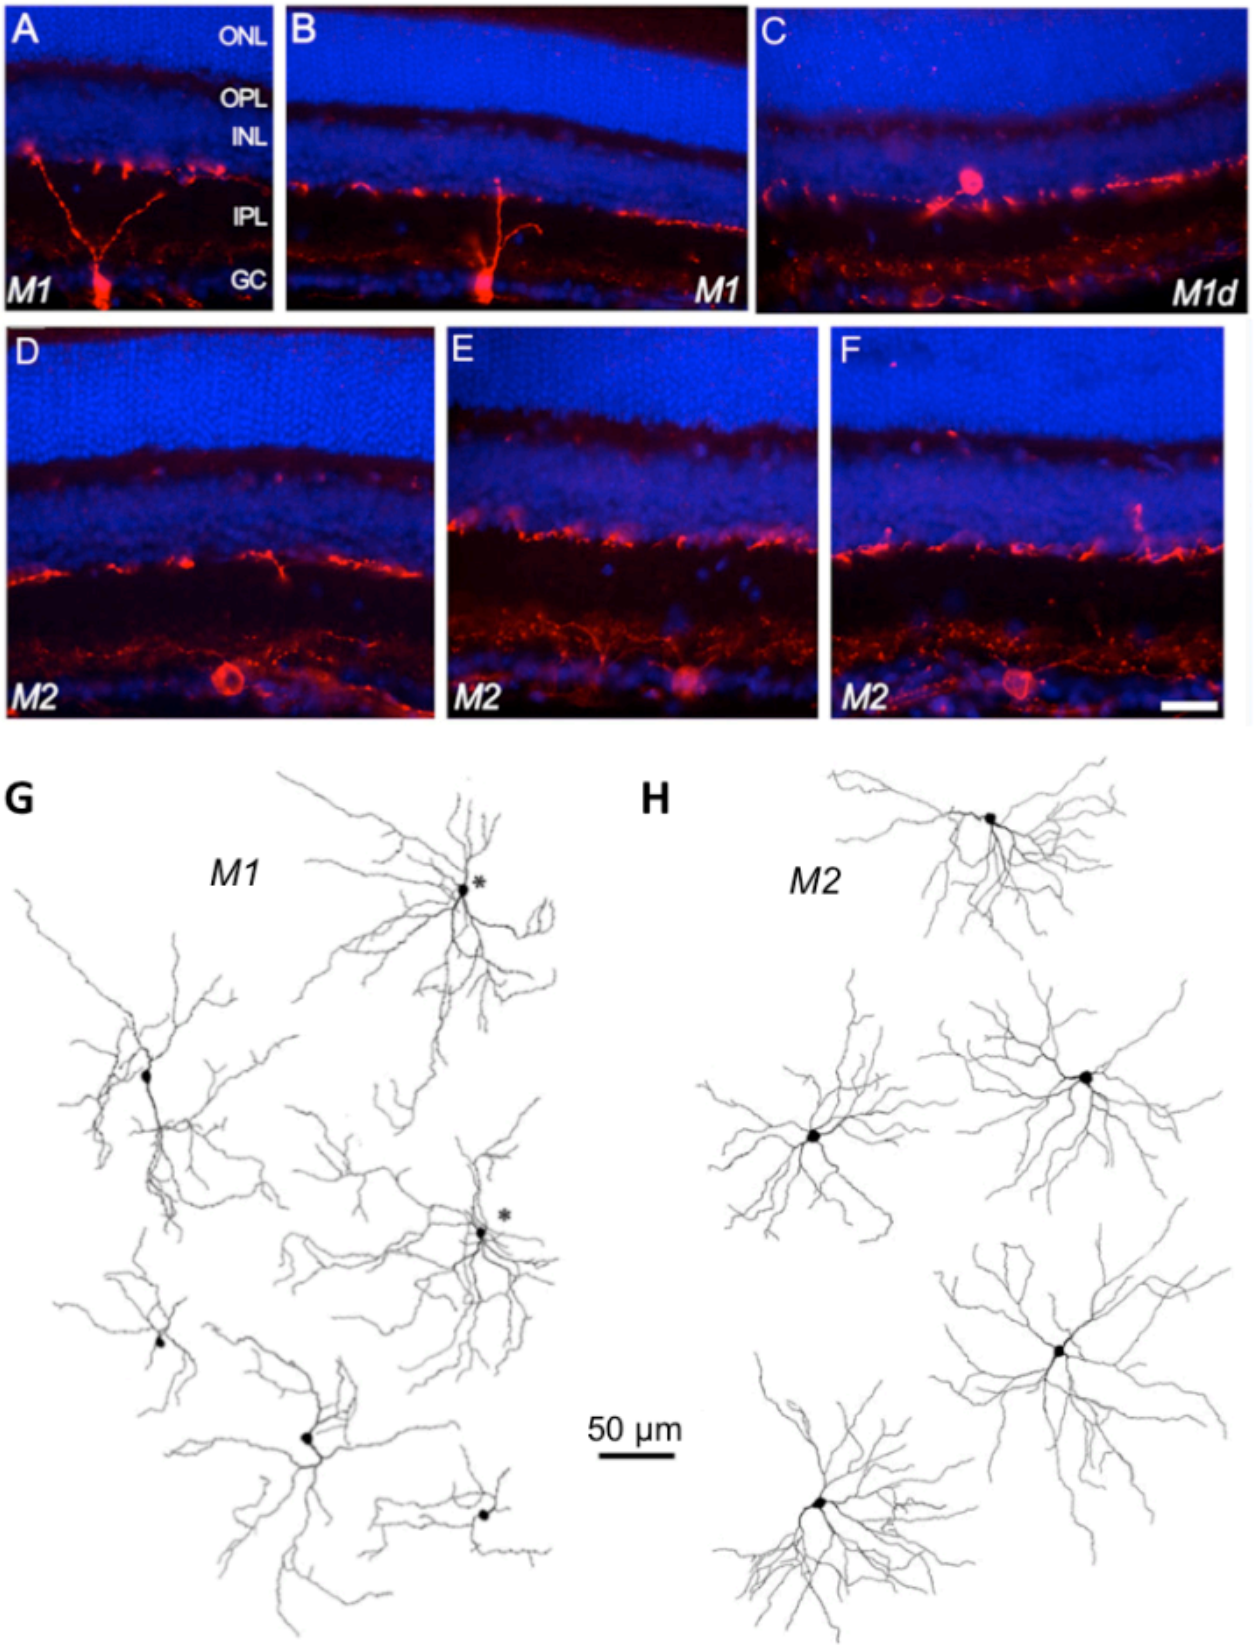

Figure 16. Morphologies of M1-type and M2-type mouse ipRGCs. (A-F). The morphologies of M1 and M2 cells as seen in vertical sections of immunostained (melanopsin, red; DAPI, blue) mouse retinas. systems (rods and cones) that operate over different light intensity ranges, some of the capacity is due to the ability of both rods and cones to change their sensitivity to light, a process called adaptation (104). When

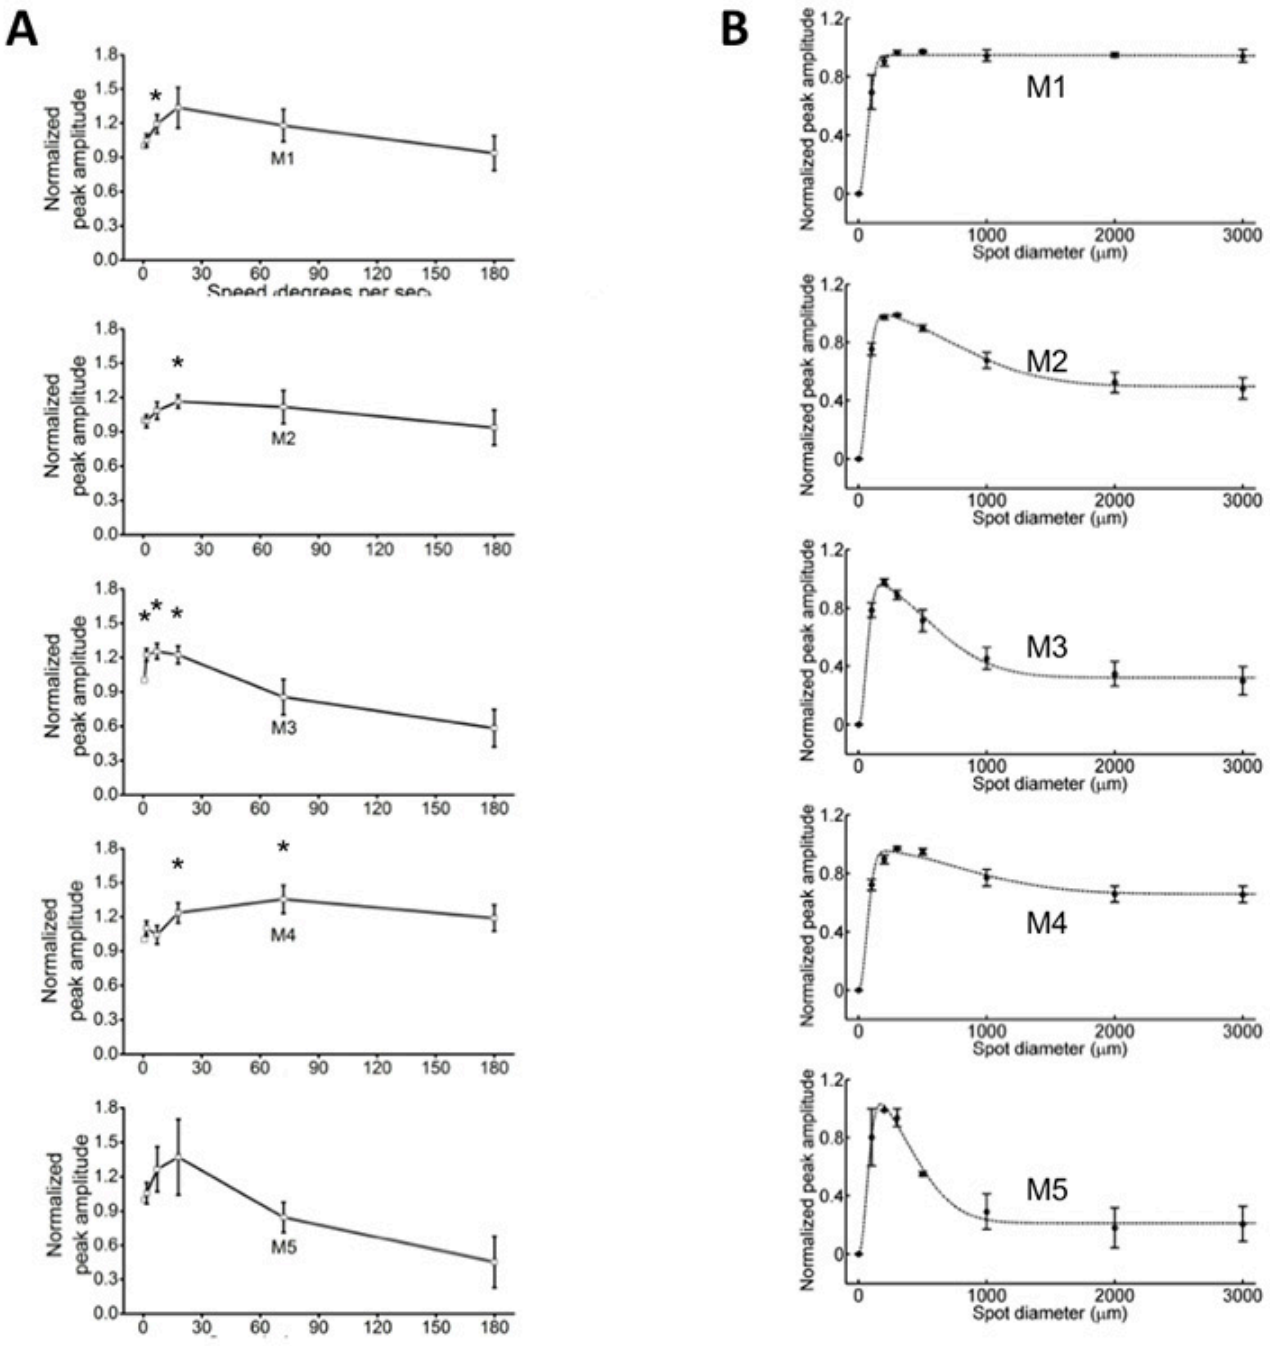

Figure 18. Mouse ipRGCs' responses to motion and receptive field organization. (A) A light bar was drifted over the receptive fields of mouse ipRGCs at different speeds and peak response amplitudes measured. The five cell types responded best to different speeds of motion. (B) Light spots of various diameters centered within the receptive field were presented to the five types of ipRGCs. For M1 cells, response amplitude increased as the spot diameter increased to 300 μm, beyond which no further amplitude change was observed, indicating the absence of an antagonistic surround in the receptive field. But for M2 – M5 cells, response amplitude declined as the spot diameter exceeded a certain value, indicative of a suppressive OFF surround. Adapted from Zhao et al. 2014 (58).

presented with a constant background light, rods and cones generate an initial peak response which relaxes during the steady illumination, indicating desensitization to the light over time. This desensitization allows the photoreceptors to increase their dynamic range, so they can respond to light intensities that would otherwise be saturating. This is termed "light adaptation". Conversely, when placed back into a dark environment, rods and

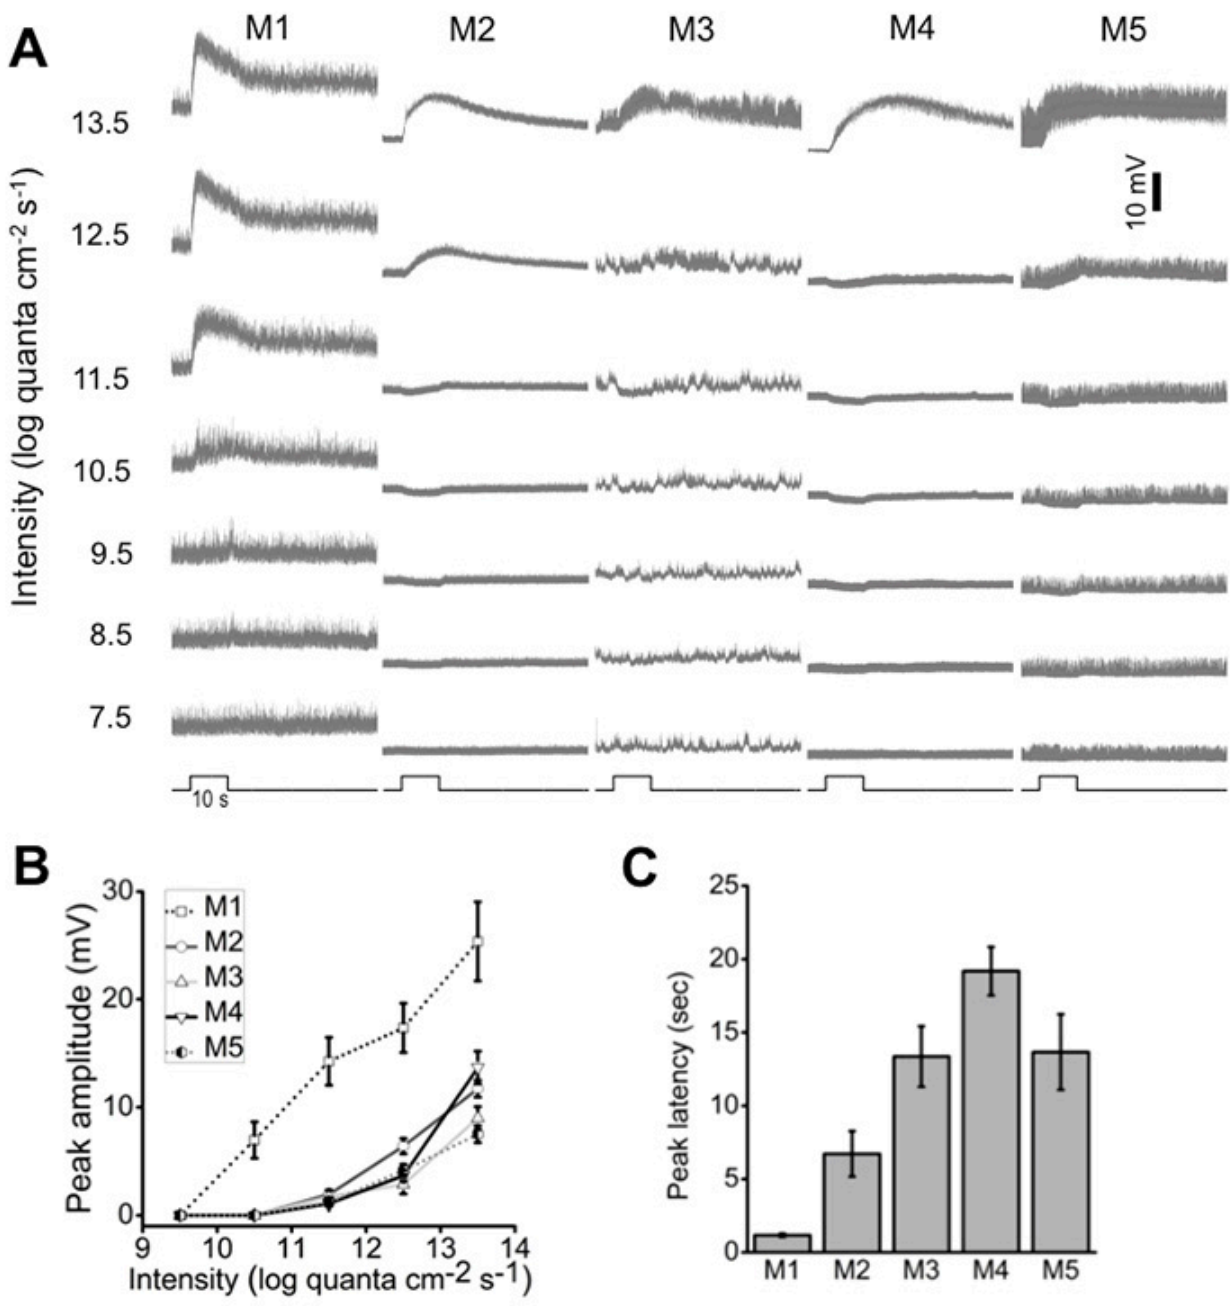

Figure 19. The five types of mouse ipRGCs generate diverse intrinsic photoresponses, recorded during rod/cone signaling blockade. (A) The averaged intrinsic light responses of the five cell types. The *gray* regions indicate S.E.M. (B) At all light intensities, M1 cells generate larger intrinsic light responses than the other four ipRGC types. (C) Peak latencies for the five cell types' responses to the 13.5 log quanta cm^{-2} s^{-1} stimulus (top recordings in panel A). Adapted from Zhao et al. 2014 (58).

cones gradually regain their sensitivity, a process called "dark adaptation". Both light and dark adaptation are a direct consequence of changes in the phototransduction cascade. While rods have a relatively limited ability to adapt to background illumination, saturating at high light levels, cones exhibit an almost infinite capacity to adapt to light levels (105, 106).

Due to their role in stable representations of absolute light levels, and their unusually tonic response properties, it was initially not clear whether ipRGCs' intrinsic photosensitivity would display similar adaptation

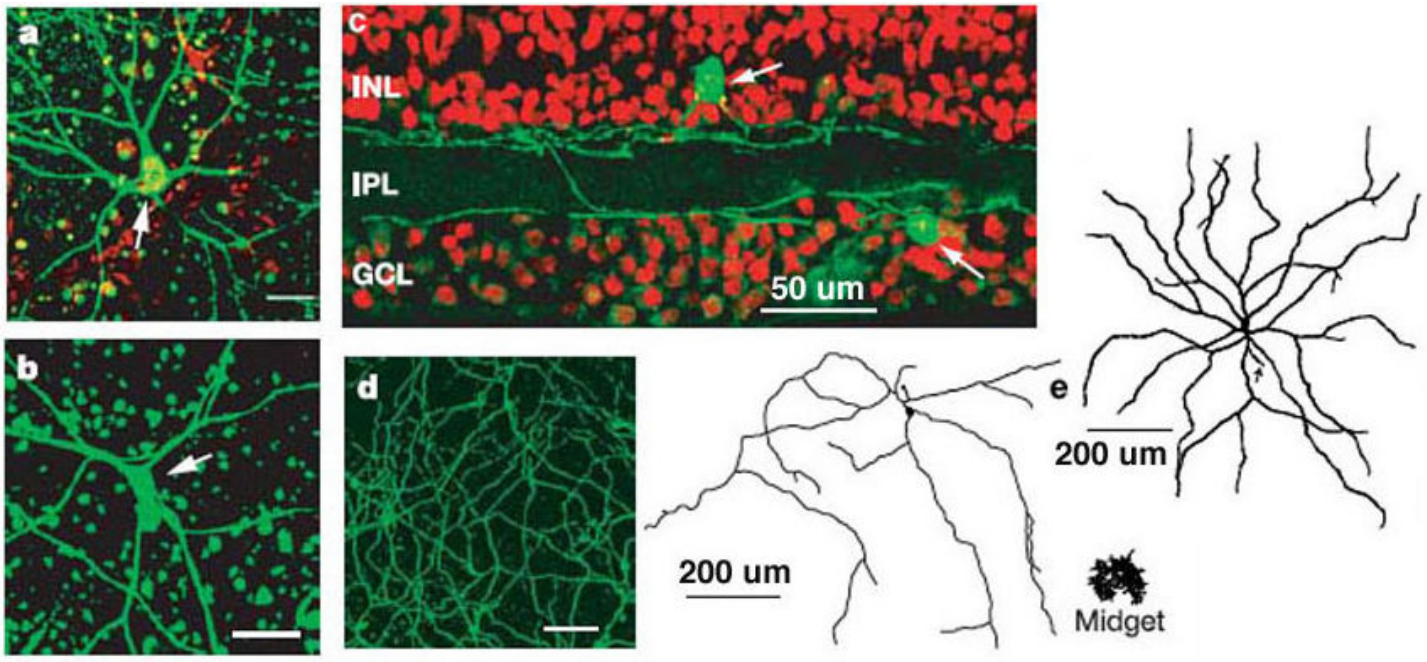

Figure 20. The morphology of melanopsin-expressing ganglion cells in monkey and human retinas. (A) A melanopsin-immunopositive human ganglion cell (green) as seen in peripheral retina wholemount. (B) A macaque melanopsin-immunopositive ganglion cell. Scale bars are both 50 μm. (C) Dendrites of melanopsin-immunopositive ganglion cells running in S1 and S5 of the inner plexiform layer. (D) Melanopsin-immunopositive ganglion cells in peripheral retina. Scale bar, 200 μm. (E) Drawings of two melanopsin-immunopositive ganglion cells in the peripheral retina (left and right cells). A peripheral midget ganglion cell (center) is drawn for size comparison in this part of peripheral retina. Adapted from Dacey et al., 2005 (30).

mechanisms as rods and cones. David Berson and colleagues found that when ipRGCs were exposed to a nearly saturating background light, these cells gradually became desensitized, while responses to a brighter pulse of light on top of the background light became larger over time (Figure 23).

Background light also accelerated photoresponse kinetics, so that the response to a light pulse peaked faster, and also decayed faster toward to the baseline after cessation of the pulse. These are hallmarks of light adaptation. Furthermore, when previously light-adapted ipRGCs were left in the dark for increasing periods of time, their responses to the same light stimulus intensity increased, a clear indication of dark adaptation (Figure 24) (107). Although Wong *et al.*2005 (107) found that ipRGCs light-adapt and dark-adapt much slower than do the classical photoreceptors, subsequent work revealed two important similarities between ipRGC and rod/cone adaptations: for all three photoreceptor classes, the flash sensitivity *vs.* background intensity relationship can be described by the Weber-Fechner law, and light adaptation is at least partly mediated by Ca^{2+} (108). These similarities are somewhat surprising, considering that ipRGCs use a phototransduction cascade that differs drastically from rods' and cones' (see the "Phototransduction" section above).

In addition to the above acute adaptational effects on ipRGCs' intrinsic photosensitivity, prolonged exposure to light or darkness significantly modulates melanopsin mRNA levels. In rats maintained in constant darkness, melanopsin expression rose progressively for at least 5 days, whereas those kept in constant light became nearly completely devoid of melanopsin mRNA after 7 days (109).

As mentioned earlier in the "Intraretinal synaptic output" section, dopamine is an important neuromodulator that has widespread influences on retinal function. Thus, not surprisingly, it has been shown to modulate ipRGCs. Dopamine and an agonist for D1-class dopamine receptors were found to acutely attenuate the intrinsic light responses of dissociated ipRGCs (71). Moreover, prolonged application of a D2-class dopamine agonist

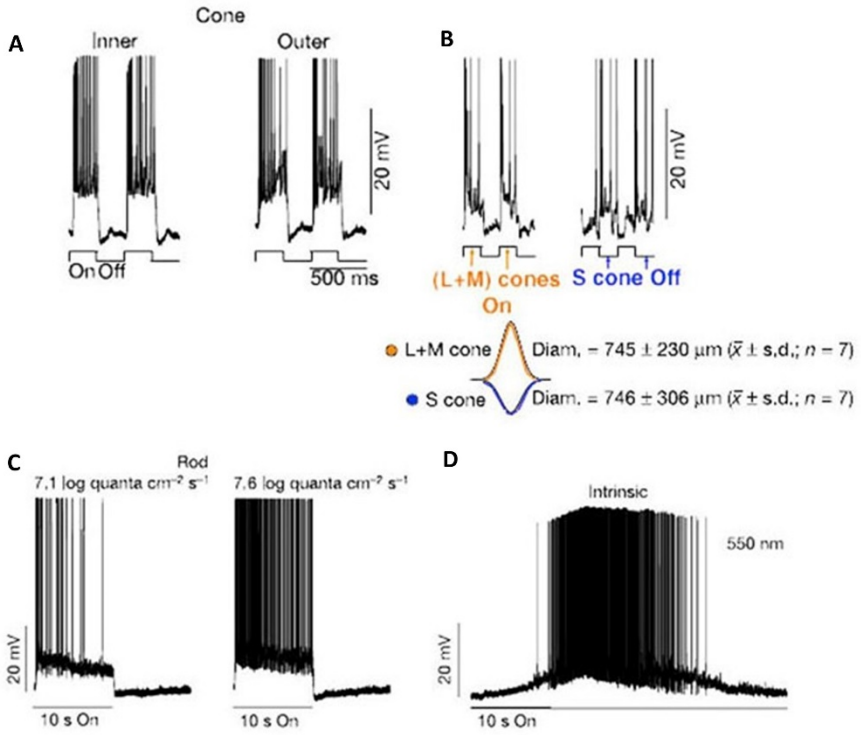

Figure 21. Intracellular recordings of primate ipRGCs' light responses. (A) Primate ipRGCs depolarize to a light that stimulates all cone types. (B) When stimuli selective for specific cone types are used, primate ipRGCs show ON responses to L+M cone input (*yellow*) but OFF responses to S-cone input (blue). The receptive field has coextensive "blue OFF" and "yellow ON" regions with no surround inhibition, as shown in the difference-of-Gaussians plot at the bottom. (C) Primate ipRGCs give a strong ON response to rod-selective light steps. Responses to two light intensities are shown. (D) After blocking rod/cone input with drugs, the slow, excitatory, sustained, intrinsic response to light is revealed. Adapted from Dacey et al., 2005 (30).

enhanced the mRNA levels of melanopsin and pituitary adenylyl cyclase-activating peptide (PACAP), a peptide present in ipRGCs (110). Adenosine, which appears to rise at night and during prolonged darkness (111), has been reported to shorten the duration of ipRGCs' intrinsic photoresponses, but unlike dopamine, it does not significantly reduce the peak amplitude of these responses (112). Melatonin, which is also released primarily at night, has been reported to modulate the rod/cone-driven light responses of M4-type rat ipRGCs (113). Finally, there is indirect evidence that cholecystokinin released from amacrine cells modulates retinal input to the central circadian clock (114).

IpRGCs are well known to mediate photoentrainment of the central circadian clock (see "Behavioral aspects of ipRGC function). But there is evidence that these RGCs are themselves under circadian regulation. In both light/dark ("LD") and constant dark ("DD") conditions, melanopsin mRNA levels in rat retinas display a daily rhythm. This rhythm disappeared in rod/cone degenerate rats, suggesting it is driven by the retinal circadian clock rather than the SCN's central circadian clock (115). Multielectrode-array extracellular recording indeed demonstrated a statistically significant increase in the amplitude of rat ipRGCs' intrinsic photoresponse early in the subjective night compared to all the other circadian times examined (116), although this increase was much smaller than the amplitude of the circadian rhythm in melanopsin mRNA expression (115). The synaptically driven light response of M4 ipRGCs also exhibits circadian variation (113).

10. Behavioral aspects of ipRGC function

Daily rhythms in mammalian physiology and behavior, collectively called circadian rhythms, are controlled by a tiny cluster of cells in the SCN of the hypothalamus. SCN neurons possess a transcription/translation-based

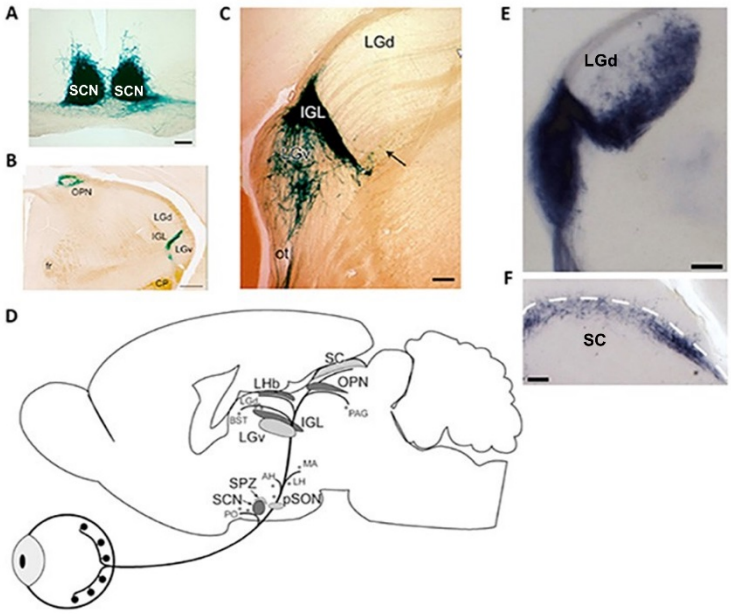

Figure 22. Axonal projections of mouse ipRGCs. (A-D) X-gal staining of axonal projections from M1 cells in tau-LacZ mice. A; M1 cells send a very dense projection to the suprachiasmatic nuclei (SCN) located in the hypothalamus, consistent with their known role in regulating photoentrainment of the central circadian clock, located in the SCN. B: Staining showing M1 projections to the intergeniculate leaflet (IGL) and the olivary pretectal nucleus (OPN). Cerebral peduncle (CP) and fasciculus retrofelxus (fr) are also shown. C: Close-up view of staining in the IGL, the ventral region of the lateral geniculate nucleus (LGv), and a few stained fibers in the dorsal lateral geniculate nucleus (LGd). The optic tract (ot) is also shown. D: Summary of the M1 ipRGC targets revealed in this study. AH, anterior hypothalamic nucleus; BST, bed nucleus of the stria terminalis; IGL, intergeniculate leaflet; LGd, lateral geniculate nucleus, dorsal division; LGv, lateral geniculate nucleus, ventral division; LH, lateral hypothalamus; LHb, lateral habenula; MA, medial amygdaloid nucleus; OPN, olivary pretectal nucleus; PAG, periaqueductal gray; PO, preoptic area; pSON, peri-supraoptic nucleus; SC, superior colliculus; SCN, suprachiasmatic nucleus; SPZ, subparaventricular zone. Adapted from Hattar et al. 2006 (103). (E & F) Axons of M1 – M5 ipRGCs revealed by alkaline phosphatase labeling in Opn4Cre/+; Z/AP mice, showing substantial projection to image-forming visual nuclei. E: Staining in the lateral geniculate nucleus (LGN). A comparison with panel C shows that the LGv and LGd are far more heavily innervated in this mouse line, presumably due to axons from one or more of the non-M1 ipRGC types. F: Staining in the superior colliculus (SC). Adapted from Ecker et al. 2010 (93).

molecular clock that allows them to autonomously regulate activity patterns in near 24-hour rhythms, which ultimately lead to daily changes in behaviors such as sleep/wake cycles and rhythms in core body temperature. However, the circadian clock is not tuned perfectly to 24 hours, and in order to adjust to changes in the animals' environmental light/dark phases, the SCN must be reset periodically so that circadian rhythms are synchronized (or "entrained") to the light/dark cycle. Light is by far the most potent circadian entrainment cue, and ipRGCs are the primary cells that carry this signal since eliminating these neurons abolished photoentrainment in mice (117-119). Melanopsin-knockout animals have relatively normal circadian rhythms, and do not display any overt dysfunction in their ability to entrain to light. However, light pulses induced significantly smaller phase shifts in these animals' circadian rhythms (Figure 25), revealing a crucial role for melanopsin signaling (20, 21). On the other hand, rods are essential for photoentrainment to dim light (120, 121), whereas cones are important for proper responses of the photoentrainment system to short-duration light pulses (122, 123).

The SCN signals through various neural circuits to coordinate circadian rhythms throughout the body. In one of these circuits, the SCN regulates secretion of the sleep-promoting hormone melatonin from the pineal gland into the bloodstream: SCN → paraventricular nucleus of the hypothalamus → intermediolateral nucleus of the spinal

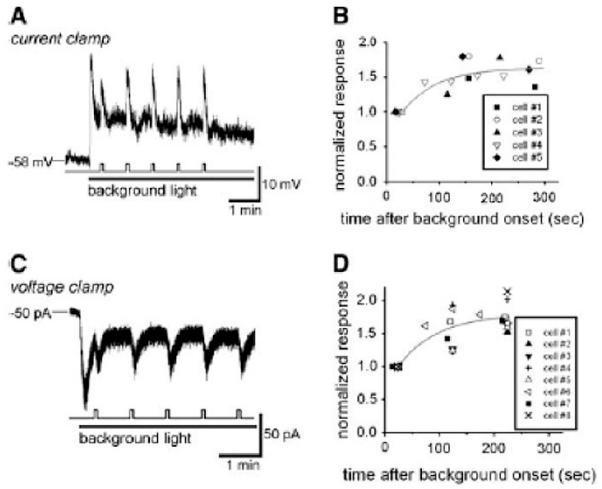

Figure 23. Evidence for light adaptation in ipRGCs. All recordings were made in the presence of rod/cone signaling blockers to isolate the intrinsic light response. (A) Current-clamp recording from a rat ipRGC with test pulses superimposed on an adapting background light. The cell decreased its sensitivity to the background light over time and was able to generate a larger response to the test pulse towards the end of the recording compared to the response to the same test pulse right after onset of the background light. (B) Summary data for current-clamp recordings from five ipRGCs subjected to the panel A experiment. (C) Voltage-clamp recording using same conditions as in panel A showing similar adaptation to the background light, demonstrating that voltage change is not required for light adaptation. (D) Summary data for voltage-clamp recordings from eight ipRGCs subjected to the panel C experiment. Adapted from Wong et al. 2005 (107).

cord → superior cervical ganglion → pineal gland (124). As a result of this SCN regulation, melatonin is released from the pineal only during subjective night. Upon exposure to sufficiently intense light, however, ipRGC input acutely suppresses this release of melatonin (125-127). Because ipRGCs remain photosensitive in the absence of rods and cones, rodless coneless mice and some blind patients continue to exhibit this non-image-forming visual response (Figure 26) (5, 128, 129).

IpRGCs are also responsible for light-evoked constriction of the pupil. Projections of ipRGC axons to the OPN, the retino-recipient site responsible for the pupillary light reflex, make them likely candidates for regulating this response. Indeed, melanopsin-knockout animals had diminished pupillary light reflexes at high irradiance levels (Figure 27A, B) (18). In addition, melanopsin-knockout mice without functional rods or cones were completely unable to constrict their pupils in response to light (Figure 27C) (19, 22). Furthermore, killing ipRGCs using various methods dramatically attenuated the pupillary light reflex (117, 119).

Numerous additional non-image-forming photic responses have been reported to be at least partly mediated by ipRGCs. These include acute suppression of the nocturnal locomotor activity of mice ("negative masking") (130), light-induction of sleep ("photosomnolence") (131-134) and maintenance of light-induced sleep in mice (135), modulation of cognitive performance in humans (136, 137), enhancement of alertness in humans (138), antidepressant effect in rats (139) and humans (140), light-induced exacerbation of headache in humans (141), photophobia and light avoidance in mice (142, 143), light-dependent relaxation of blood vessels (144), and stimulation of the secretion of follicle-stimulating hormone (FSH) in women (145).

In addition, there is emerging evidence that melanopsin contributes to visual perception, which is probably mediated by ipRGC projection to the LGN and/or SC (30, 58, 93, 95, 146). Some blind patients with severe outer retinal degeneration but relatively normal ipRGCs possess a rudimentary ability to detect the presence of intense blue light (129), and fully sighted humans as well as mice appear to depend partly on melanopsin for brightness discrimination (147). Mice lacking rod/cone photoreception (but with intact melanopsin photoreception) were able to distinguish a computer screen displaying black and white stripes from a uniform gray screen of an equal

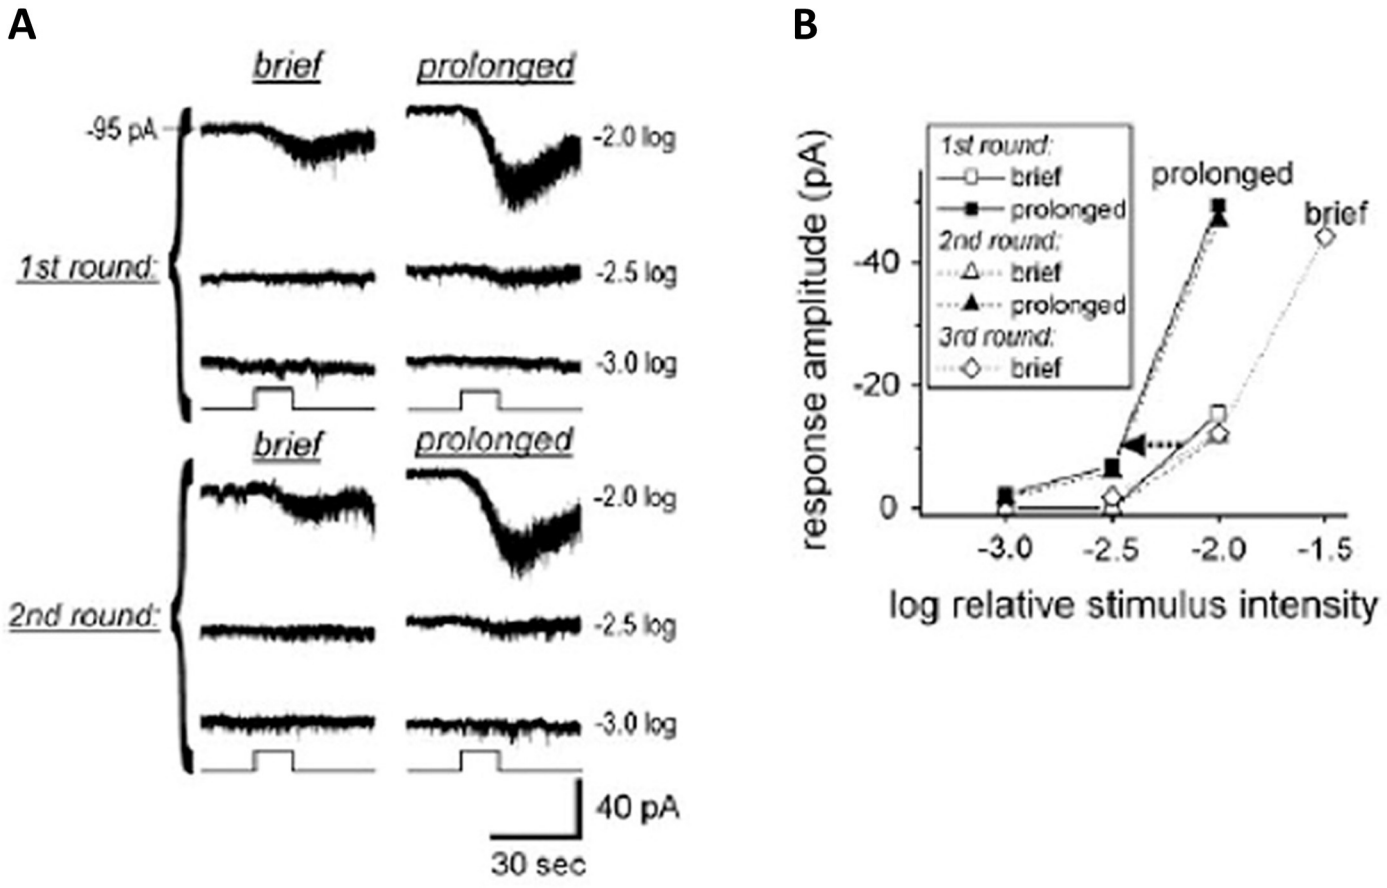

Figure 24. Evidence for dark adaptation in ipRGCs. All recordings were made in the presence of rod/cone signaling blockers. (A) Voltage-clamp recordings from a rat ipRGC responding to different light intensities after multiple rounds of brief and long periods of dark adaptation. Notice that for each light intensity, the cell consistently generated a larger response after longer periods of being in the dark. (B) Summary data from all cells tested. Adapted from Wong et al. 2005 (107).

mean intensity, suggesting melanopsin is sufficient for a certain degree of pattern vision (93). There is also preliminary psychophysical evidence that melanopsin directly contributes to color vision in humans, challenging the trichromatic theory (148). Most recently, mice lacking melanopsin were shown to have behavioral deficits in contrast sensitivity (96).

IpRGCs are likely to perform additional image-forming visual functions because under conditions preserving synaptic input, primate ipRGCs receive color-opponent (blue OFF, yellow ON) input from cones (Figure 21B), implicating a capacity for color discrimination (30). Furthermore, with the exception of M1 cells, all the other four types of mouse ipRGCs have receptive fields with antagonistic ON-center, OFF-surround regions (Figure 18B), suggesting these cells perform spatial analysis (58, 95). Finally, the five types of mouse ipRGCs are tuned to different speeds of motion (Figure 18A), raising the possibility that they contribute to motion analysis (58).

11. Roles in development

Melanopsin expression begins before birth (149) and ipRGCs become photosensitive earlier than either rods or cones (31, 150). One function for this early emergence of melanopsin-based photosensitivity is negative phototaxis, which causes mouse pups as young as P6 (postnatal day 6) to turn away from bright light (142). Melanopsin has also been shown to regulate the early development of retinal neurons, retinal blood vessels and retinogeniculate circuits. In wild-type mice reared under normal light/dark conditions, embryonic hyaloid vasculature regresses and the retinal vasculature starts to form during early postnatal days. But in melanopsin-

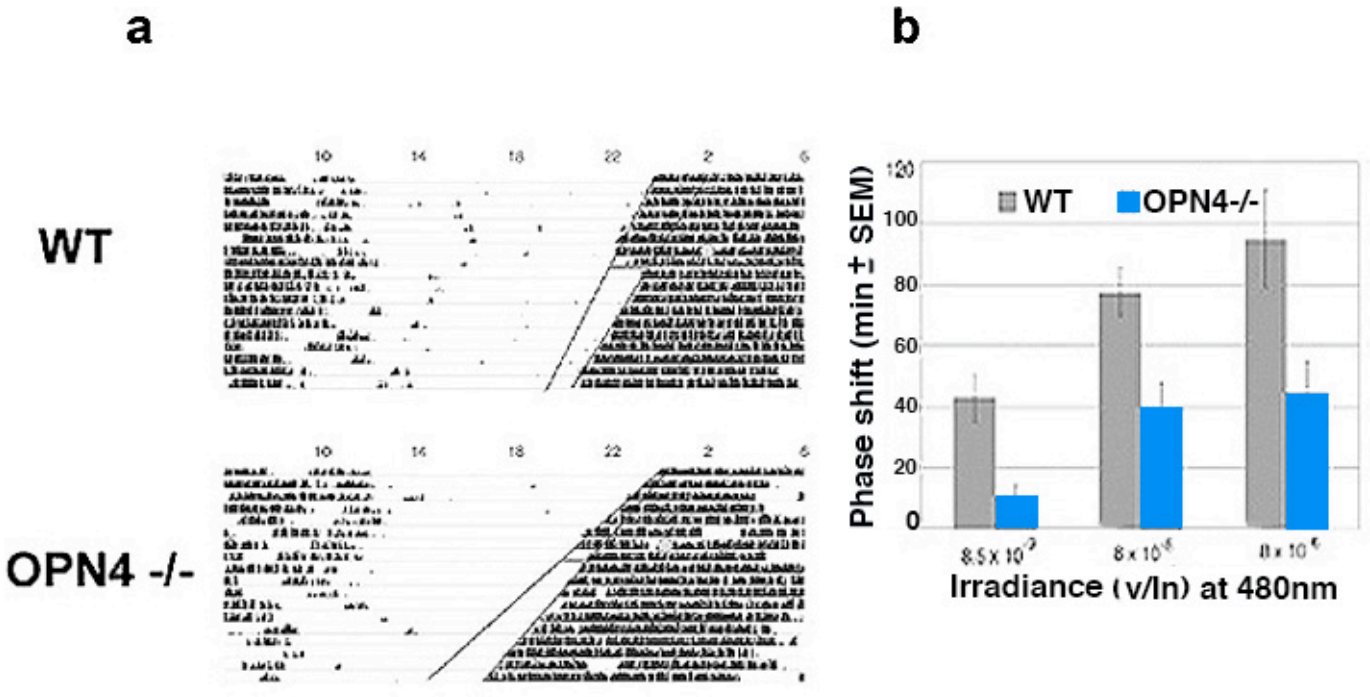

Figure 25. (A) The circadian rhythms of wild-type mice (WT) are more sensitive to phase-shifting light pulses than for melanopsin-knockout animals (OPN4 -/-). In this experiment, mice were kept in sound- and light-proof boxes with no outside indication of time of day. The tick marks indicate rotations of a running wheel present in the cages, and the animals are said to be awake and active during persistent times of wheel-running activity. Under these conditions the animals are "free-running", which means the rhythm of running and sleeping is determined solely by their internal circadian clock, and not outside cues. The magnitude of phase-shifting is measured as the shift in the rhythm of wheel running activity in the days following a pulse of light (gray circles) presented during the so-called "subjective" night phase (period of high wheel-running activity). A comparison of the gray horizontal bars in panel A, representing the degree of change in the wheel-running rhythm, demonstrates the wild-type animal's wheel-running rhythm was shifted further to the right (longer gray horizontal bar) by the light pulse than was the melanopsin-knockout animal's rhythm. B: A comparison of the degree of phase shift by the three light intensities for wild-type (grey) versus melanopsin-knockout animals (blue). Adapted from Panda et al. 2002 (20).

knockout mice or mice dark-reared from late gestation, the regression of the hyaloid vasculature was delayed and the retinal vasculature overgrew (Figure 28A, bottom row). Furthermore, the number of RGCs and amacrine cells increased (Figure 28B, blue). These observations suggest that during late gestation, melanopsin-mediated light detection activates a signaling pathway that suppresses the number of GCL neurons and regulates the timing of vasculature development (151).

As mentioned in the "Intraretinal synaptic output" section above, ipRGCs signal not only to the brain but also within the retina. Intraretinal signaling by ipRGCs is already apparent by P4. Besides participating in ion regulation (152), such early signaling also controls the temporal properties of retinal waves. Retinal waves are spontaneous bursts of action potentials that propagate across RGCs during early postnatal development, and they contribute to the refinement of retinogeniculate projections. In wild-type mice, light increases the duration of each burst of spikes, and afferent axons from ipsilateral and contralateral retinas terminate in largely distinct parts of the dorsal LGN. In melanopsin-knockout mice, however, this effect of light on burst duration was absent, and ipsilateral and contralateral retinal inputs to the dorsal LGN became less segregated (153).

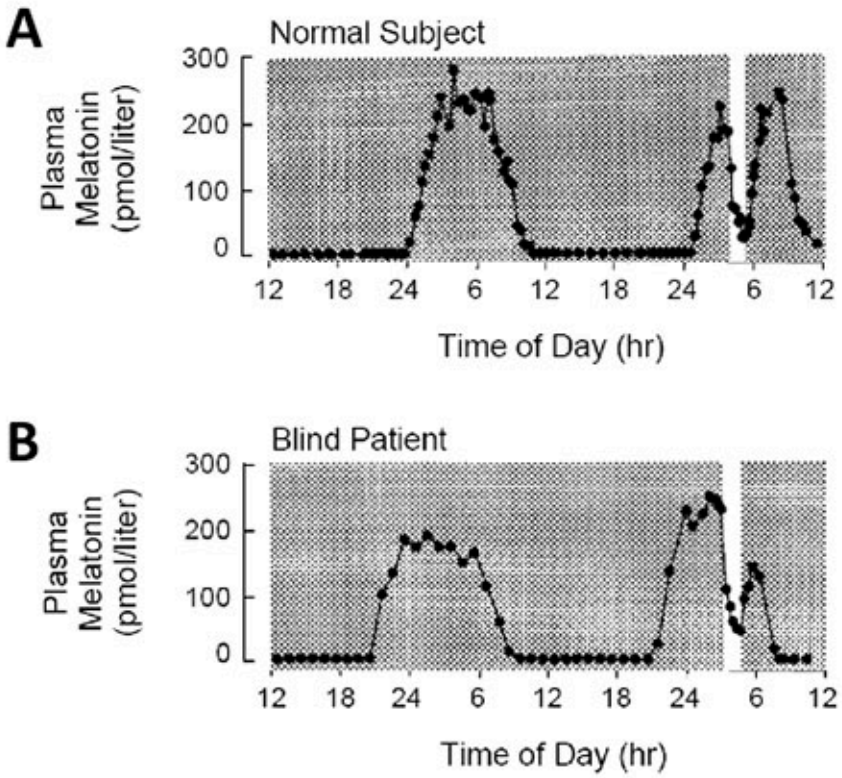

Figure 26. Photic suppression of nocturnal pineal melatonin secretion in humans. A normal, sighted subject (A) and a blind subject (B) were kept in a dim (< 15 lux) environment for 48 hours. A ~10,000 lux light pulse lasting 90 – 100 min (*white vertical bars*) was presented during the second subjective night. In both subjects, plasma melatonin levels were acutely suppressed by the light pulse. Adapted from Czeisler et al. 1995 (128).

12. Conclusions

IpRGCs are mammalian photoreceptors whose morphological and physiological characteristics seem well suited for their primary role as light detectors for non-image forming visual reflexes. Because they were discovered so recently, many mysteries remain, and an untold number of functions for this rare and special type of ganglion cell should not be overlooked. Their invertebrate-like phototransduction cascade makes them unique among known vertebrate photoreceptors, and provides a window into possible mechanisms of the evolution of the retina. In addition to their intrinsic melanopsin-driven photosensitivity, ipRGCs receive rod and cone synaptic input and thus may provide the brain with different information in series, separated by complex spatial and temporal dynamics. Although they drive a number of tonic behaviors, requiring accurate representation of ambient light levels of long periods of time, ipRGCs can adapt to both light and darkness. They have an ability to communicate back to the retina, possibly changing the functional properties of image-forming retinal circuitry. Emerging evidence suggests that ipRGCs can also directly contribute to conscious visual perception. Finally, these RGCs regulate the early development of the retina and the retinogeniculate pathway. As the years catch up with this relatively young field of ganglion-cell photoreceptors, it is beginning to look like many RGC types are photoreceptive and perform diverse functional roles.

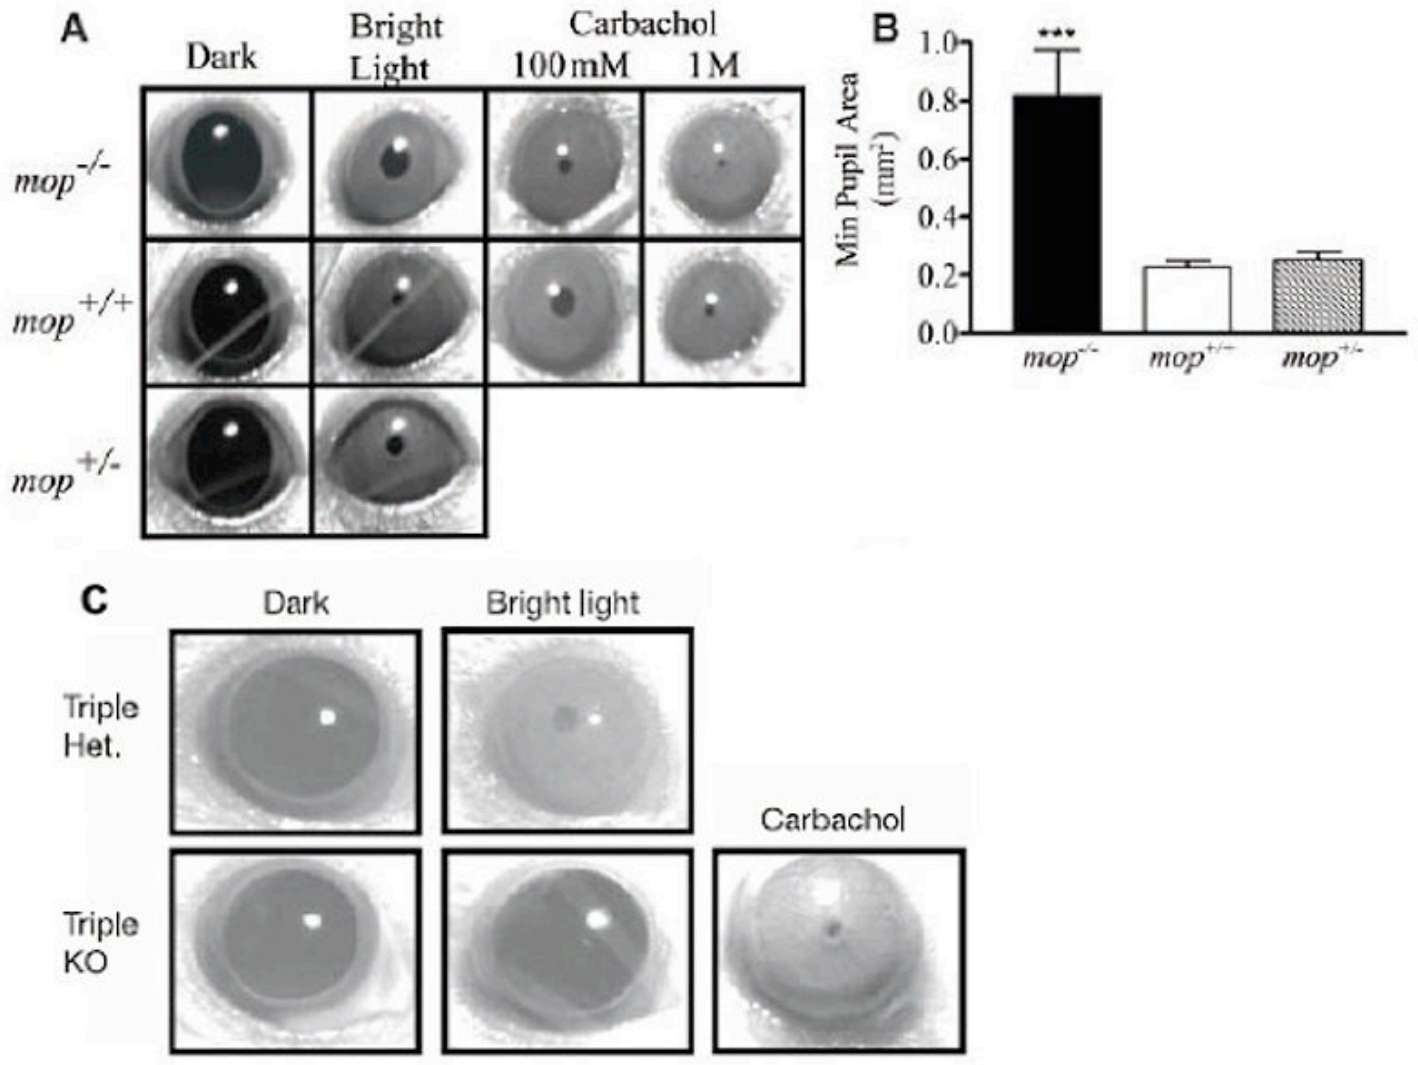

Figure 27. IpRGCs mediate light-evoked pupillary constriction. (A) Melanopsin-knockout mice (mop-/-) showed a defect in their ability to fully constrict their pupils in response to bright white light compared to wild-type animals (mop+/+), while the effect of the drug carbachol (which acts directly on the muscles that constrict the pupil) had the same effect in both melanopsin-knockout and wild-type animals suggesting the defect was due to ipRGC signaling. (B) Summary data on pupil constriction for all melanopsin-knockout and wild-type animals in response to bright light. Adapted from Lucas et al. 2003 (18). (C) Animals with no functioning rods or cones, and missing the melanopsin gene (Triple KO) completely lost the ability to constrict their pupils in response to light, indicating a requirement for melanopsin-based signaling in ipRGCs as well as signaling via synaptic input from rods and cones. Adapted from Hattar et al. 2003 (22).

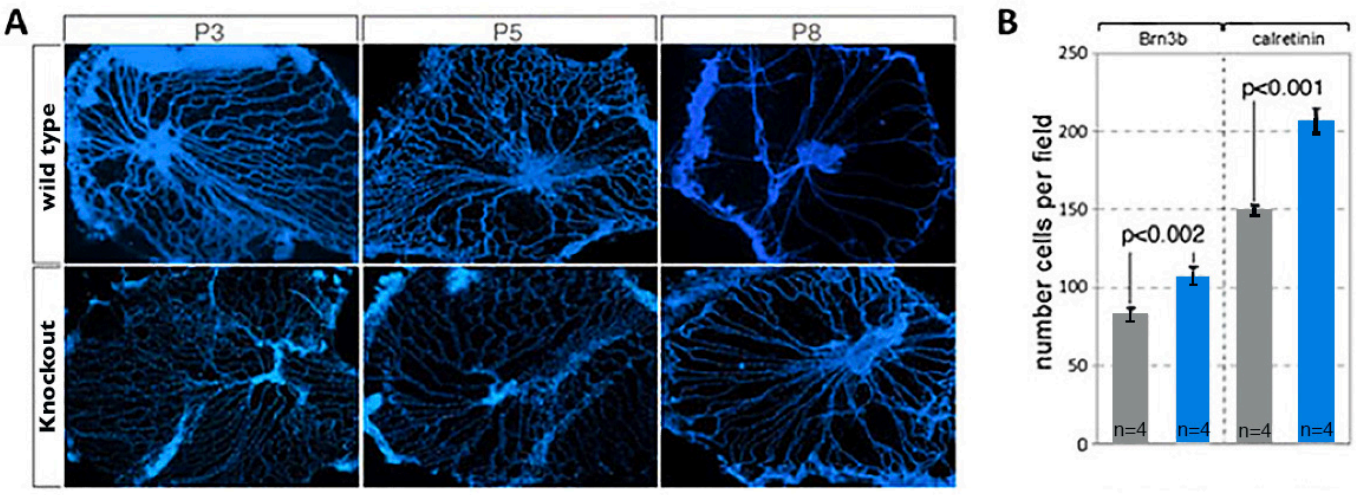

Figure 28. Eliminating melanopsin alters the development of hyaloid blood vessels and retinal neurons. (*A*) Hyaloid vessels persist at P8 in melanopsin-knockout mice. *Top row*: Whole-mount retinas obtained from wild-type mice at P3, P5 and P8. *Bottom row*: Whole-mount retinas from melanopsin-knockout mice at P3, P5 and P8. (*B*) Quantification of Brn3b-positive RGCs and calretinin-positive amacrine cells in wild-type (grey) versus melanopsin-knockout mice (blue) Adapted from Rao et al. 2013 (151).

About the authors

Dr. Kwoon Wong grew up in Hong Kong, when it was still a British colony. His undergraduate major at the University of Texas at Austin was biochemistry, and as he started his PhD career at Harvard he was convinced that he wanted to study cancer biology. But an immensely satisfying rotation in Prof. John Dowling's lab lured Kwoon into the world of neurophysiology, and he has been studying the visual system ever since. For his PhD thesis, he studied glutamate receptors and transporters at the photoreceptor-bipolar cell synapse in fish retinas. Then, at the 2002 Society for Neuroscience conference, he saw Prof. David Berson's fascinating symposium presentation on melanopsin-expressing ganglion cells, a novel class of retinal photoreceptors involved in non-image-forming visual behaviors. Awestruck by this talk, Kwoon decided to do his postdoctoral work with Prof. Berson at Brown. During Kwoon's six years in the Berson lab, he investigated melanopsin ganglion cells' light responses and synaptic circuits. Since Jan 2010, he has been an Assistant Professor at the University of Michigan, where he has continued to study these exotic ganglion cells.

Dr. Dustin M. Graham was born and raised in Pleasanton, California and received his Ph.D. in Neuroscience from Brown University. He began his research career at Santa Clara University in the lab of Dr. David Tauck, studying neural pathways of learning and memory in the pond snail Lymnaea stagnalis. His interests turned to the retina while working with Dr. Ralph Nelson at the National Institutes of Health. There he helped develop a rapid labeling technique to delineate morphological subtypes of retinal neurons in zebrafish. As a graduate student, Dustin studied mammalian circadian rhythms and the newly discovered melanopsin ganglion cell activity in Dr. David Berson's lab. He focused on the phototransduction cascade in ipRGCs, and developed a dissociation and culturing procedure to identify and record light responses from isolated ipRGCs. Dustin has since completed research fellowships in the Department of Psychology, University of Virginia, and in the Department of Neurobiology & Behavior, Stony Brook University, NY. He is currently an editor in the Nature Publishing Group, New York, NY.

The Anatomy and Physiology of Direction-Selective Retinal Ganglion Cells

Jinyue Liu, B. A.[1,*]

Created: August 20, 2015.

1. Introduction

The ability to detect moving objects in the visual scene is fundamental to our daily survival. It originates within the sensory organ, the retina, where a significant proportion of retinal ganglion cell (RGC) responses is dedicated to detecting motion in different directions (Figure1).

The first evidence for such retinal computation was established in the rabbit retina by Barlow and colleagues in the 1960s. By moving small spots of light across parts of the receptive field of a direction-selective RGC (DSGC), they showed that a moving stimulus can elicit strong spiking of action potentials in one direction (henceforth referred to as the preferred direction) but not in the opposite, or null, direction (Figure 2) (1).

In fact, there are different types of DSGCs and they can be segregated based on two criteria. First, they either respond to both light onset and offset (ON-OFF), or just to the former (ON). Second, they prefer different directions of motion. These functional characteristics give rise to four types of ON-OFF DSGCs and three types of ON DSGCs. The ON-OFF DSGCs (ooDSGCs) each detect motion in one of four cardinal axes while the ON DSGCs detect movement in the dorsal, ventral and nasal directions (2) (Figure 3).

Since then, advances in mouse genetics has enabled the study of analogous DSGC populations in the mouse retina, and also led to the discovery of an OFF DSGC type that detects upward motion in the visual scene (3). These new tools complement existing technologies like electron microscopy and dye-filling techniques by allowing specific types of RGCs to be genetically labeled and manipulated. This facilitates the search for morphological correlates of their physiological function. In the following segments, I shall describe the morphology and physiological properties that underlie the direction-selective responses of each DSGC type.

2. ON-OFF DSGCs (ooDSGCs)

ooDSGC morphology and electrophysiological responses

ooDSGCs are the most extensively studied population of direction-selective RGCs, in part due to their more frequent occurrence. They have bistratified dendrites, laminating in both the ON and OFF sublaminae of the inner plexiform layer (IPL) within the retina (Figure 4) (4). Within each sublamina, the dendrites co-laminate with those of interneurons, namely glutamatergic bipolar cells that provide the main source of excitatory input, and starburst amacrine cells (SAC) which provide largely inhibitory input.

A stimulus entering the receptive field of an ooDSGC in its preferred direction will elicit the most robust action potential spiking and little or no response in the null direction (Figure 5) (5). This directional preference persists regardless of changes in the size, shape, contrast or trajectory of the moving stimulus (1).

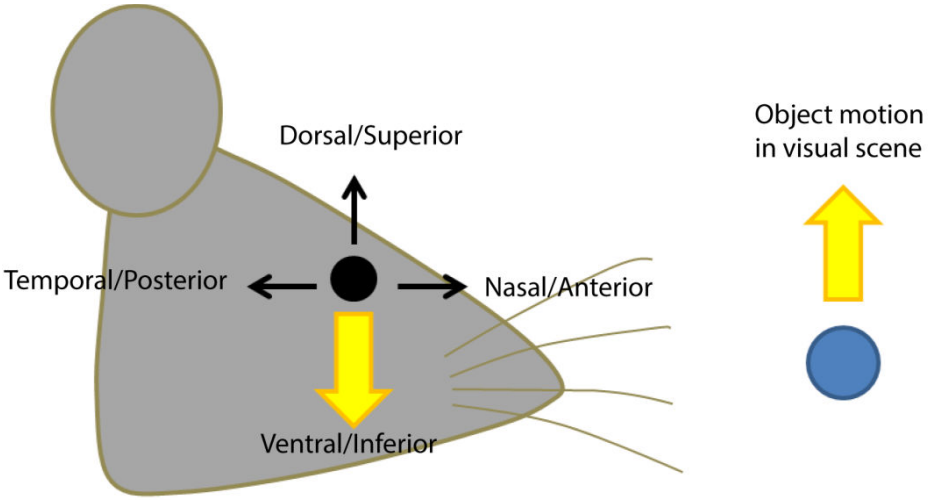

Figure 1. Cardinal axes of the visual field of a mouse. DSGCs in the retina respond best to motion in one of these directions. Due to inversion of light by the lens, the direction of movement of an object in the visual scene corresponds to movement in the opposite direction along the retinal plane. In the example, a DSGC that detects ventral motion responds best to an object moving upwards in the visual scene.

Mechanisms of direction selectivity in ooDSGCs

There are potentially three mechanisms by which direction-selective responses in ooDSGCs can be generated. Interaction with their presynaptic interneurons can produce 1) stronger excitation in the preferred direction or 2) stronger inhibition in the null direction. 3) Postsynaptic integration of excitation and inhibition within the ooDSGC can also give rise to robust response in the preferred but not the null direction. In order to address these possibilities, an understanding of the components of the direction-selective circuit is first needed.

Starburst amacrine cells are a key component of the ooDSGC direction-selective circuit

Since SAC dendrites interact extensively with those of ooDSGCs (6, 7) (Figure 6), SACs were thought to be key mediators of the direction-selective responses of ooDSGCs. Indeed, ablating SACs in mouse retinas abolishes direction-selective responses in ooDSGCs (Figure 7) (8).

SACs provide asymmetric inhibitory input onto ooDSGCs

In fact, SACs are a key source of inhibitory input for ooDSGCs (9). Using paired patch-clamp recordings, it was shown that depolarizing a SAC located on the null side of an ooDSGC elicits inhibition in that ganglion cell (Figure 8). On the other hand, SACs on the preferred side contribute relatively little inhibition.

Excitatory input, namely cholinergic input from SACs and glutamatergic input from bipolar cells, lack direction selectivity, implying that asymmetric SAC inhibition is the primary mechanism for generating direction-selective responses in ooDSGCs (9, 10).

How is this asymmetric wiring between SACs and ooDSGCs established? Direction selectivity is present before eye opening at two postnatal weeks, so visual experience does not seem to be necessary for establishing the circuit (11). A clue came from performing paired recordings of SACs and ooDSGCs in transgenic mice over postnatal development (12). SAC-ooDSGC connections on both the null and preferred sides of the ooDSGC are of equal strength during the first postnatal week, but only those made by null-side SACs strengthen significantly over the second postnatal week. Such developmental sculpting gives rise to a circuit where inhibitory currents from null-side SACs are larger while excitatory currents from SACs on either side are similar (Figure 9).

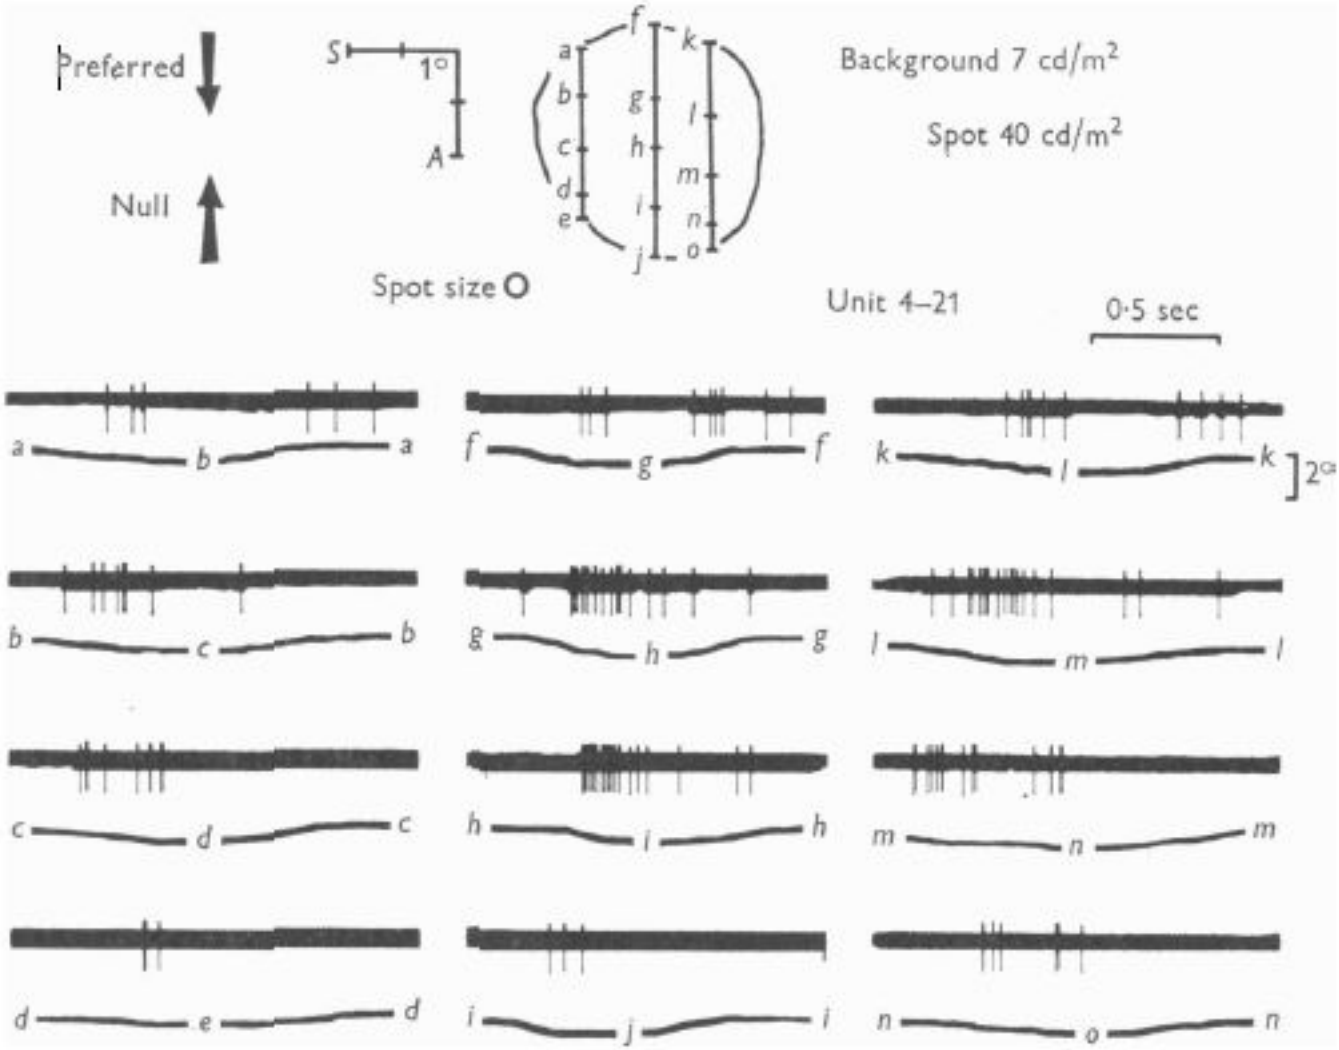

Figure 2. Small spots of light were moved across parts of the receptive field of a DSGC as indicated by the alphabetic letters (top) and spiking responses were recorded from the cell (bottom). Each tick along the horizontal time axis is an action potential. The cell is more responsive when the spot moves downwards (for example g to h or l to m) rather than upwards (for example h to g or m to l). From Barlow and Levick, 1965 (1).

Structural basis for the asymmetric inhibitory SAC input onto ooDSGCs

A landmark experiment by Briggman and colleagues (13) provided a structural basis for this functional asymmetry. By correlating physiological responses of each ooDSGC with structural evidence from serial block-face electron microscopy of putative synapses on these same cells, they showed that the SACs on the null side of ooDSGCs make more inhibitory synapses onto ooDSGC dendrites compared to SACs on the preferred side. In particular, individual SAC dendrites that are oriented antiparallel to the null direction of the ooDSGC contribute to the majority of these inhibitory synapses (Figure 10). Hence, an increase in the number of SAC-ooDSGC inhibitory synapses, rather than the strength of individual ones, accounts for the direction-selective responses of ooDSGCs.

Individual SAC dendrites are direction-selective

Each SAC can wire to multiple ooDSGCs and contribute to their direction-selective responses. This is possible because each SAC dendrite is an independent direction-selective unit (14) (Figure 11). When a stimulus is presented in a centrifugal direction, moving from its cell body out to the distal tips, the SAC dendrite inhibits the

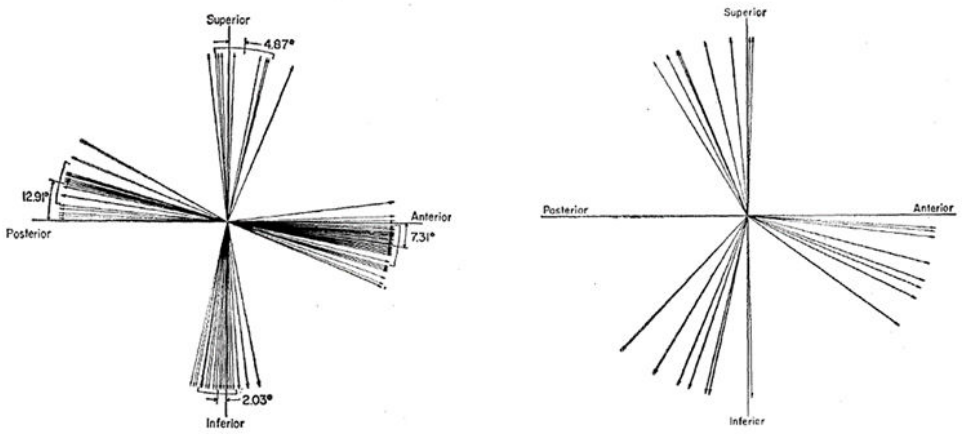

Figure 3. DSGCs can be classified into discrete types based on their functional properties. Distributions of directional preferences reveal four types of ooDSGCs (left) and three types of ON-DSGCs (right). Each vector indicates preferred direction of one DSGC. Axes represent the visual field. From Oyster and Barlow, 1967 (2).

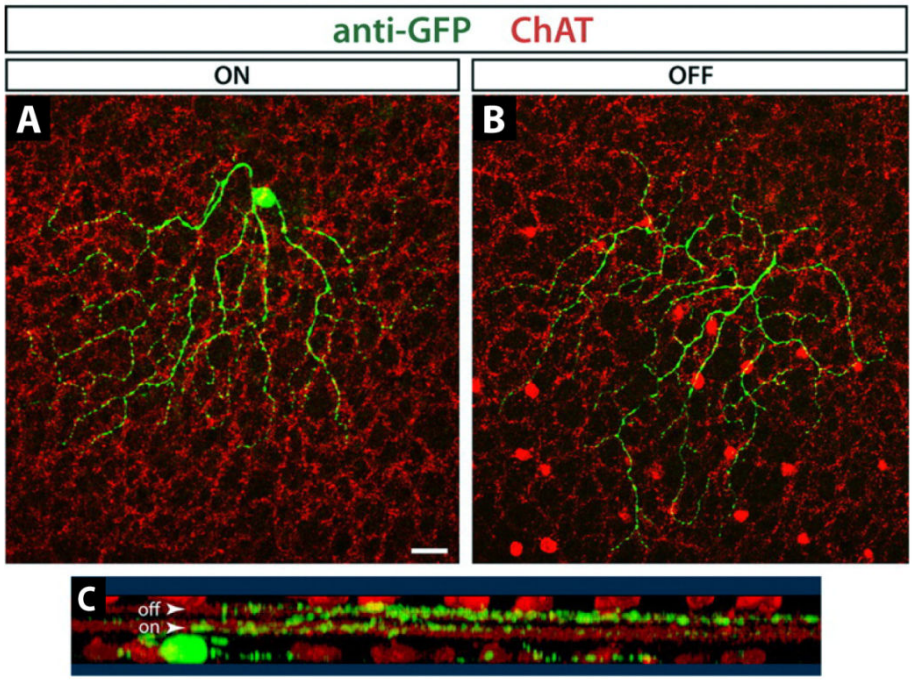

Figure 4. Morphology of an ooDSGC revealed by GFP labelling in a transgenic mouse line. (A-E) En face views of the ON (A) and OFF (B) dendritic arbors and their co-stratification with the ON and OFF SAC plexus (in red) respectively, indicated by immunostaining to choline acetyltransferase, a SAC marker. (C) Rotated view of the ooDSGC to illustrate its bistratified dendrites and colamination with SACs. Adapted from Kay et al., 2011(4).

ooDSGC that it connects to. Therefore, each SAC dendrite responds best to motion in the opposite direction relative to that preferred by its postsynaptic ooDSGC (Figure 12).

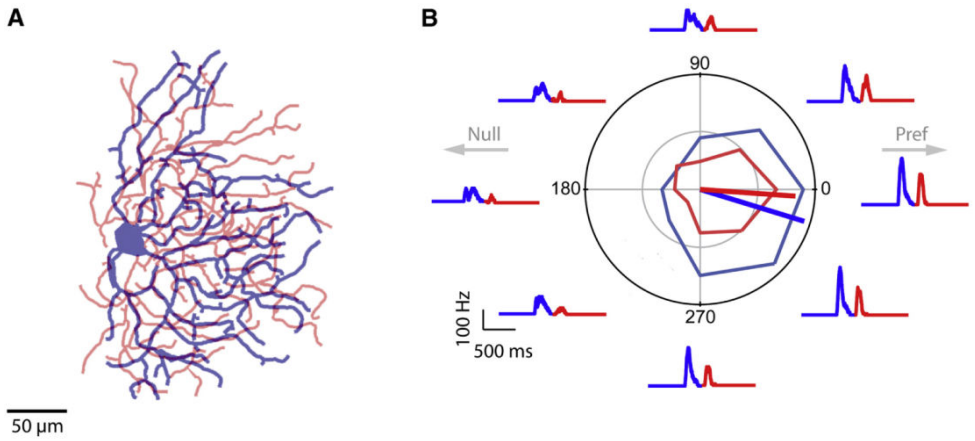

Figure 5. (A) Reconstruction of the ON (blue) and OFF (red) dendritic arbors of an ooDSGC. (B) ON (blue) and OFF (red) responses of an ooDSGC (similar to that in A) to a spot of light moving in eight directions across its receptive field. Distance from origin of the polar plot indicates spike rates. Preferred direction is indicated by the vector and the extent of the preference by its length. Surrounding traces are spike rate histograms in each direction. From Trenholm et al., 2011 (5).

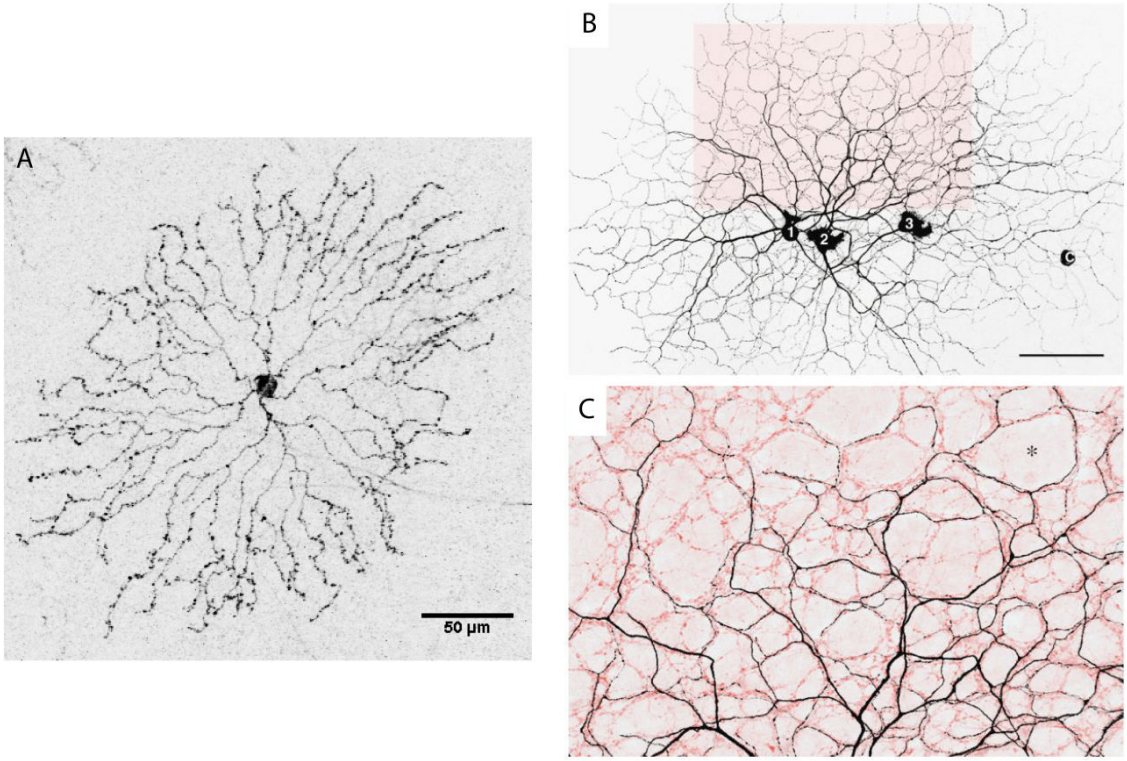

Figure 6. (A) A starburst amacrine cell (SAC) in the mouse retina. As the name suggests, it has radially symmetric dendrites. (B-C) The dendrites of SACs cofasiculate with ooDSGC dendrites in the rabbit retina. (B) The dendritic morphologies of three ooDSGCs as revealed by neurobiotin injections. (C) High-magnification view of highlighted region in (B), showing the ON dendritic plexi of SACs in red and ooDSGCs in black. The close interaction between the dendrites of these two cell types form a series of lacunae, or gaps, one of which is marked by the asterisk. (B-C) are from Vaney and Pow, 2000 (7).

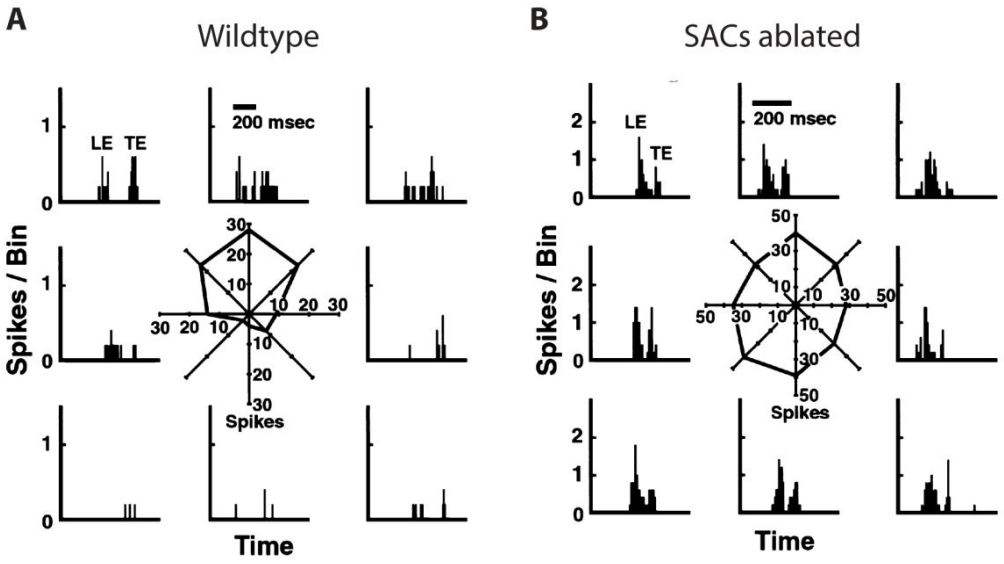

Figure 7. Responses of ooDSGCs in wildtype mouse retinas (A) or SAC-ablated retinas (B) to a moving bar. Polar plots are a sum of responses from four trials in eight directions. Surrounding traces are representative responses from a single ooDSGC. The cell fires when the bar enters (leading edge, LE) and leaves (trailing edge, TE) its receptive field. Normal ooDSGCs respond most strongly for bars moving in their preferred direction, while ooDSGCs in SAC-ablated retinas respond similarly in all directions. From Yoshida et al. 2001 (8).

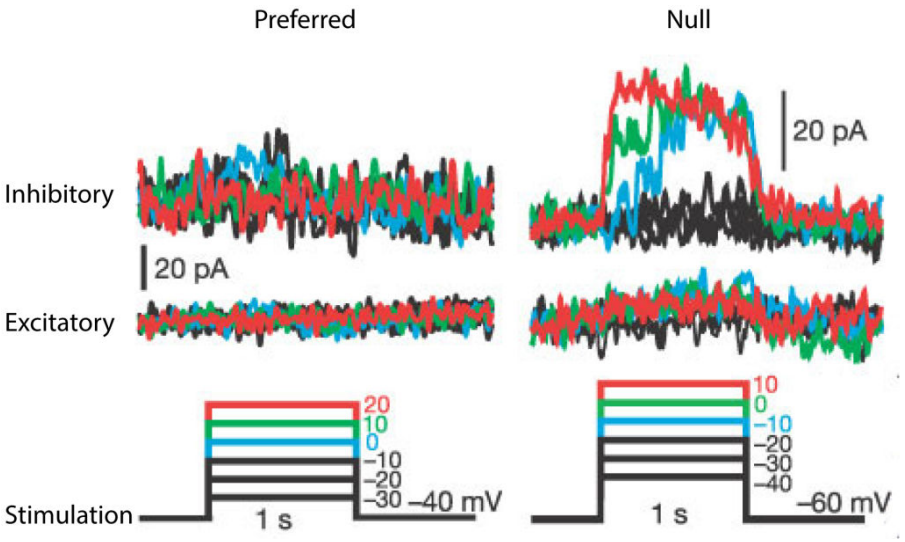

Figure 8. Inhibitory and excitatory currents recorded from ooDSGCs when neighboring SACs on their preferred or null side are stimulated with depolarizing voltage steps. Stimulation and corresponding responses are color coded. Depolarization of SACs on the null side, and not those on the preferred side, elicits inhibitory currents. There is a lack of excitatory inputs from SACs on either side. Adapted from Fried et al., 2002 (9).

3. ON DSGCs

Response properties of ON DSGCs

A separate class of direction-selective RGCs responds only to light increments. Called ON DSGCs, they detect stimuli moving in one of three directions: dorsal, ventral and nasal, with a slight offset from the horizontal and

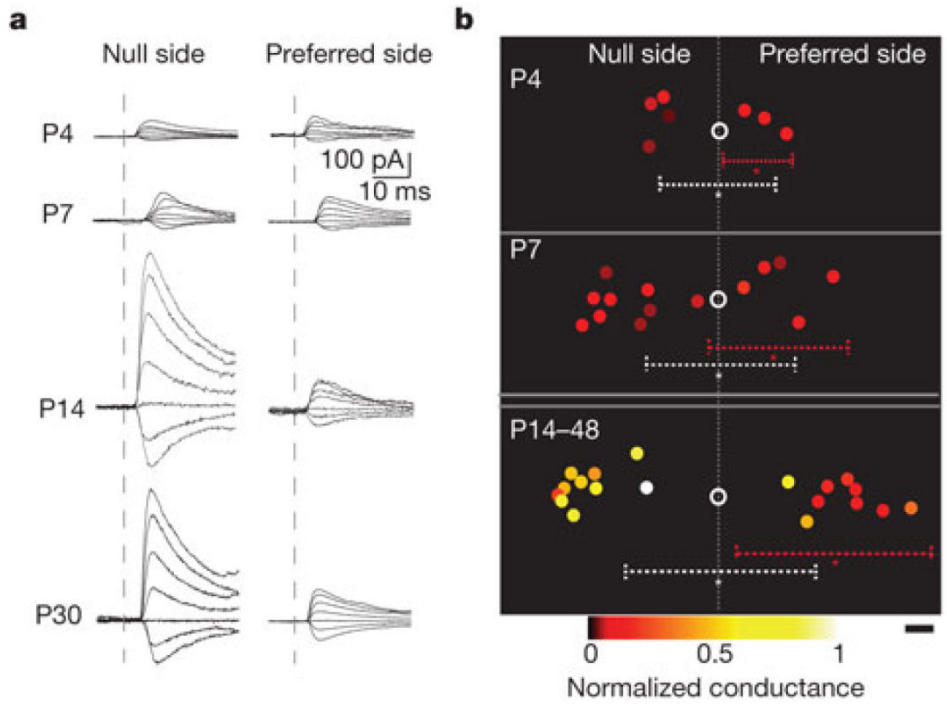

Figure 9. (a) Postsynaptic GABAergic currents measured from ooDSGCs in response to depolarizations of neighboring SACs on the null or preferred sides at postnatal days 4, 7, 14 and 30. (b) Relative positions of the cell bodies of the ooDSGCs and interacting SACs. Open circles in the middle represent ooDSGCs. Filled circles represent SACs, color-coded for whole-cell GABAergic conductance strength (normalized across all ages) elicited in the postsynaptic ooDSGC. Dashed lines represent average dendritic arbor diameter of the ooDSGC (white) and SACs (red), and asterisks, the average cell body locations. From Wei et. al., 2011 (12).

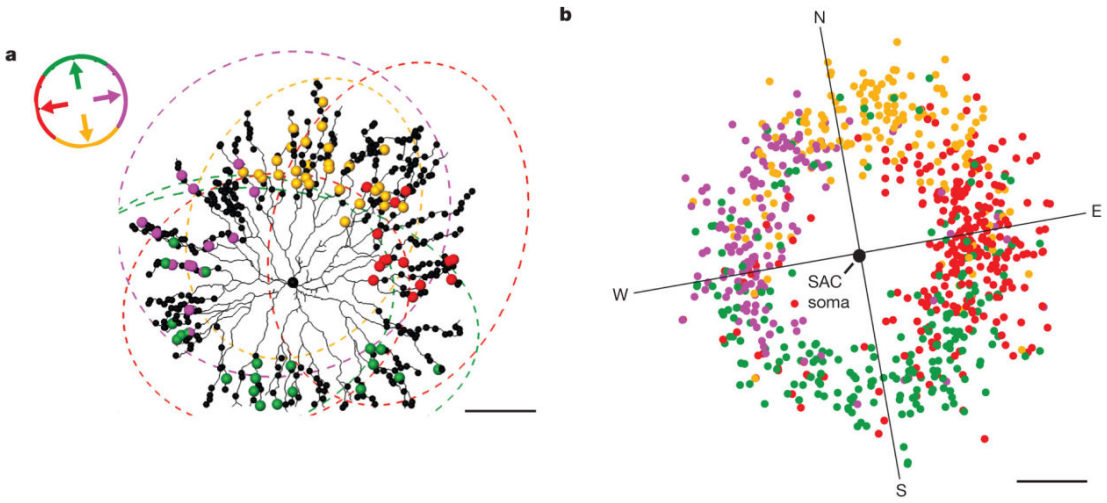

Figure 10. (a) An OFF SAC and its putative output synapses along the distal tips (black dots). The dendritic trees of nearby ooDSGCs are outlined in color-coded dashed ellipses and their preferred directions indicated in the top-left. The SAC-ooDSGC synapses are similarly color-coded. Although the dendritic trees of single ooDSGCs and SACs can overlap extensively, ooDSGCs mostly connect to individual SAC dendrites that are oriented along their null direction. For instance, southward-pointing SAC dendrites tend to make synapses onto ooDSGCs preferring northward direction. (b) Output synapse locations of 24 SACs overlaid on one another. From Briggman et al., 2011 (13).

vertical axes (Figure 3) (1, 15, 16). Each direction is encoded by two types of ON DSGCs with different response properties: one has sustained spike responses while the other has transient responses (Figure 13).

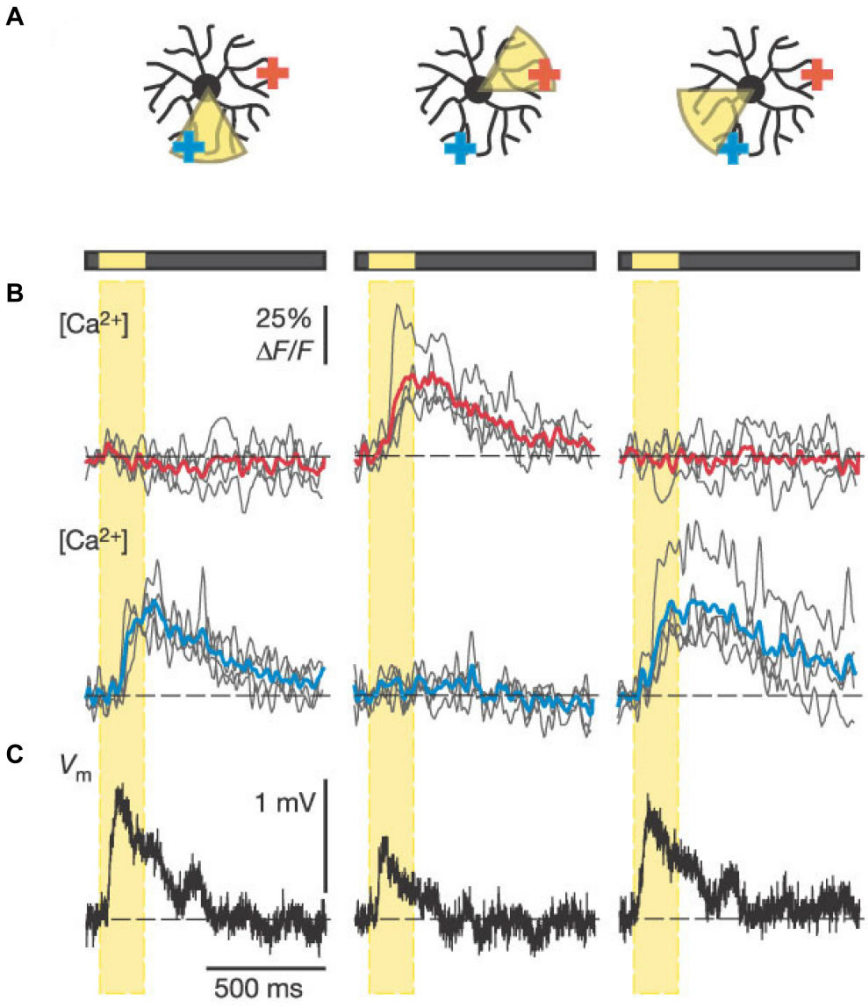

Figure 11. Local stimulation of SAC dendrites evokes calcium signals which are required for neurotransmitter release. (A) Sectors of the dendritic field of a SAC are being illuminated (in yellow) at random while dendritic calcium concentrations [Ca^{2+}] are being measured locally at two sites within its dendritic arbor. Stimulation sites and corresponding Ca^{2+} traces are color-coded in blue and red. While the cell is depolarized (C, membrane voltage V_m) regardless of the site of illumination, calcium signals are only evoked when the recording site is illuminated. In the instance shown on the left, illumination over the blue cross elicits an increase in [Ca^{2+}] at the blue cross but not at the red cross. From Euler et al., 2002 (14).

Morphology of ON DSGCs

As their functional properties suggest, ON DSGC dendrites ramify in just the ON sublamina within the IPL, co-stratifying with the dendritic plexus of ON SACs (Figure 14). Occasional processes to the OFF sublamina have been observed (15, 17). However, the morphologies of sustained and transient ON DSGCs differ in various aspects. First, sustained ON DSGCs have more terminal dendrites arising perpendicularly from their parent dendrites. Second, transient ON DSGCs show tracer coupling to non-SAC amacrine cells while sustained ones do not (18, 19).

Mechanism of direction selectivity in ON DSGCs

The direction-selective responses of ON DSGCs, just like their bistratified counterparts, are generated by asymmetric inhibition from ON SACs on their null side. This was shown by expressing channelrhodopsin in SACs, photostimulating them, and recording responses from their postsynaptic, ON DSGCs (20). Stimulating null-side SACs elicited more inhibitory currents than those on the preferred side while cholinergic input was

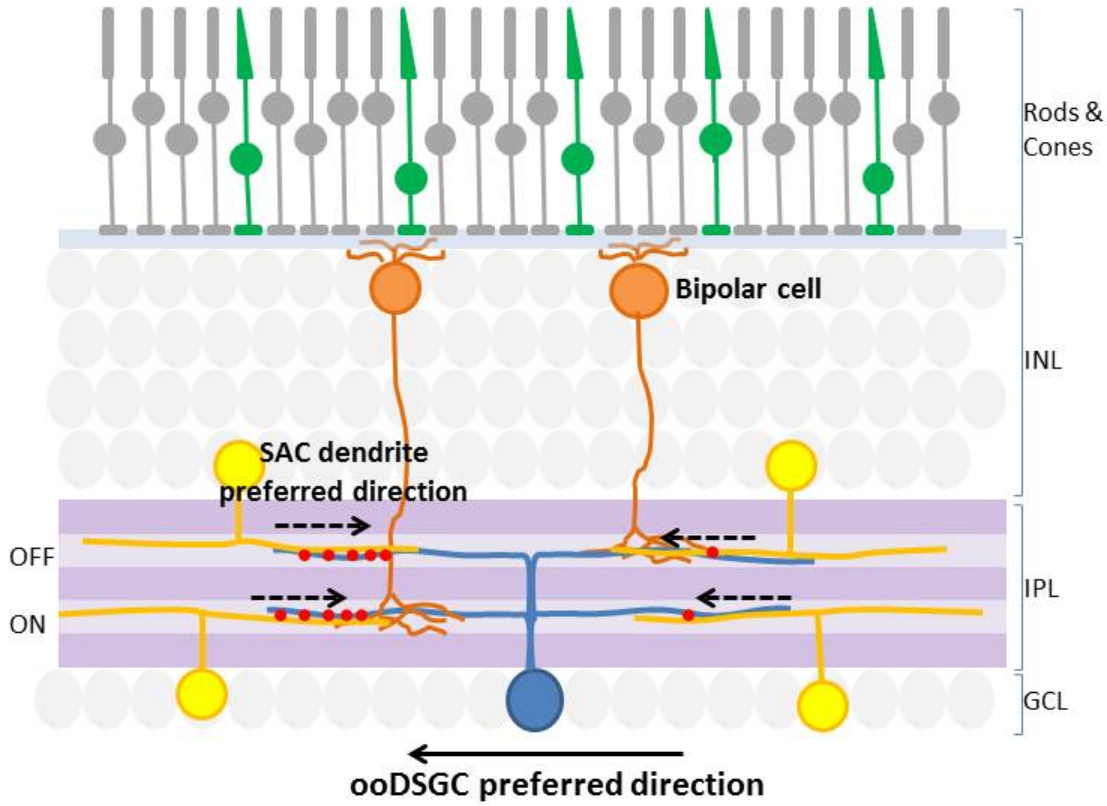

Figure 12. Schematic of a retinal cross-section illustrating the ooDSGC direction-selective circuit. In this model, the ooDSGC (in blue) prefers direction to the left (solid arrow). SAC dendrites are in yellow, with their preferred direction marked by the dashed arrows. SAC dendrites preferring motion direction opposite to that of the ooDSGC make more inhibitory synapses (red dots) onto the ooDSGC. INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. OFF, OFF sublamina of the IPL containing the dendrites of OFF SACs. ON, ON sublamina of the IPL containing the dendrites of the ON SACs.

symmetric throughout. Glutamatergic input from ON bipolar cells are not direction-selective either (21). ON-DSGCs, however, respond better to slower stimuli compared to ooDSGCs (22).

4. OFF DSGCs

The latest DSGC type to be discovered is an OFF DSGC in the mouse retina (3). Called J-RGCs for their enriched expression of junctional adhesion molecule B (JAM-B), they have remarkably asymmetric dendrites that point ventrally and laminate within the outermost sublamina of the IPL (Figure 15).

These ventrally asymmetric J-RGCs respond to upward motion in the visual scene. Interestingly, a small fraction of J-RGCs residing in the most dorsal and ventral parts of the retina have symmetric dendritic arbors and are not direction-selective (Figure16) (3, 23). Such remarkable correlation between the dendritic structure and their direction-selective responses is unprecedented.

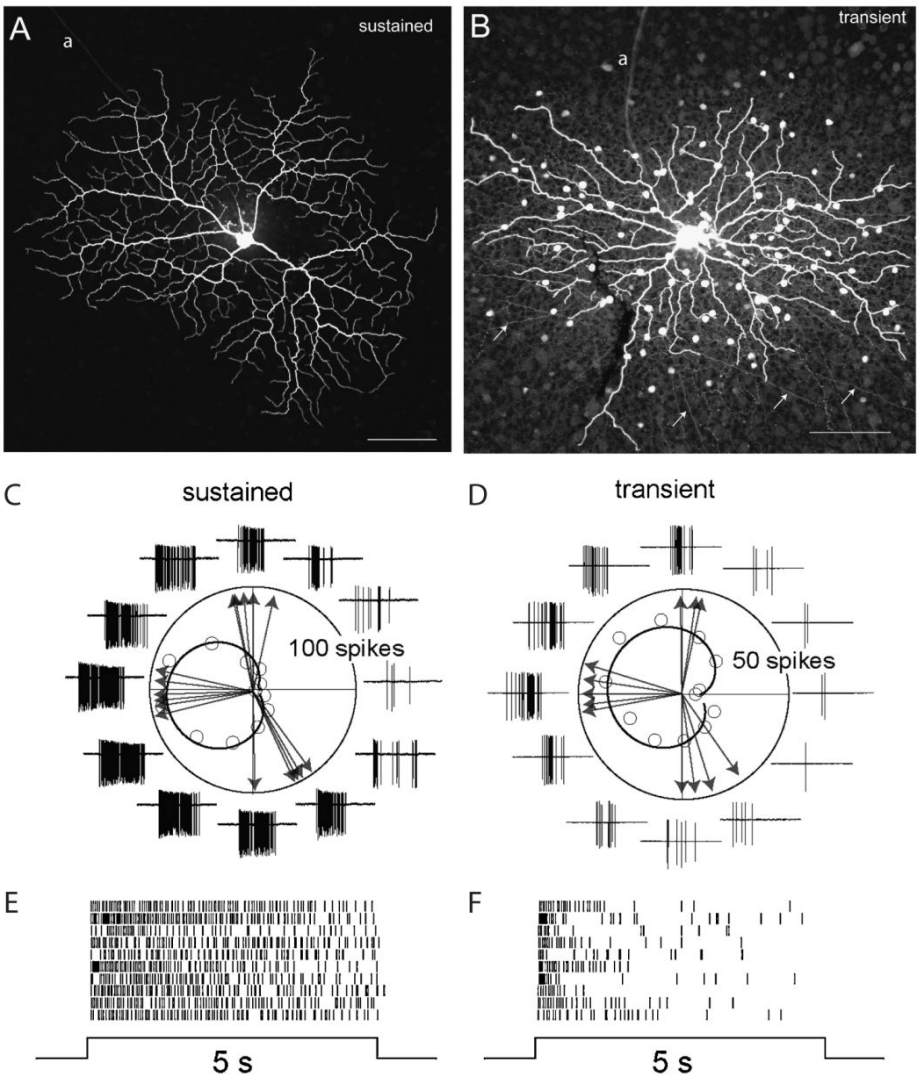

Figure 13. Dendritic morphologies of sustained (A) and transient (B) ON DSGCs in the rabbit retina. 'a' marks the axon. (C, D) Responses to a moving bar in 12 directions from multiple ON DSGCs reveal three subtypes within each type of ON DSGC. Each arrow represents the preferred direction of one cell. Traces around the polar plot are responses from a single ON DSGC; its mean number of spikes in each direction is indicated with open circles. (E, F) Responses to a stationary spot of light at the receptive field of sustained (E) and transient (F) ON DSGCs. Each row of ticks represents action potential spikes from one cell. From Kanjahan and Sivyer, 2010 (19).

The mechanism by which J-RGCs generate their direction selectivity remains unclear. It is probably very different from the SAC-mediated circuit that the ooDSGCs and ON DSGCs utilize, since J-RGCs do not co-laminate with SACs. Finding out the interneuron types that interact with J-RGC dendrites will be a key step towards elucidating its direction-selective circuit.

5. Conclusion

The DSGCs covered above make up most of the direction-selective ganglion cell types but are, by no means, exhaustive. With more extensive functional analyses, additional DSGC types may be revealed (24). Further structural analysis at both the dendritic and synaptic level will also shed light on the precise mechanisms that create direction-selectivity. It will be equally intriguing to understand how these direction-selective computations from the retina are integrated at higher brain centers.

Glial Cells of the Retina

Helga Kolb

Created: May 1, 2001; Updated: April 17, 2007.

Three basic types of glial cell are found in the human retina: Muller cells, astroglia, and microglia. All were described for the retina by Cajal (1) more than 100 years ago in 1892.

Muller Cells

Muller cells are the principal glial cell of the retina. They form architectural support structures stretching radially across the thickness of the retina and are the limits of the retina at the outer and inner limiting membrane, respectively. A complete understanding of the shape of a Muller cell is best seen after Golgi staining, as shown originally by Cajal (1) below (Fig. 1).

Muller cell bodies sit in the inner nuclear layer and project irregularly thick and thin processes in either direction to the outer limiting membrane and to the inner limiting membrane. Muller cell processes insinuate themselves between cell bodies of the neurons in the nuclear layers and envelope groups of neural processes in the plexiform layers. In fact, retinal neural processes have direct contact, without enveloping Muller cell processes, only at their synapses.

A single progenitor cell gives rise to both Muller cells and retinal neurons (2), although apparently in two phases. The earliest phase neurons born at the apical margin of the neuroepithelium, adjacent to the pigment epithelium, produces primary neurons consisting of cone cells, horizontal cells, and ganglion cells. The second phase of cells, also born at the apical margins, produces Muller cells and rod photoreceptors, bipolar cells and amacrine cells (3). All of the developing neurons and the Muller cells have to migrate inward to their final position, and it is thought that the Muller cell processes and trunks guide much of the neuron migrations and direct the neurite differentiations (Fig. 2).

The junctions forming the outer limiting membrane are between Muller cells and other Muller cells with photoreceptor cells as sturdy desmosomes' coronial adherents. In some species, gap junctions (specialized membrane associations and channels that allow passage of small molecules and ions) or tight junctions are part of these Muller cell junctions (4) but not so in mammalian species, where no dye coupling has ever been observed (3, 5). The surface of the Muller cell facing the pigment epithelium and subretinal space is expanded by many projections of the Muller cell membrane, known as apical villi. The inner limiting membrane, on the other hand, is formed by the conical endfeet of the Muller cell, but no specialized junctions are seen here. Muller cells also form endfeet on the large retinal blood vessels at the inner surface of the retina. The surface of the Muller cell membrane facing the vitreous is covered with a mucopolysaccharide material and thus forms a true basement membrane.

Muller cells contain glycogen, mitochondria, and intermediate filaments that are immunoreactive for vimentin and to some extent to glial fibrillary acidic protein (GFAP). The latter filaments are normally in the inner half of the Muller cells and their endfeet, but after trauma to the retina, such as retinal detachment, both vimentin and GFAP are massively upregulated and found throughout the cell (see below) (6, 7) (Fig. 3).

Muller cells have a range of functions, all of which are vital to the health of the retinal neurons. Muller cells function in a symbiotic relationship with the neurons (for an excellent review, see Reichenbach and Robinson (3)). Thus, Muller cell functions include:

1. Supplying end products of anaerobic metabolism (breakdown of glycogen) to fuel aerobic metabolism in the nerve cells.
2. They mop up neural waste products, such as carbon dioxide and ammonia, and recycle spent amino acid transmitters.

3. They protect neurons from exposure to excess neurotransmitters, such as glutamate, using well-developed uptake mechanisms to recycle this transmitter. They are particularly characterized by the presence of high concentrations of glutamine synthase.
4. They may be involved in both phagocytosis of neuronal debris and release of neuroactive substances such as GABA, taurine, and dopamine.
5. They are thought to synthesize retinoic acid from retinol (retinoic acid is known to be important in the development of the eye and the nervous system) (8).
6. They control homeostasis and protect neurons from deleterious changes in their ionic environment by taking up extracellular K^+ and redistributing it.
7. They contribute to the generation of the electroretinogram (ERG) b-wave (4, 9), the slow P3 component of the ERG (10), and the scotopic threshold response (STR) (11). They do so by regulation of K^+ distribution across the retinal vitreous border, across the whole retina, and locally in the inner plexiform layer of the retina (see figure below from Reichenbach and Robinson (3), adapted from Newman (12)) (Fig. 4).

Astrocytes

Astrocytes are not glial cells of the retinal neuroepithelium but enter the developing retina from the brain along the developing optic nerve (13, 14). They have a characteristic morphology of a flattened cell body and a fibrous series of radiating processes. Intermediate filaments fill their processes, and thus they stain dramatically with antibodies against GFAP (15). Astrocyte cell bodies and processes are almost entirely restricted to the nerve fiber layer of the retina. Their morphology changes from the optic nerve head to the periphery: from extremely elongated near the optic nerve to a symmetrical stellate form in the far peripheral retina (15) (Fig. 5 and Fig. 6).

In Golgi and immunocytochemical staining, they look like cell bodies with fibrous tangles aligned along the ganglion cell axons coursing through the nerve fiber layer. In distribution, astrocytes reach their peak on the optic nerve head and have a fairly uniform decline in density in radiating rings from the nerve head. They are not present in the avascular fovea or ora serrata (Fig. 7).

Thick and thin astrocytes have been distinguished on the basis of staining with antibodies to GFAP (16). Thus, astrocytes are arranged over the surface of the ganglion cell axon bundles as they course into the optic nerve head, forming a tube through which the axons run. Gap junctions and zonula adherens junctions have been described between astrocytic processes in cat retina (17).

The blood vessels running in and among the ganglion cell bundles are also covered by both processes and even an occasional cell body of an astrocyte. The function of astrocytes enveloping ganglion cell axons and the relationship to blood vessels of the nerve fiber layer suggest they are axonal and vascular glial sheaths and part of a blood-brain barrier. Similar to Muller cells, they are known to contain abundant glycogen, and they may form a nutritive service in providing glucose to the neurons. In addition, they probably serve a role in ionic homeostasis in regulating extracellular potassium levels and metabolism of neurotransmitters like GABA (Fig. 8).

Microglial Cells

The third glial cell type is supposedly of mesodermal origin and thus, strictly speaking, are not neuroglial as the astrocytes and Muller cells are. They enter the retina coincident with the mesenchymal precursors of retinal blood vessels in development (14). Microglial cells are ubiquitous in the human retina, being found in every layer of the retina.

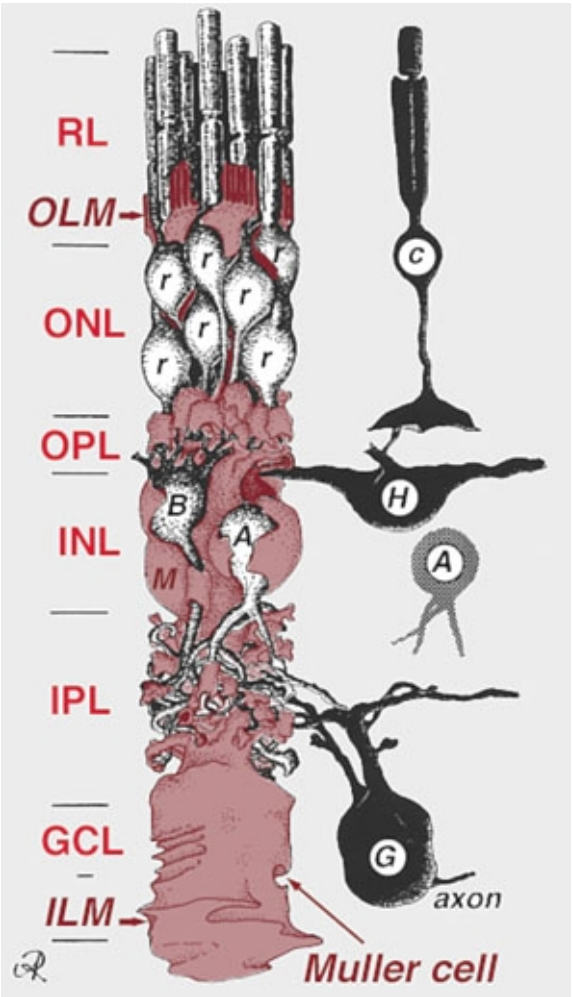

Figure 2. 3-D schematic drawing of the relationship between Muller cell and other retinal neurons.

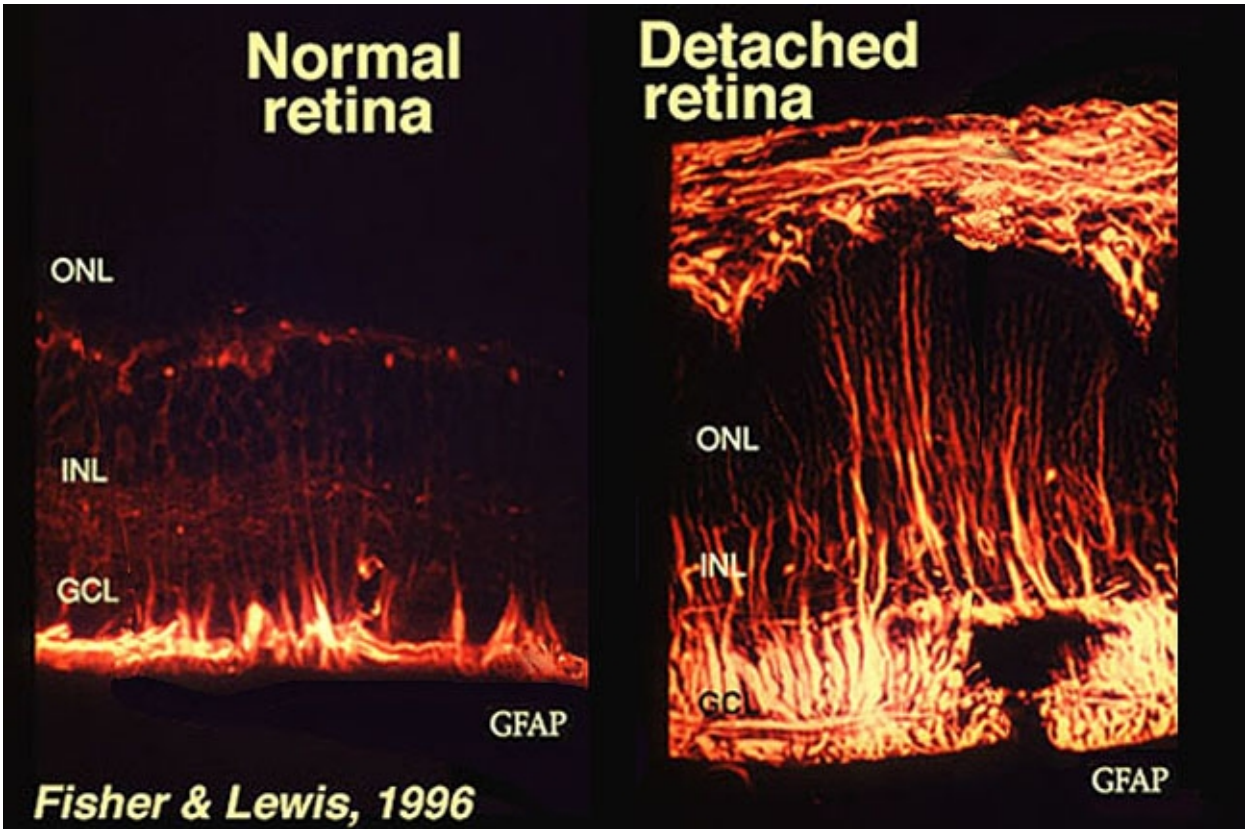

Figure 3. GFAP immunoreactivity in Muller cells. From Fisher and Lewis (7).

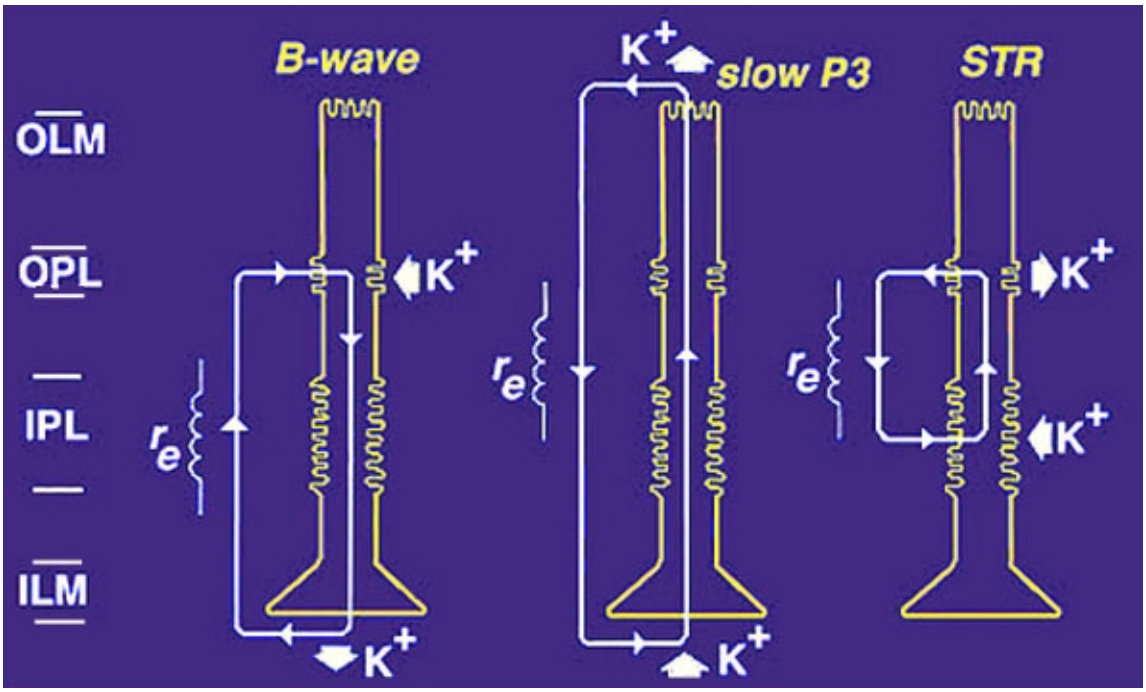

Figure 4. Regulation of K^+ by Muller cells in Muller cells.

In Golgi-stained retina, they look like strange, multipolar forms with small cell bodies and irregular short processes. In fact, in Golgi preparations they have sometimes been mistaken for nerve cells, particularly when they lie in a nuclear layer with a single orientation of their processes in the plexiform layer (Fig. 9).

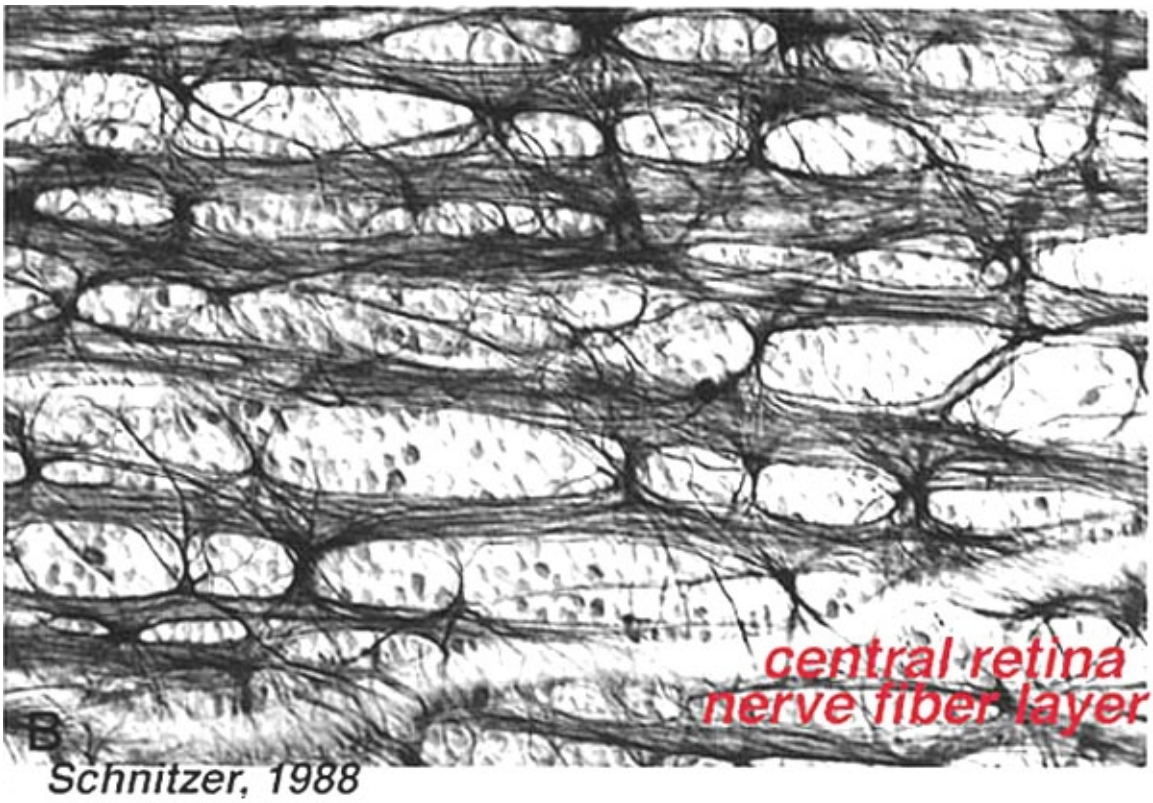

Figure 6. Astrocytes in central retina. From Schnitzer (15).

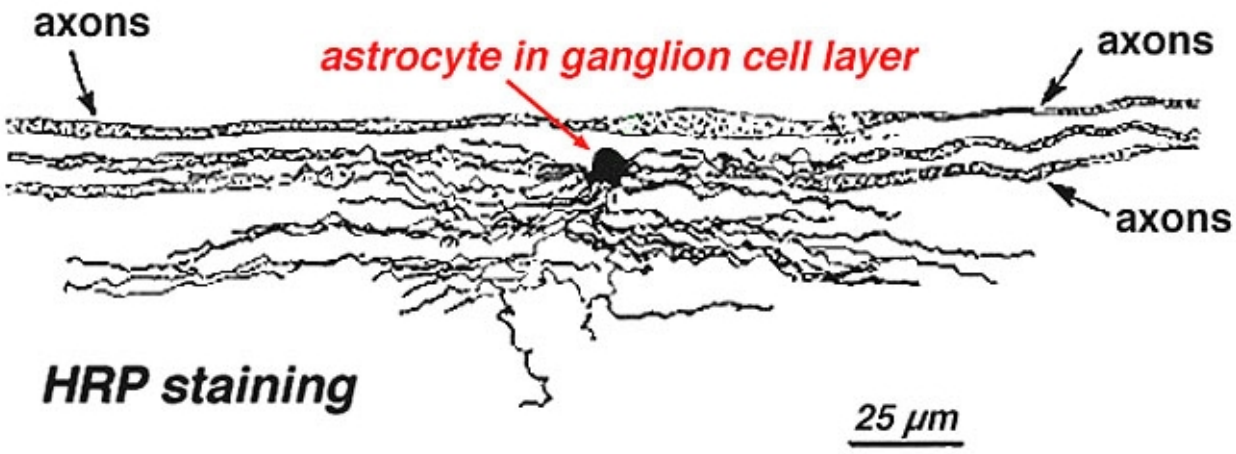

Figure 7. HRP staining of astrocytes in the ganglion cell layer.

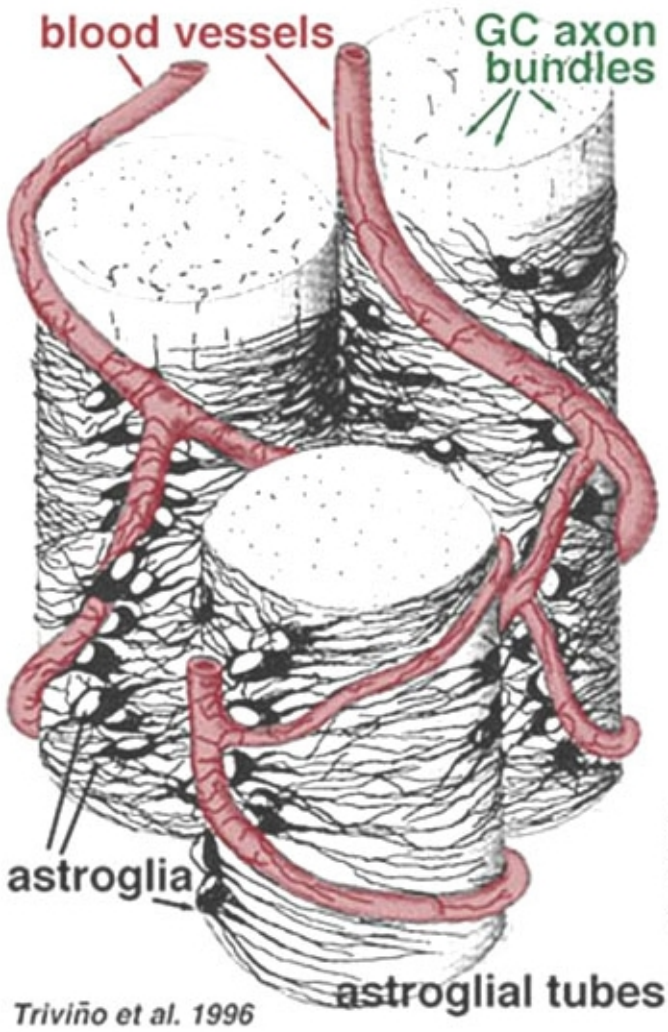

Figure 8. 3-D block of astrocytes arranged over the surface of ganglion cell axon bundles. From Trivino et al. (16).

Microglial cells may be of two types. One form is thought to enter the retina at earlier stages of development from the optic nerve mesenchyme and lie dormant in the retinal layers for much of the life of the retina. The other form of microglia appear to be blood-borne cells, possible originating from vessel pericytes (18, 19). Both types can be stimulated into a macrophagic function on trauma to the retina, and then they engage in phagocytosis of degenerating retinal neurons (Fig. 10).

Abstract

We summarize the development, structure, different neural types and neural circuitry in the human fovea. The foveal pit is devoid of rod photoreceptors and of secondary and tertiary neurons, allowing light to directly stimulate cones and give us maximal visual acuity. The circuitry underlying the transmission to the brain occurs at the rim of the fovea. The predominant circuitry is concerned with the 'private' cone to midget bipolar cell and midget ganglion cell pathways. Every cone drives two midget bipolar cells and two midget ganglion cells so that the message from a single cone is provided to the brain as a contrast between lighter signals (ON pathways) or darker signals (OFF pathways). The sharpening of this contrast message is provided by horizontal-cell feedback circuits and, in some pathways by amacrine circuitry. These midget pathways carry a concentric color and spatially opponent message from red and green cones.

Blue cones are sparse, even largely missing in the foveal center while occurring at somewhat higher density than elsewhere in the cone mosaic of the foveal slope. Signals from blue cones have different pathways to ganglion cells. The best understood is through an ON-type blue-cone-selecting bipolar cell to a non-midget, small bistratified ganglion cell. An OFF-center blue midget bipolar is known to be present in the fovea and connects to a blue OFF midget ganglion cell. Another OFF blue message is sent to a giant melanopsin ganglion cell that is present in the foveal rim area, but the circuitry driving that is less certain and possibly involves an intermediate amacrine cell. The H2 horizontal cells are thought to be feedback neurons primarily of the blue cone system.

Amacrine cells of the fovea are mostly small-field and glycinergic. The larger field GABAergic amacrines are present but more typically surround the fovea in a ring of processes, with little or no penetration into the foveal center. Thus, the small field glycinergic amacrines are important in some sort of interplay with the midget bipolar–midget ganglion cell channels. We have anatomical descriptions of their synaptology but only a few have been recorded from physiologically. Both OFF pathway and ON pathway amacrines are present in the fovea.

Introduction

The central point of the visual field ahead of us is the image falling on the fovea in the human retina. This is the area of our visually sensitive retina where the cone photoreceptors are tightly packed, where rod photoreceptors are excluded and where all intervening layers of the retina are pushed aside concentrically to allow light to reach

the densely packed sensory cones with minimum scatter from overlying tissues. The fovea is where focusing on fine detail in the image is perfected, allowing us to read, discriminate colors well and sense three-dimensional depth.

General features of the fovea

Looking at the retina lining the back of the eyeball in a human, we can see the clear landmark of the optic nerve head (papilla) and radiating blood vessels (Figure 1). Temporal to the optic nerve head at a distance approximately 2.5 optic nerve (disk) diameters at roughly 3.4 mm distance lies a dark brown-yellowish area (Figure 1), in the center of which is the tiny circular fovea. The position of the fovea can be seen clearly in the retina illustrated in Figure 2A. This eye was treated with RNA-later for preservation, allowing for a clear view of a yellow macula lutea area and including the brown central point, (foveal pit) (Figure 2A).

The area called the macula by ophthalmologists is a circular area around the foveal center of approximately 5.5 mm diameter (Figure 2B) The macula lutea with the yellow pigmentation extends across the fovea into the parafoveal region and a little beyond. This area is about 2.5 mm in diameter (Figure 2B). The actual fovea is about 1.5 mm in diameter and the central fovea consists of a foveal pit (umbo) that is a mere 0.15 mm across (Figure 2B). This foveal pit is almost devoid of all layers of the retina beneath the cone photoreceptors. On the edges of the foveal pit the foveal slope is still mainly devoid of other layers but some cell bodies of retinal interneurons, bipolar and horizontal cells and even some amacrine cell processes are becoming evident. By the 0.35 mm diameter circular area the first ganglion cell bodies, the retinal neurons sending signals to the brain, are beginning to appear. All the central fovea that measures 0.5 mm across is avascular (FAZ).

The avascular nature of the central fovea is depicted in Figure 3. A human retina wholemount has the blood vessels immunostained with antibodies against Collagen IV and is photographed by stacked images in a confocal microscope. It is absolutely clear that the smallest capillaries even, do not intrude into the foveal center (Figure 3, f) of 500 μm diameter, thereby known as the avascular zone.

In vertical section of the human retina from the optic nerve head through the foveal pit and beyond (Figure 4), it is clear where the fovea is located relative to the nerve head (on). Figure 4 (a) is a confocal image after immunostaining with antibodies that are specific for cone photoreceptors [arrestin antibodies for cones, green; cytochrome C antibodies for mitochondria, blue; and for Müller glial cells and RPE, antibodies against cytoplasmic retinaldehyde binding protein (CRALBP), red]. In comparison is seen an optical coherence tomography (OCT) picture in Figure 4 (b) of exactly the same area of human retina. In both images it is clear that the second and third order neurons of the inner nuclear and ganglion cell layers respectively are not present in the foveal pit.

In the foveal pit the only neurons are cone photoreceptors, all with slim inner segments, packed cell bodies, up to 6 layers deep reaching to the floor of the foveal pit (Figure 5, green cells). However, there are many expanded-looking Müller glia surrounding these cones (Figure 5, red profiles). A central bouquet of cones has their synaptic pedicles ending at the foveal pit floor (Figure 5, green spots, arrows), whereas the cones surrounding them stretch their axons (known as Henle fibers) and presynaptic pedicles away from the center of the foveal pit to the foveal slope area (Figure 5, green spots form a continuous line, arrows). The lack of blood vessels in the central pit can be seen by the absence of the blue circular profiles there (Figure 5, bv).

O'Brien and colleagues (1) very elegantly illustrated the cone axons radiating out from the foveal pit forming the Henle fiber layer and terminating in distant pedicles in a whole mount monkey retina (Figure 6). The picture would be very similar in a human retina. The Henle fiber layer is a combination of outward radially directed axons of the cones, and where rods begin to appear, also rod axons, and Müller cell processes. It is interesting to note in Figure 5 that the pedicles of the very central bouquet of cones are widely spaced ending on the foveal pit

floor. We know from Figure 5 that these central bouquet cone pedicles are separated by voluminous Müller cell elements.

Development of the fovea

Understanding how the primate fovea develops from fetal to adult stage of the retina has been a very difficult task in vision research. This has, of course been due to the difficulty of obtaining retinas from human pre-birth and baby eyes. Even fetal monkey material has been scarce to obtain. Dr. Anita Hendrickson (Figure 7) at the University of Washington, Seattle, spent most of her career pursuing this subject of retinal research, and has contributed almost all we know.

The earliest fetal retinas examined (2) were from a week-22 eye. The fovea is not recognizable at this stage, because the central region of the retina, where the fovea will develop, consists primarily of several layers of ganglion cell bodies and inner nuclear layer cells (INL), presumably amacrine and bipolar cells (Figure 8, a). A single layer of developing cones stretches from outer plexiform layer (OPL) to pigment epithelium and choroid (Figure 8, a, right inset). A hint of a developing cone pedicle is seen (Figure 8, right red arrow) but there is no sign of outer segments of cones (Figure 8, right, apposing red arrowheads). By fetal week 28, an indentation of the retina at the thickest ganglion cell layer appears and can be considered the earliest sign of the foveal pit (Figure 8, b, P). The inner nuclear layer has become thinner and appears pushed out of the pit (P) but a kind of split is occurring in the middle of the INL known as the transient layer of Chievitz (TC, Figure 8, c) (3). By fetal week 37 (Figure 8, c) a pronounced foveal pit is evident (P), the ganglion cells are thinned to 2 or 3 deep and the TC area in the INL appears like a sheared, radially projecting area of probable Müller cell fibers. Through the latter two fetal stages, where the foveal pit is becoming obvious, the cones are still immature, arranged in a single layer and have no visible outer segments (Figure 8, b and c). However, there is the first suggestion of the cone axons being tilted away from their cell bodies to form the early Henle fiber layer.

It is interesting to closely examine the cone photoreceptors in the fetal 35-to-37-week retinas as illustrated by Hendrickson and coauthors (2). Figure 9 shows how immature the cones of the foveal pit are compared with those of the cones at some distance from the fovea (Figure 9. 2 mm from fovea). At the foveal pit area, the cones are just stubby cells with a synaptic pedicle, little to no lengthened inner segment and zero outer segments (Figure 9, fovea). By 800 μm to 2 mm from the developing foveal pit, the cones become elongated vertically and have definite cone pedicles. Most cell bodies descend away from the external limiting membrane and have elongating axons that are angled away from the foveal pit, forming the early Henle fiber layer. Inner segments are long, but the outer segments are still not formed. (Figure 9, 800 μm and 2 mm).

At birth of the human baby the retina in the eye is looking recognizably foveate (Figure 10, a). The foveal pit now contains a very thin, only one layer thick, ganglion cell layer, a thin inner plexiform layer (IPL) but a prominent inner nuclear layer (INL) (Figure 10, a). The cones are now evident as straight vertical cones with synaptic pedicles, cell bodies and inner segments. There are probably developing cone outer segments too (not easy to see at this magnification). But the pit is still several cell layers thick with only the cones on the foveal slope beginning to angle away from the pit. Further out on the foveal slope the cone Henle fiber layer is obvious now (Figure 10, a). By 15 months after birth, the baby retina has a definite fovea and even the central cones are angling out to the foveal slope. Inner and outer segments are well developed in the pit and no other layers of the retina are here anymore (Figure 10, b and c). By 13 years the fovea is completely developed (Figure 10, d) (2).

What forces could cause this remarkable transformation of an evenly thick multi-cell, layered retina to become concavely dimpled, buckled up and stretched outwards to form a single layered pit at the fovea and a high sided sloping tissue with the highest concentration of cell layers at the foveal rim. The developmental effort is to ensure that a central area of the retina is concentrated with the slimmest packed cones with no obstruction of incoming light by secondary and tertiary cell layers.

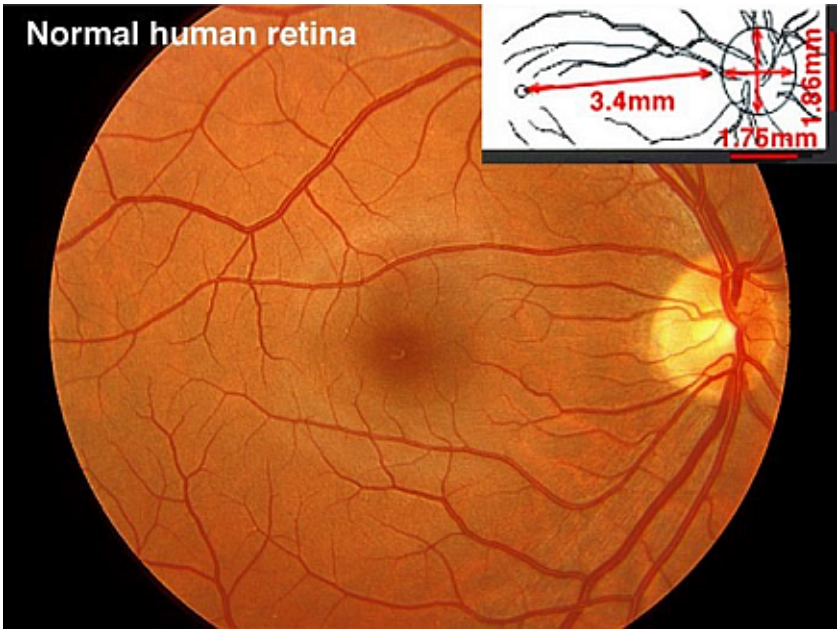

Figure 1. The normal human retina fundus photo shows the optic nerve (right), blood vessels and the position of the fovea (center).

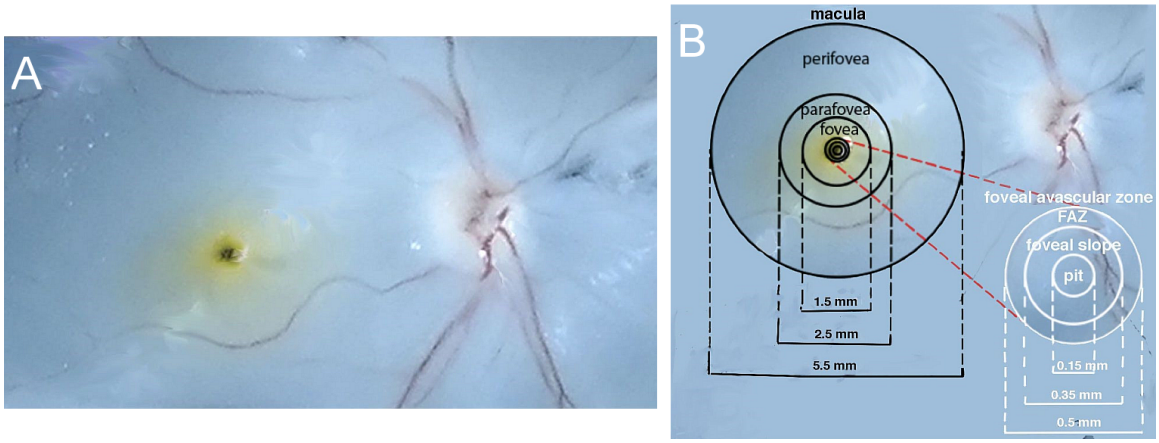

Figure 2. (A) An isolated human retina shows the optic nerve (right), blood vessels and the fovea (center) with surrounding macula lutea (yellow). Cuenca et al, prepublication. (B) A map of the whole macular area to show the dimensions of the foveal pit, foveal avascular zone, parafovea, perifovea, and the limits of the macula. Inset shows the dimensions of the foveal avascular zone, which is the fovea we are discussing here. Cuenca et al, prepublication.

The most recent investigations on this developmental phenomenon in the human (primate) retina provide evidence that the radial retinal glia - the Müller cells and possibly the astrocytes of the ganglion cell layer - are instrumental in this process (4). The Müller cells of the foveal pit are closely associated with the cone fibers and together they make up the Henle fibers layer (Figure 11A, red profiles). Bringmann and colleagues suggest that the Müller cells exert tractional forces onto cone axons fibers by a vertical contraction of the central most Müller cells and cones so they become elongated and very thin (Figure 11, B, blue arrows). After widening of the foveal pit by elimination of astrocytes in the pit and ganglion cell layers, the Henle fibers are forced, by horizontal contraction of their surrounding Müller cell processes in the outer plexiform layer, to pull the cone and then rod photoreceptor centrifugally away from the pit (Figure 11, B, orange arrows).

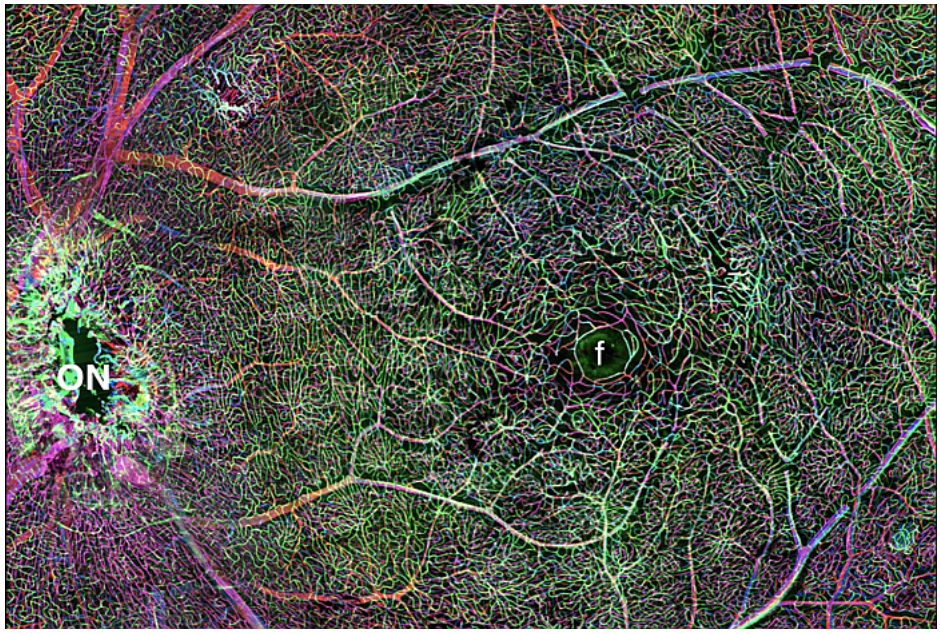

Figure 3. Wholemount of human retina with blood vessels immunostained with Collagen IV. The confocal microscopy of stacked images clearly shows the optic nerve head (ON) and all the blood vessels to the smallest capillaries. The capillaries surround the fovea (f), but do not enter it, thereby making the fovea avascular.

(b) An OCT image of the same retinal area in a normal human subject. The second and third order neurons of the retinal inner nuclear and ganglion cell layers respectively are not present in the foveal pit. Adapted from Cuenca, Ortuño-Lizarán and Pinilla 2018 (110).

The mosaic of cones in the fovea

The term "foveal cone mosaic" generally refers to the strikingly regular patterns of condensed cone inner and outer segments with largely triangular crystalline organization, which nevertheless includes non-randomly distributed discontinuities (5, 6). The less familiar and less understood part of foveal cones is the further course towards their synaptic terminals. It includes a two-step transition. From a two-dimensional mosaic for image reception it is rearranged into to a three-dimensional somata tiling, which then again spreads out to establish the concentric monolayered pedicle meshwork (7-9).

The mature human fovea consists of 3 spectral types of cone: red or long wavelength sensitive cones, L-cones; green or medium wavelength cones, M-cones; and blue or short wavelength cones, S-cones. These three types of

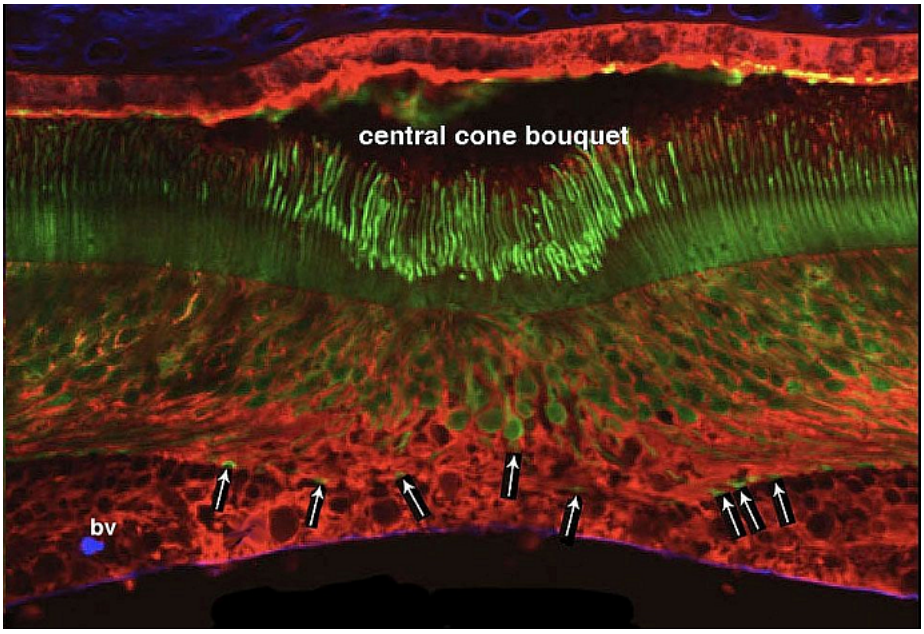

Figure 5. Vertical section of the human fovea immunostained with antibodies to cone arrestin (green), CRALBP (red) and Collagen IV (blue).

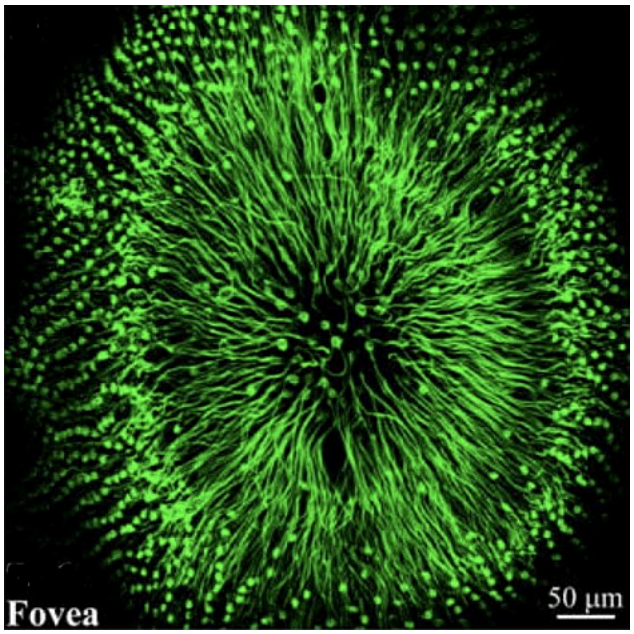

Figure 6. A wholemount monkey fovea immunostained with cone arrestin. The axons of the cones radiate out to a ring of cone pedicles. Central bouquet cone axons stay in the foveal pit. From O'Brien et al., 2012 (1).

cone are tightly packed and at their most concentrated (up to 200,000/mm^2 in the fovea (8, 10) (see Webvision Facts and Figures). Rods are not present in the foveal pit, appearing first halfway into the foveal slope, beyond the 300 µm diameter area (see Figure 2B).

It is extremely difficult to get a horizontal section through the central fovea particularly including the central bouquet of cones because of the concave nature of the fovea. Figure 12 (a) manages to get such a view of a horizontal slice through the inner segments of the cones of a human fovea (7). The tiniest central cones in the center of the photograph (Figure 12 a) are very slim at 2.5-3 µm in diameter and become progressively larger as

Figure 7. A young Anita Hendrickson at her microscope. From her obituary in 2017 (111).

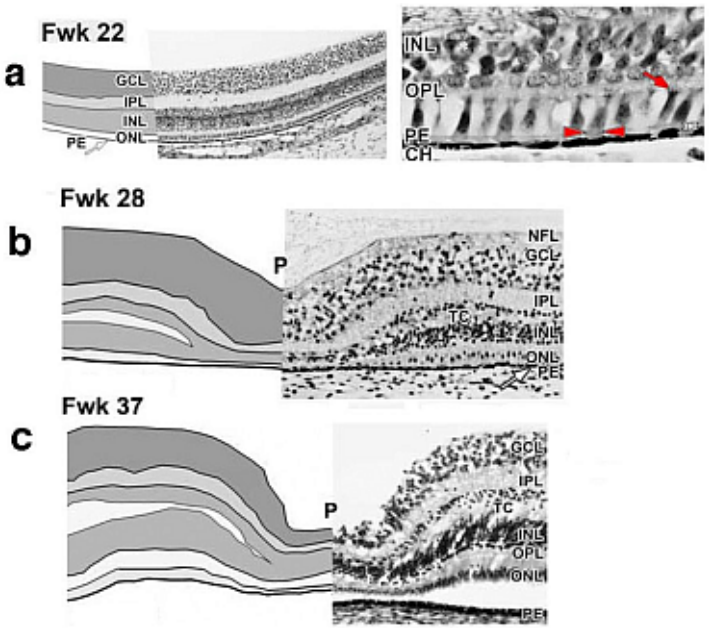

Figure 8. Foetal human retina at (a) foetal week (Fwk) 22, (b) Fwk 28, and (c) Fwk 37. The foveal position is not noticed at week 22 but in later weeks becomes dimpled as ganglion cells become displaced out radially from the developing foveal pit. In the beginning the retina is thick, multilayered and cones are undeveloped with no outer segments or visual pigment (a: right enlarged photo, red arrow heads point to a cone nucleus, a stubby inner segment, and a developing cone pedicle). From Hendrickson et al., 2012 (26).

they move along a radial gradient from the central bouquet. It is noticeable that the cones are not uniformly distributed in a hexagonal mosaic. Small patches of cones are hexagonal and then the patch is interrupted and shifts the surrounding patches slightly (Figure 12 a). Ahnelt and coauthors (11) noticed that these shifts in the mosaic usually were associated with the position of a slightly larger diameter cone. They proposed that these larger cones were the short wavelength cones, the S-cones, and described their morphological differences from the surrounding, more common L- and M-cones (11).

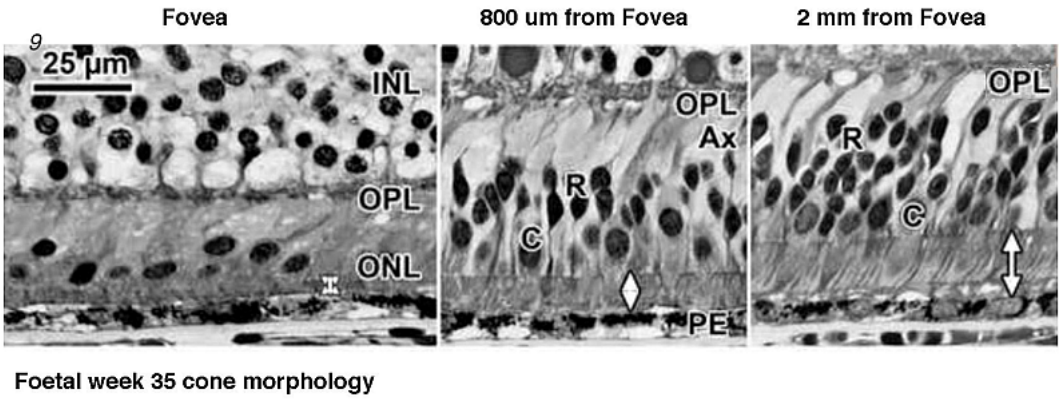

Figure 9. Sections of the retina of a human foetus at 25 weeks gestation. The cones of the fovea are still undeveloped with no outer segments, and a synaptic area with no axon. From 800 µm to 2 mm from the foveal center there are clear elongated inner segments but still no outer segments. The slanting of the cone axons out radially is beginning to be evidence of a developing Henle fiber layer. From Hendrickson et al., 2012 (26).

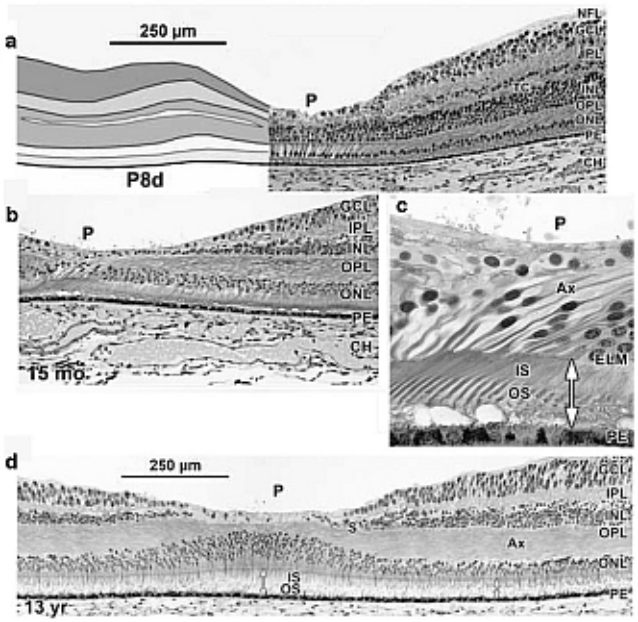

Figure 10. The foveal retina sections of a human from (a) postnatal 8 days (P8d), through (b) 15 months, to fully formed (d) 13 years. (c) At 15 months the cones are thin, have outer segments and squash together and, except for the central bouquet, send axons radially outwards as the Henle fiber layer. Second order neurons and ganglion cells are pushed along the foveal slope to form a pile of ganglion cell bodies at the foveal rim. From Hendrickson et al., 2012 (26).

S-cones are relatively rare in the retina compared with the much more dominant L- and M- cones. The S-cones are, however, ubiquitous in all vertebrate retinas, with the exception of cetaceans (12). As far as other mammals are concerned S-cones are commonly paired with L-cones to give them a dichromatic color sense. These L-cones vary in spectral peak, and the more mid-spectral types are called M-cones. In old world monkeys and apes, and in man an L-opsin gene duplication and further mutation produced an extra mid-spectral L-cone opsin subtype, M-cone opsin. The combination of L-cones, M-cones and S-cones provides trichromacy. This trichromacy allows discrimination of green, yellow and blue/purple hues.

There are differences in the genetic structure and locus of the S-cone visual pigment compared with the M- and L-cone pigments (13), yet the S-cones always form a consistent 8-10% of the mammalian cone photoreceptor population (14, 15). In primates and humans of course, the S-cones are rather scarce in the foveal pit. Some

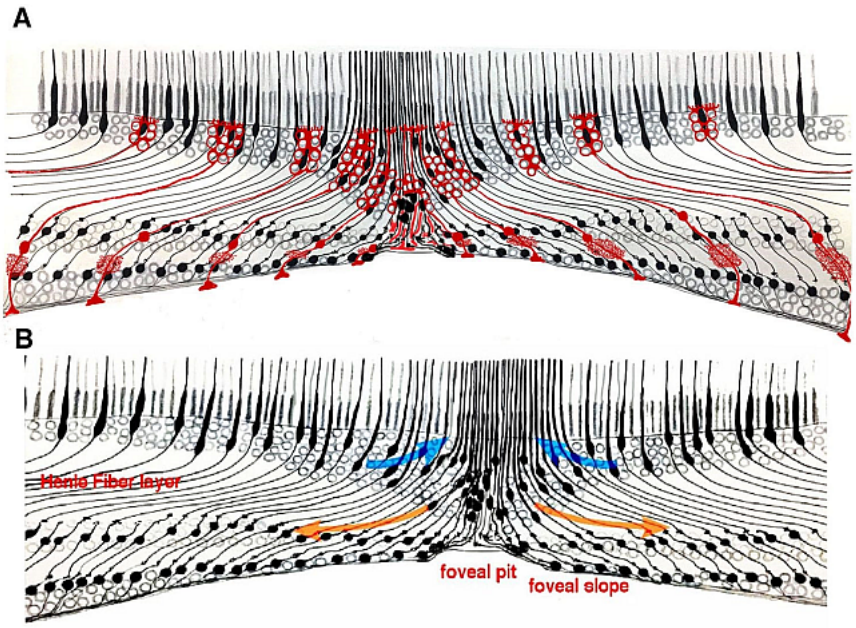

Figure 11. (A) A human fovea drawing to show that the Henle fiber layer consists of cone photoreceptor axons as well as envelopingMüller cells and fibers (red). B) Drawing to show the central foveal cone bouquet of thin and closely packed cones in the foveal pit. The cone axons on the foveal slope move radially out with the Müller cells to form the Henle fiber layer and end in pedicles that make connection with bipolar cells at some distance from the foveal pit. Blue arrows show the vertical squeezing and packing of the cones in the foveal pit and orange arrows show the displacement horizontally of the foveal cone axons, during development of the adult fovea.

authors suggest that there is a so-called blue cone blind spot (16). However, S-cones peak in number on the foveal slope of the human retina and here form about 12% of the population. Figure 12 (b) shows the peak S-cone distribution on the foveal slope in a human retina as identified by the larger size and arrangement in the mosaic breaking up the regular hexagonal pattern distribution of the other cone types. In Figure 12 (c) the S-cones have been colored in for clarity.

Since these earlier identifications of foveal S-cones on morphological criteria (11), antibodies against the S-cone pigments in the cone outer segments have been developed and are able to positively identify the S-cones in the overall population by immunocytochemical methods. In figure 13, the human foveal pit (FP) and foveal slope are immunostained with an S-cone antibody and illustrate the S-cones as black spots and angled black cone outer segments. In the foveal pit only a few S-cones appear interspersed in the mosaic of highest density (Figure 13). However, their proportion increases in surrounding areas and are at their highest density on the foveal slope (Figure 13 brown spots, top and right-hand side).

Figure 14 illustrates immunostaining in vertical section and the scarcity of S-cones in the foveal pit compared to the increase in number of this population of cones on the foveal slope, of a human retina. A map of the S- cone distribution in another human fovea is shown in Figure 15. The lighter to darker blue shading indicates less dense to denser S- cone presence. Note in both images (Figs. 14 and 15) there are very small numbers of S-cones in the foveal pit.

It has been rather easy to identify S-cones in the human fovea and the rest of the retina by these immunocytochemical techniques where S- cones can be visualized and distinguished from the surrounding L- or M-cones. Figure 16 shows a spectacular confocal image of the cones in near peripheral human retina by immunolabeling with cone arrestin, and by the HJ455 antibody to S-cones, that shows up the S-cone opsin both in the outer and inner segments.

Sadly, the L-cones and M-cones are not distinguishable on immunostaining techniques because their visual pigments are so close in structure. There is presently no antibody developed to separately mark them into L- or M- cone types. So, to identify L- and M-cones in the human fovea we must go to other more sophisticated techniques. Psychophysical measurements have suggested that L- cones usually outnumber M-cones by 2:1 in the human fovea (17). Microspectrophotometry of all cones in small patches of cones in the fovea of monkeys, has revealed that L- and M-cones occur in about equal proportion (18).

Newer techniques, introduced by Roorda and Williams (19), use adaptive optics to make direct measurements of spectral sensitivity of foveal cones in the living human eye (Figure 17). They found that humans varied greatly in the proportions of L-cones to M-cones: some individuals have almost equal proportions while others have a higher proportion of L-cones, even to the extreme of 16 L-cones to every M-cone (Figure17, BS). While the sparser S-cones are spaced regularly, the L- and M-cones lie randomly in the mosaic meaning that clusters of cones of the same spectral type will occur together as suggested from Mollon and Bowmaker's paper (18). Roorda and coauthors (20) concluded that L- and M-cones are in a random distribution in the foveal center (21). Nevertheless, the human subjects HS and BS in Figure 17 would seem intuitively to have a different perception of color. But both subjects were reported to have normal color vision (19). A single cone is achromatic, and its stimulation doesn't result in color vision unless there is comparison to stimulation of a neighbouring cone with different opsin (22). This comparison is done by retinal and brain neural circuitry (see later section on horizontal cell roles in spectral antagonism). Some elegant recent human adaptive optics studies and psychophysical reporting found that 79% of targeted cones in the foveal center, tested for color perception, correctly identified the color (hue) (22). Interestingly, others, using similar techniques of adaptive optics and human reports of hue for single cone stimulation with colored light in the fovea, found a considerable proportion of cones produced only white sensations (21).

The architecture of foveal fibres of Henle and pedicles

The process of centrifugal displacement by the Henle layer affects cone pedicles in different ways, depending on their eccentricity (Figure 18).

In the central bouquet of cones in the foveal pit, the pedicles appear to stay in place (Figure 18). In serial semithin (Figure 19, a) and electron microscopic (Figure 19, b) sections, a few roundish pedicles can be found at the foveal floor (Figure 19, a-c, circles). They are isolated from each other, thus lacking any connections to other cones via telodendria. Still they are contacted by dendritic processes running horizontally from a few interneurons (presumably bipolar and horizontal cells) from the foveal slope or even those neurons lying embedded in voluminous Müller cell processes (Figure 19 b-c, red circles around pedicles).

From the outer central cones, Henle fibers of short length terminate in peculiar tadpole-like pedicles (Figure 18, Figure 19, d-e). They too are largely isolated from neighboring terminals and are characteristic of the cone pedicles until about 1° or 288 µm out (23). Beyond this zone – still almost entirely established by cone terminals only – the pedicles make up a patchy mosaic (Figure 19, f-g). These terminals elaborate telodendrial networks that end on neighboring cone pedicles at gap junction connections (1, 24). This pedicle mosaic tends to establish radial arrays yet is locally influenced by interspersed glia (Figure 19, g).

The cones of the foveal pit project vertically downwards (Figure 20, a). As the concentrated central cones have to extend their axons radially out of the pit they, together with Müller cells, become the Henle fibers. The cone axons become longer and longer as they project onto the foveal slope and into the parafovea (Figure 20, b, 200-400 µm long). From then on, further out into the perifovea, the axons begin to shorten and by 3 mm eccentricity from the foveal pit axons are essentially no length at all (Figure 20, c-d, 4000 µm periphery). The Henle fiber layer is over as is the macula lutea (Figure 2A, Figure 2B).

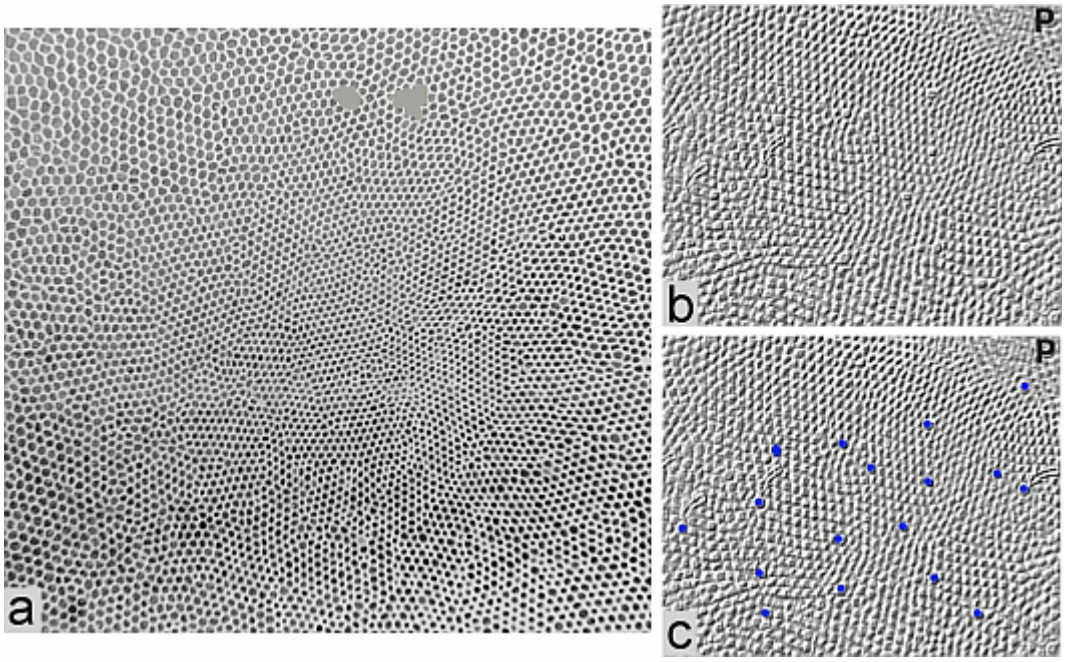

Figure 12. (a) A horizontally sectioned and stained human retina at the foveal pit and rod free area. (b) A whole-mount photograph of the foveal slope of a human retina. **P** (upper right corner) is the foveal pit. The larger S-cone profiles break up the mosaic of cones into disjointed groups of closely packed smaller profile cones [arrows in (a, b)]. (c) The larger S-blue cones in (b) are colored in as blue. From Ahnelt et al., 1987 (11).

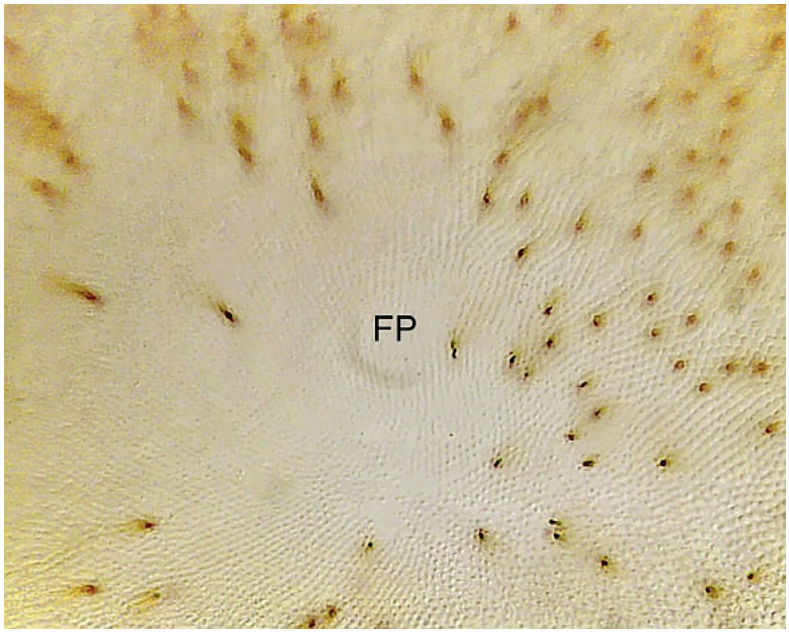

Figure 13. The foveal pit (FP) and part of the foveal slope are immunostained with an S-cone opsin in a human retina.

Substructure of the foveal cone architecture

S-cones and M/L-cones differ in the time course of mitotic differentiation and expression of opsins. According to Xiao and Hendickson (25), S-opsin and various synaptic proteins are detectable at fetal week 11, while various synaptic and transduction proteins appear in M/L cone subclasses before their opsin visual pigments are detected at fetal week 13 (26). It is clear that S-cones develop in a different mosaic than M/L-cones. Ahnelt and

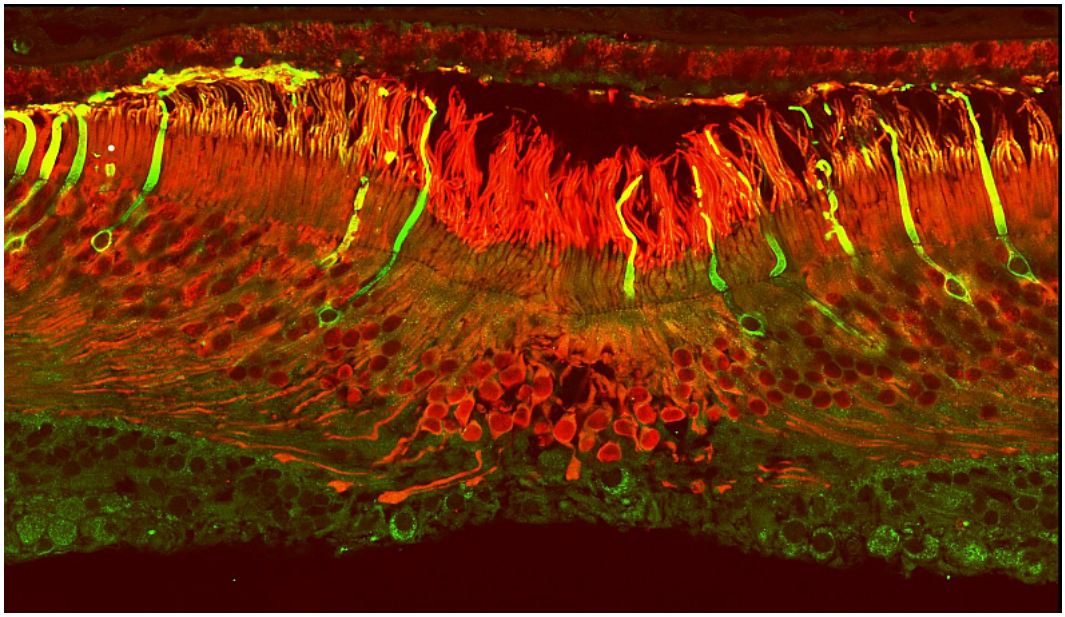

Figure 14. Vertical section of a human foveal pit immunostained with antibodies against cone arrestin for all cones (red), and JH455, which labels S-cones (green). Few S-cones are found in the foveal pit.

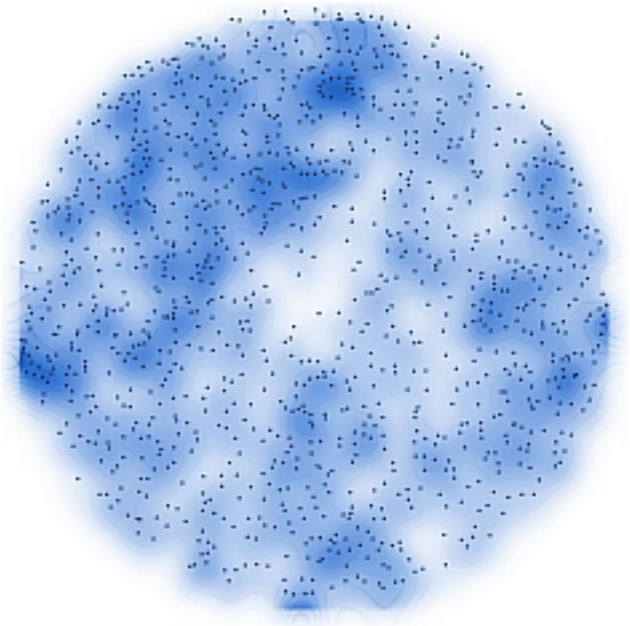

Figure 15. Every S-cone is labelled with S-cone opsin antibody in a human fovea. The more intense blue shading indicates greater densities of S-cones in the foveal slope where they reach 12% of the cone population.

coworkers (7) have noted that cones likely to be short wavelength sensitive tend to occur in irregular positions in both, foveal and peripheral areas. Figure 21A shows an opsin labeled S-cone (asterisk) positioned between seemingly linear series of unlabeled M/L-cone inner segments. Thus in the foveal all-cone mosaic, S-cones appear to interrupt the linear beads of L/M cone-cell inner segments and clearly do not belong to the mosaic of M- and L-cones (6).

The S-cones form a random mosaic like the M/L cones except at the foveal slope area where they are at highest concentration. Here they approach a non-random distribution (25).

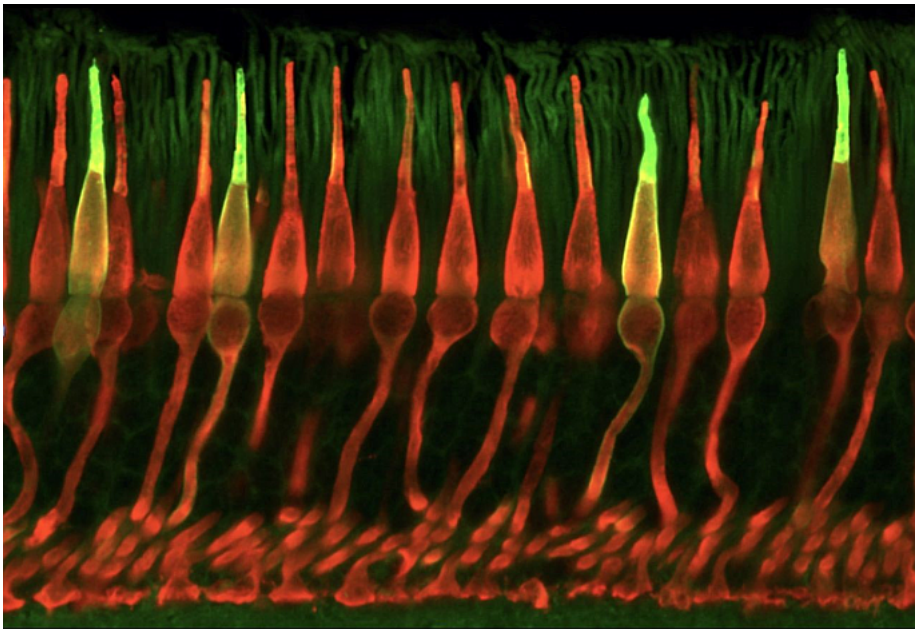

Figure 16. Near peripheral retinal human cones stained with HJ455 antibody that identifies the S-cones (green) amongst the arrestin (red) labeled cones.

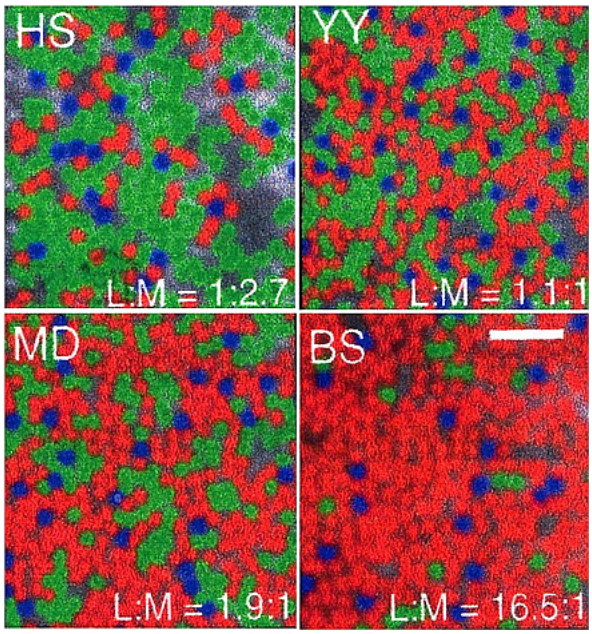

Figure 17. Method of adaptive optics shows mosaics of L (red), M (green) and S (blue) cones in four human subjects with normal color vision. The ratio of S to L and M cones is constant, but that of L to M cones varies from 2.7:1 (L:M) to 16.5:1 (L:M). Adapted from Roorda and Williams, 1999 (19).

Figure 21B shows a schematic summary (7) of cone arrangement in the mosaic of the foveal slope area where the S-cones develop first and reach the non-random mosaic arrangement (25, 27). Three L/M cone patches are exemplified with false colors (yellow, dark blue green and light green). These have migrated downward from an initial position near the external limiting membrane (ELM) to form bead-like arrangements of M/L cone cell bodies in the depths of the outer nuclear layer (ONL). Their axons (Henle fibers) emerge from the cone nuclear layer and radiate centrifugally towards their pedicles. At the intersection of the L/M patches sits an S-cone always with its cell body, unmigrated, up at the outer limiting membrane. Figure 21B left top, indicates the

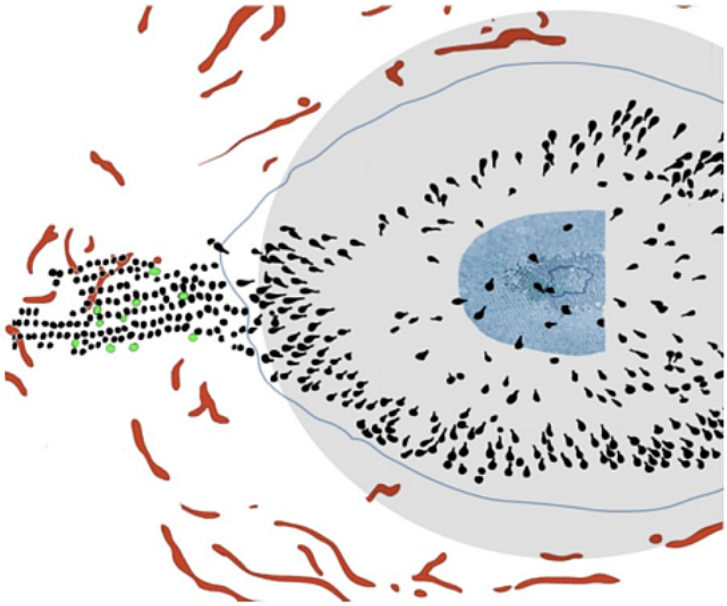

Figure 18. Foveal pit in blue and the foveal slope to the foveal edge in grey. Cone pedicles lack telodendria in the foveal pit. Pedicles with increasing eccentricity along the slope have tadpole-like shape. More peripherally cone pedicles are round in shape and have telodendrial interconnections. The transition coincides with the appearance of capillaries (red) and microglia (green spots). The thin blue line denotes the elliptical course of the external limiting membrane sectioned at the foveal slope at 1 degree (300 µm eccentricity).

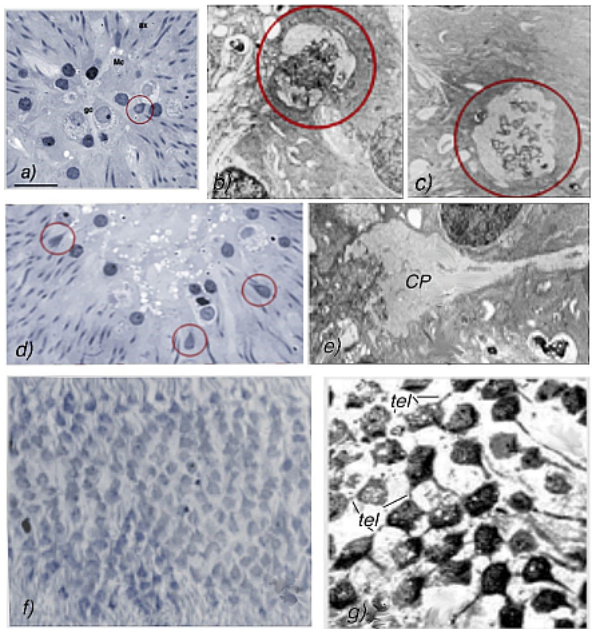

Figure 19. LM and EM appearances of cone pedicles. (a), (b) and (c) are isolated pedicles of the foveal pit (red circles). There are large Müller-cell processes and neural processes running to the cone pedicles. (d) and (e) show tadpole-like cone pedicles on the foveal slope. (f) Pedicles at the first capillary zone are arranged in curved, bead-like series. (g) Higher magnification shows the telodendrial network between most cone pedicles in (f). original position (transparent ovals) of M/L cell bodies before mosaic condensation and their presumed path (tapered rays) to their adult positions.

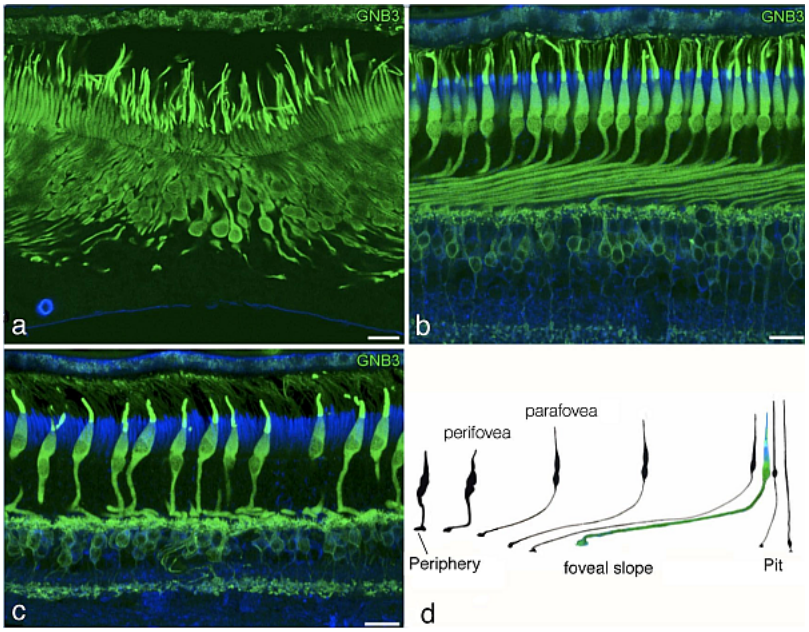

Figure 20. Cone morphology in the foveal pit (a), foveal slope (b) and peripheral retina (c). Cones and ON bipolar cells are immunostained with GNB3 (green). Drawing (d) shows the cone morphologies in the different areas. An S-cone (blue-green) is shown in comparison with the M/L-cone types.

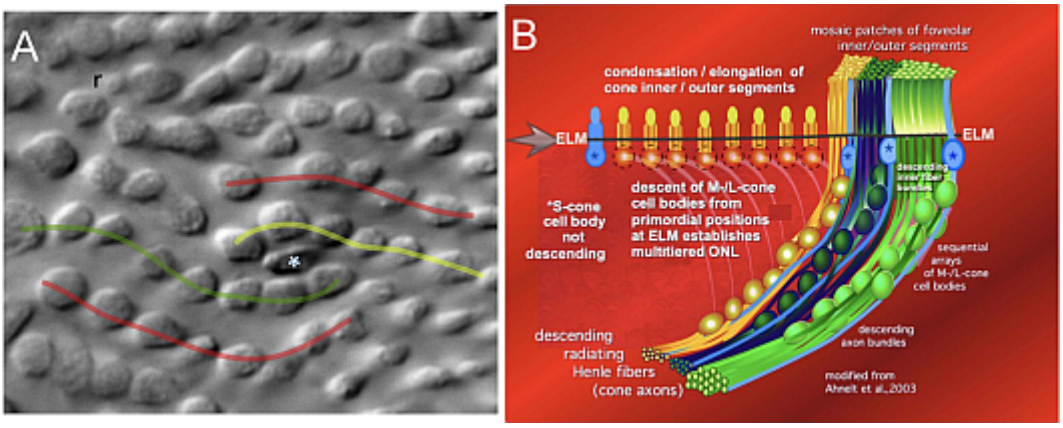

Figure 21. (A) Human cone inner segment mosaic on the foveal slope. Note the first rod (r), and the bead-like arrangement (colored lines) of the M- and L-cones circumventing an S-cone labeled by an S-opsin antibody (asterisk). (B) The transformation of the foveal cone mosaic groups (yellow, dark green, light green) by condensation of their inner/outer segments to vertical sequences of beaded cell bodies and descending, radiating axons in the Henle fiber layer. At left, the original position of the yellow group's cell bodies (line of ovals) before mosaic condensation is indicated, as well as their eventual path (curved lines) to their adult positions. Apparently, S-cones (blue) do not participate in this process, as their cell bodies stay close to the ELM (external limiting membrane, large arrow). Adapted from Ahnelt et al, 2004 (7).

Horizontal cells of the fovea

As we have illustrated in Figure 2B, the whole fovea is roughly 1.5 mm across and so any cell found within 750 µm of the foveal center is considered a foveal associated cell. It has been hard to get good staining of horizontal cells (HC) of the fovea but some Golgi impregnated human retinas in our possession did allow us to see a few within the 750 µm of eccentricity around the central foveal pit (Figure 22) (28).

The closest to the foveal center, which is of course cell free except for cone photoreceptors and some dendrites running up to synapse with the central cones, would be the HC at 200 μm from the foveal center (Figure 22, top cell). These horizontal cells are elongated and arranged concentrically in a circle around the foveal center and on the far edge of the foveal pit. The area could still be in the avascular zone. Note the dendrites are reaching quite far to contact central cones. The cells are axon bearing, but morphologically it is difficult to judge of which type. The cells at 350 μm (Figure 22) are much smaller than the foveal edge HC but now recognizable as H1, H2 and H3 cell types (28). The smallest are the H1 cells that appear to contact about 4-5 cones, judging by their dendritic clusters. H2 cells are wirier and more irregular than H1 and H3 cells but have quite closely packed and profuse dendrites (Figure 22). These H2 cells would be reaching into the foveal slope area, where we know there is the highest density of S-cones, to contact the latter cone type. H3 cells may also be reaching into the foveal slope but we know from previous data they do not receive synapses from S-cones (29, 30). There are no evident axons on these Golgi stained horizontal cells (Figure 22, 350 μm), which probably reflects understaining.

The three horizontal cells at 500 μm from the foveal center (Figure 22) would also be foveal HCs but in an area where blood vessels occur and the first rod photoreceptors are present. As can be seen they are a little larger in dendritic field size (Figure 22). The H1 cell contacts 6 cones and the H3 about 8-9 cones (Figure 22). H1 and H2 types here have axons (small arrows in Figure 22), which will expand into axon terminals in contact with rods in the case of H1, and with S-cones in the case of H2 cells (31).

By confocal microscopy the central human fovea can be seen to contain parvalbumin immunoreactive horizontal cells (Figure 23, a-b; green cells under the cone pedicles). Parvalbumin identifies H1/H3 horizontal cell types and it is likely that the Golgi staining at the 200 μm distance from the central foveal pit is therefore of these types. They are elongated and not closely packed. Their dendrites would be reaching to contact central foveal bouquet cones (Figure 23, b). In contrast, the H1s of the foveal slope are closely packed with vertically squashed cell bodies and small bushy dendrites reaching to the closely packed cone pedicles at the ends of the Henle-fiber-layer cone axons (Figure 23, c). These HCs are clearly the same as those in the Golgi preparations at 300-500 μm (Figure 22).

The H2 cells of the human retina are known to be particularly associated with the S-cone (blue) photoreceptors (see Webvision chapter on S-cone pathways). We know that H2 cells stain with antibodies to calbindin in the human retina as compared to parvalbumen staining for H1/H3 cells. Figure 24 (white arrows) shows a few calbindin positive HCs (red cells, arrows) on the foveal slope in human retina. In addition to the H2 cells with cell bodies close to the OPL, there are diffuse cone bipolar cells contacting several cones, and amacrine cells stained with calbindin. These red, diffuse bipolar cells have cell bodies lower in the inner nuclear layer and long slanted single apical dendrites as compared to the red H2 cells. Note in this section of human fovea the first rods are present on the foveal slope and the first rod bipolar cells are staining for the antibody to PKC (Figure 24, green cells).

Horizontal cells of the vertebrate retina are known to have important roles in sharpening and scaling of responses from photoreceptors through the subsequent retinal pathways to influence the ganglion cell output (32). At the first level of the outer plexiform layer, horizontal cells are involved in feedback of signal from surrounding cones to each individual cone's receptive field. This surround input is expanded well beyond the horizontal cell's dendritic connectivity field by virtue of gap junctions that join the dendrites of many horizontal cells of the same type together. i.e. in human retina the H1-H1 cells would be joined in gap junctions and the H2 cells would likewise be joined to other H2 cells (See the Webvision chapter Myriad roles for gap junctions in retinal circuits). This large feedback effect provokes an expanded region of antagonistic signal compared with the central cone signal. In the case of M- or L-cones the antagonistic surround is a mixed M- and L-cone signal. In other words, individual M- and L-cones do not show classic spectral opponency just mixed M- / L-cone surround antagonism (33). The feedback in the case of an S-cone would come from H2 cells, whose contacts include surrounding M- and L-cones. Indeed S-cones have been recorded from in monkey retina and found to

have blue–yellow spectral opponency as well as center-surround organization (34, 35). Presumably spatial opponency would be transmitted from the M- and L-cones to their respective bipolar cell connections, and in the case of the S-cone, a true spectral opponency has been proven to be transmitted as well (34). No recordings have been made in foveal cones to really see if an M- or L-cone has a spectrally opponent surround like that of (albeit peripheral) S-cones (35).

Midget bipolar cells of the fovea

A long time ago the great Spanish anatomist, Santiago Ramón y Cajal described the neurons of the different vertebrate retinas as seen by sectioned Golgi-stained material. He noted many different types of bipolar cells in the various species and that there were particularly tiny dendritic spreads for some bipolar cells in the bird retina (36). He suggested that these bipolar cells contacted single cones.

In 1941, Stephen Polyak (Figure 25) published books on the neural cell types revealed by Golgi and other silver methods in monkey and human retinas and brain. In central monkey and human retinas Polyak observed and illustrated several types of bipolar cells, but he was very concentrated on the remarkably small dendritic tops of some types that he construed as contacting single cones. He named these bipolar cells, midget bipolar cells (mbc).

Figure 26 shows Polyak's original drawing of these midget bipolar cells and larger dendritic field size bipolar cells that would appear to contact several cones (Figure 26, imb, fmb and dfb). Polyak also drew and commented briefly that the midget bipolar cells appeared to be of two varieties, one that had a long axon to the inner plexiform layer, and the other a much shorter axon ending higher in the inner plexiform layer. At the same time, there were midget ganglion cells that had small dendritic trees that came in the two varieties possibly reaching to the axon terminals of the two types of midget bipolar cells (Figure 26, mgcs).

Some years later, we set out to see whether Polyak was correct in assuming midget bipolar dendrites synapsed only with one cone pedicle (37, 38) using the technique of performing electron microscopy on Golgi impregnated cells located by light microscopy (39). It turned out that, indeed midget bipolar cells contacted a single cone, but unexpectedly, there were two types of midget bipolar cells each having different synaptic connections with their cone pedicles (Figure 27). One type, that we called flat midget bipolar cells, had a particularly horizontally orientated and flattened dendritic top and made contacts with the cone pedicle on either side of the central dendrite at the synaptic ribbon triad of processes (Figure 27, a-c). The other type of midget bipolar that we called an invaginating midget bipolar cell had a spikey dendritic top with small finger like projections (tiny arrow, Figure 27, d) that contacted the cone pedicle as the central element of the ribbon triad of processes (Figure 27, e-f).

By careful examination of our Golgi stained monkey and human retinas we could occasionally observe that the two Golgi stained midget bipolar cells types converged on the same cone (40) (Figure 27, g).

Confocal imaging of the human foveal slope and rim can distinguish the two types of midget bipolar cell by using different immunostains. Figure 28 illustrates the GNB3 stained cones, Henle fibers and the invaginating midget bipolar cells (in green) contacting single cone pedicles and sending axonal endings to the lower (more vitread) strata of the inner plexiform layer to end close to the multitiered ganglion cell layer of predominantly midget ganglion cells. GNB3 is a G-protein subunit common to both cones and ON bipolar cells (41). The invaginating midget bipolar cells are also reaching into the foveal center to contact the central isolated cones of the cone bouquet (Figure 28, c, inset).

In contrast, Figure 29 shows a section of the human fovea immunostained with recoverin antibodies (red) known to reveal flat midget bipolar cells specifically (42), as well as photoreceptors (43). These flat midget bipolar cells are contacting each a single cone pedicle and their axons are angled with the foveal slope direction

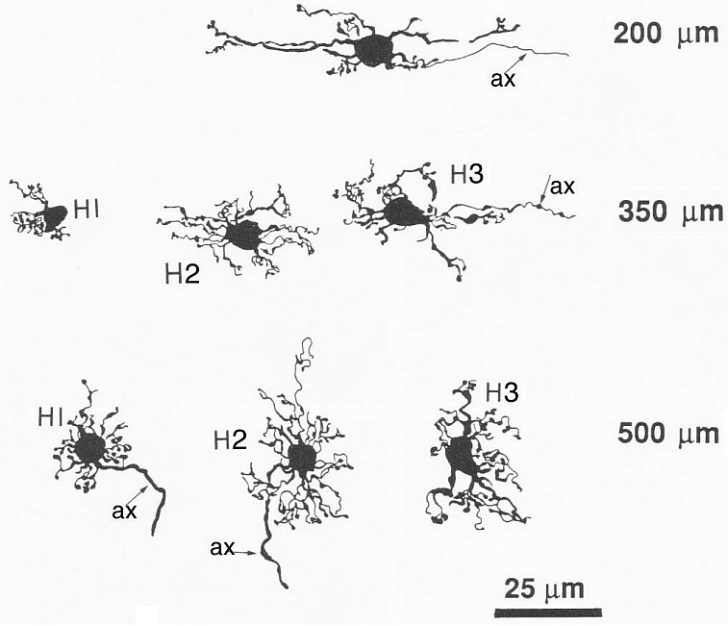

Figure 22. The shape and size of horizontal cells in the human fovea (Golgi staining). The smallest HCs are in the avascular zone edge of the foveal slope (350 µm). The closest HCs stained on the inner foveal slope (200 µm) are stretched out, with dendrites following the circular foveal pit circumference and reaching into the central bouquet of cones. From Kolb et al., 1994 (28).

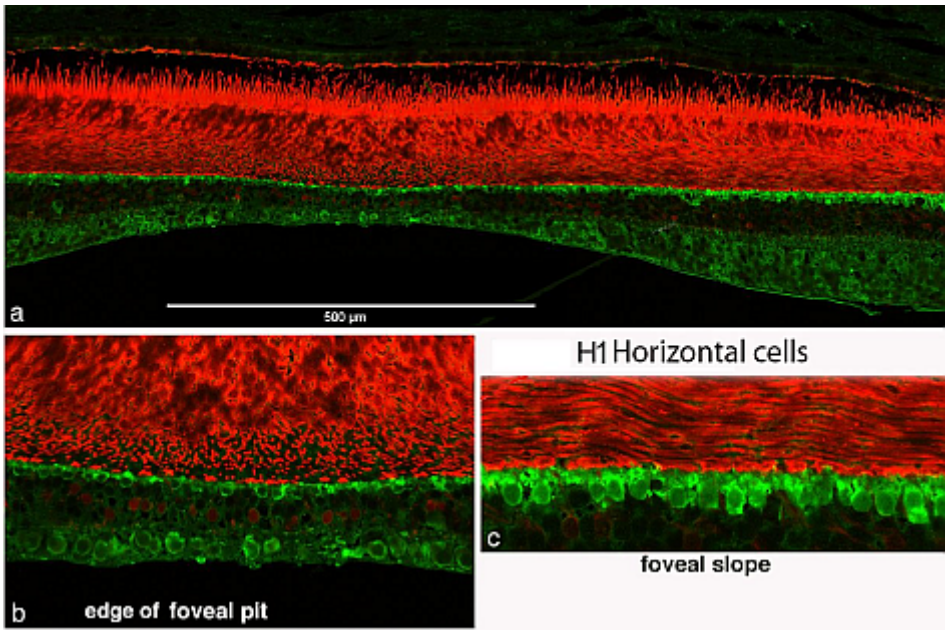

Figure 23. Vertical section of the human fovea cut along the edge of the foveal pit. H1 horizontal cells are immunostained with anti-parvalbumin (green) and cone photoreceptors with recoverin (red). H1 cells are very crowded together in the foveal slope.

to their axon terminals ending high (more sclerad) in the outer strata of the IPL. The more isolated cone pedicles of the foveal pit (Figure 29, b, inset) are clearly being contacted by these flat midget bipolar cells too.

So, we understand now that each foveal cone photoreceptor synapses with two midget bipolar cells. We also now know that there are four or five other types of cone bipolar cells (Figure 26, dfb) that overlap to contact many cones in primate retina, as in other vertebrate retinas (see Webvision chapter on Outer Plexiform Layer). Midget

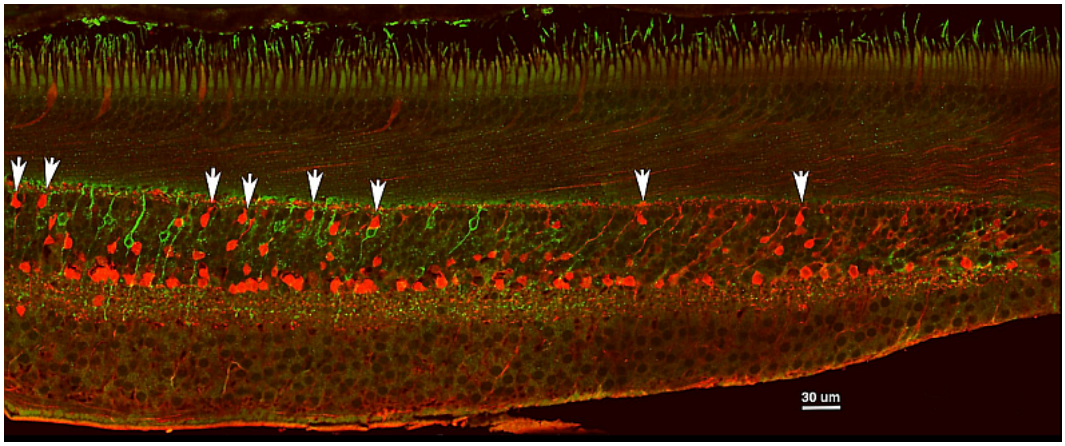

Figure 24. Human foveal slope area immunolabeled with antibodies against calbindin (red) that marks H2 horizontal cells, some bipolar and some amacrine cell types. H2 cells are marked with arrows. The first rod bipolar cells on the foveal slope are labeled with PKC-alpha antibodies (green).

bipolar cells are only found in primate and bird retinas though, and these are the only retinas that have a fovea. Hence the very special nature of the foveal midget system in high visual acuity and color processing.

Midget ganglion cells and the midget system for red L- and green M-cones in the fovea

We have seen how every cone of the foveal area contacts two types of midget bipolar cell which in turn contact a midget ganglion cell each. The flat midget bipolar cell (fmb) contacts the type of midget ganglion cell that reaches high into the IPL, while the invaginating midget bipolar (imb) cell contacts the type of midget ganglion cell that has dendrites in the lower IPL close to its cell body in the ganglion cell layer, as was first suggested by Polyak's drawing (Figure 26). Figure 30 illustrated this finding for Golgi stained midget bipolar cells (mBC) and ganglion cells (mGCs) as seen in the human fovea itself and at 2 mm distance from the fovea i.e. in perifovea. In the fovea where rods are absent (Figure 30, a, foveal cone mosaic) the midget bipolar cells and midget ganglion cells have very small axon terminals and dendrites respectively (less than 10 μm span) and in one image can be seen to stain clasped together (Figure 30, c left cell couple). In the perifovea the cones are now separated by rings of rods (Figure 30, b, receptor mosaic) and the related mb axon terminals and mGC dendrites are slightly wider spread (10-12 μm) (Figure 30, d).

We have been able to reconstruct the midget bipolar and midget ganglion cell synaptic connections by serial section electron microscopy in the fovea and perifovea, in order to see whether there is indeed a one to one relationship (44, 45). Figure 31 shows some sample micrographs from flat-midget-ganglion-cell (mgc) contacts with flat midget bipolar cells (fmb) in the foveal slope (rod free area) and both types of bipolar to ganglion cell contacts in the perifoveal (as in the area of Figure 30, b). All our EM images show all ribbon contacts from one mbc axon to dendrites of a single mGC in the perifoveal material. Typically, there is an amacrine cell companion at the postsynaptic dyad (Figure 31, a-d). Frequently the amacrine cells make reciprocal (feedback) synapses to the midget bipolar terminal, and occasionally to the midget GC involved as well (Figure 31, d). The amacrines are probably of at least two types involved in these synaptic exchanges (see later section on amacrines of the fovea).

The reconstructions of the EM serial photographs are shown in Figure 32 (44, 45). The reconstructed perifoveal invaginating and flat midget bipolar cells with their respective ganglion cells showed almost exclusive interaction between a bipolar axon and a ganglion cell dendritic tree. There were 2 or so ribbon synapses that could have been directed to another ganglion cell dendrite in the 4 pairs of cells reconstructed (Figure 32, Perifovea). In the

Figure 25. Steven Polyak circa 1940.

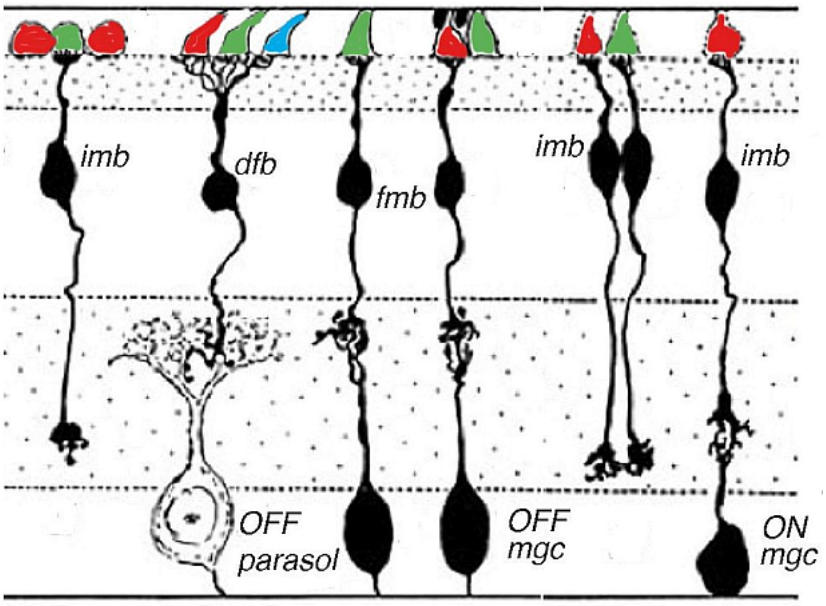

Figure 26. Original drawings of Polyak (90). Bipolar cells and ganglion cells of the central retina. We now know that the invaginating midget bipolar cells (imb) and flat midget bipolar cells (fmb) are physiologically different. Polyak described midget ganglion cells (mgc) as of two types, which we now know are OFF mgc and ON mgc. These connect to fmbs and imbs respectively. Large field bipolar cells (dfb) and parasol ganglion cells were also described by Polyak. The cone spectral types have been colored in by the present authors.

case of the reconstruction of midget bipolar cells and midget ganglion cells of the fovea (Figure 32, Fovea at 570 μm) we determined that there were 3 imbcs to 2 mgcs (Figure 32, fovea, very left-hand cells) and 2 imbcs to a single midget GC (Figure 32, Fovea, right side). However, the limits of our series of the reconstruction probably mean that we missed some adjoining mGCs in this tightly packed neuropil of very small dendritic and axonal profiles. We suggested (46) that each midget bipolar type directed the majority of its synapses to a single midget ganglion cell top, but some synapses probably got shared with a neighboring midget ganglion cell too.

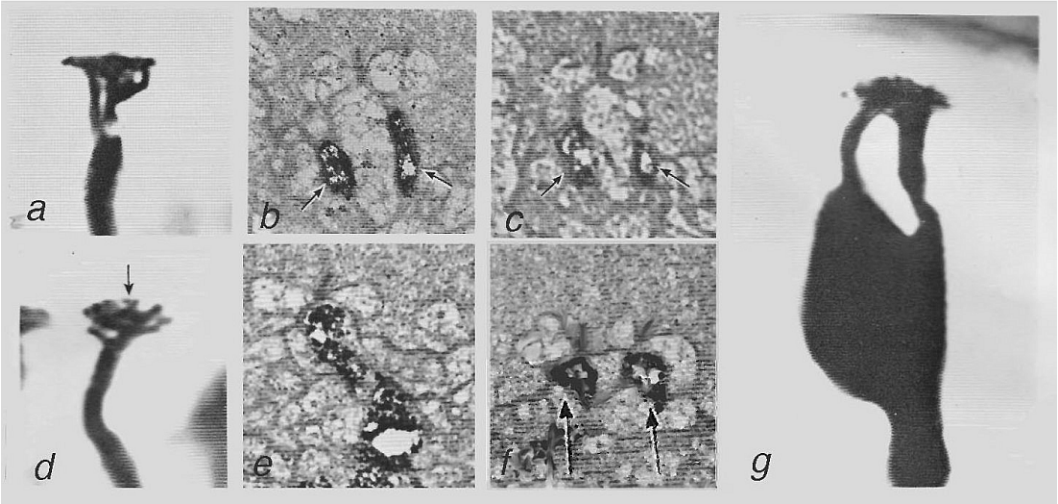

Figure 27. Golgi-stained midget bipolar cells in central monkey retina. (a) shows the flat dendritic top of a flat midget bipolar. (b) and (c) electron micrographs (EMs) show the dendritic terminals contacting a single cone at basal junctions. (d) shows the spikey top of an invaginating midget bipolar and (e) and (f) EMs show dendritic terminals making ribbon contacts with a single cone. (g) Golgi-stained pair of midget bipolar cells contacting the same cone pedicle. From Kolb, 1970 (37).

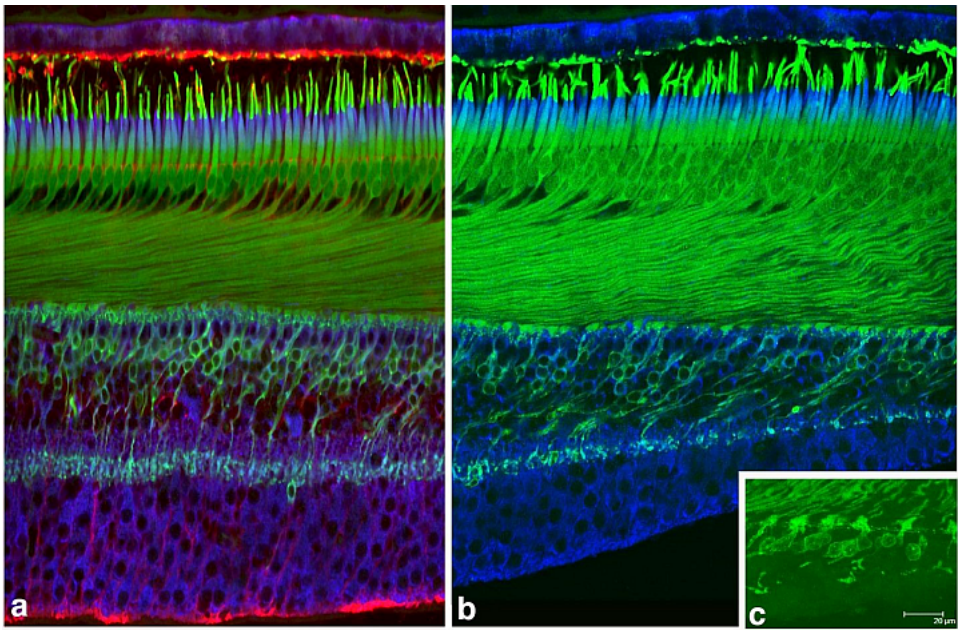

Figure 28. Vertical sections of the foveal rim (a) and the foveal slope (b) to show invaginating midget bipolar cells (imb) contacting cone pedicles of the radiating Henle fiber axons of the foveal cones. The inset (c) shows the imb cells reaching to contact foveal pit cones. Antibodies are against GNB3 (green) for cones and imb cells, CRALBP (red) marks Müller cells and pigment epithelial cells, and Cytochrome C stains mitochondria (blue).

In sum, the relationship between cones and their midget ganglion cells appears to be one cone to two midget bipolar cells and two midget ganglion cells in the foveal and perifoveal regions of the human retina. The same applies to macaque and new world monkey retinas (47).

Our understanding of the significance of every cone photoreceptor having two bipolar and two ganglion cell channels through the primate retina became clear in the 1970s when it was proved unequivocally that the IPL was divided into an OFF-center neural processing in the upper half of the IPL and an ON-center neural processing in the lower half of the IPL (48) (see Webvision chapter on Inner Plexiform Layer). The bipolar cells

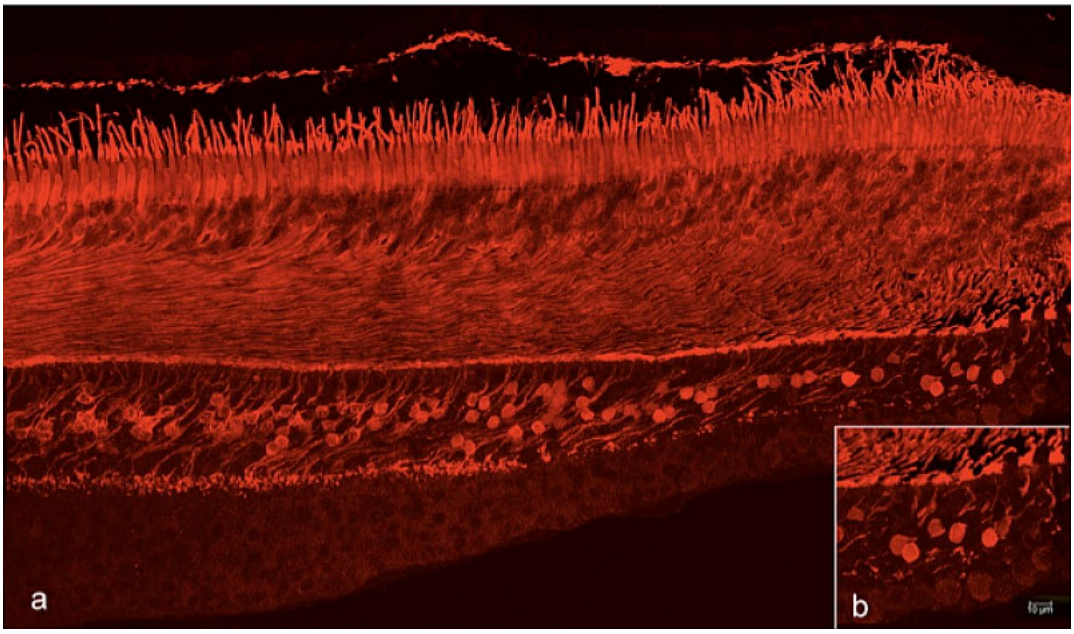

Figure 29. Vertical section of the human fovea slope (a) immunostained with antibodies to recoverin, showing cones, and flat midget bipolar cells (fmb) connecting to single cone pedicles. Inset (b) shows the fmb cells stretching into the foveal pit to make cone contacts.

that make central ribbon-related contacts give ON center (depolarizing signals to light flashes) while the bipolar cells with flat (superficial junction) contacts with the cone pedicles give OFF center (hyperpolarizing signals to light flashes). So, the invaginating midget bipolar cells are ON center and connect with the lower-IPL-branching ON-center midget ganglion cells (Figure 32, Figure 33). In contrast the flat midget bipolar cells are OFF center and connect exclusively with the OFF-center midget ganglion cells of the upper IPL (Figure 32, Figure 33). The messages from a single cone can be transmitted to the brain via exclusive (private) channels for either brighter than background light (ON center message) or darker than background light (OFF center message). Figure 33 shows diagrammatically these private pathways for the midget system in the fovea and the perifovea.

This ON and OFF segregation of the light signal to the two parallel pathways is basic to the organization of light perception of both intensity and hue in the retina and brain (49). In the human fovea and perifovea the private midget pathways dominate the architecture probably forming about 80% of the neural channels. The density of the midget bipolar cells and their midget ganglion cells bodies stacked 6-8 cells deep on the edge of the fovea can be seen in Figure 24, Figure 28, and Figure 29. Furthermore, as we saw in the mapping of cone spectral types in the fovea (19), the vast majority are red L-cones or green M-cones in the fovea and elsewhere in the retina. And these red/green cone pathways are thought to be using the midget bipolar and midget ganglion cell systems to ensure private lines for high acuity function as well as hue (see Webvision chapter on Midget Pathways).

The one-cone-to-two-ganglion-cell midget pathways break down beyond 10 degrees from the fovea in the retina. Outside of the fovea the midget system is multicone connected (50-52).

It is well established that the midget chain of neurons for M- and L-wavelength detection in the midget ganglion cells has a spectrally opponent center-surround organization (Figure 34) (53, 54), reviewed in (55). Thus, midget ganglion cells of central retina (not fovea though), when recorded from electrophysiologically, have the smallest receptive fields, and are organized as L-cone ON or OFF center, and M-cone ON or OFF center. Each midget ganglion cell type has a larger surround of the opposite polarity and of the opponent color (Figure 34). The centers of the midget ganglion cells in peripheral retina, as Chichilnisky's group have elegantly shown (50), are comprised of a predominant numerical cone type, say L-or M-cones, but many more M-, L-, and even S-cones in the larger surround receptive fields. This suggests a more mixed spectral input to surrounds. The retinal

pathways making opponent color surrounds are still not clearly understood for the red and green midget ganglion cells although the predominant theory is that HC feedback at the outer plexiform layer makes for a center surround organization in the bipolar cells (34, 56). Dennis Dacey's group (57) have recently measured the strength and opponent color of the surrounds in peripheral midget ganglion cells and using a difference of Gaussian receptive field model predicted the color opponent surround that is recorded. But as stated above the midget bipolar cells of the **fovea** have not been recorded from to understand whether the midget bipolar is already color opponent due to horizontal cell feedback.

There are also more diffuse channels mixing red and green cone signals in the fovea. Figure 24, in the horizontal cell section, showed a diffuse type of cone bipolar cell called db3 that immunostains with calbindin in the fovea. Its axon terminals are seen positioned in the center of the IPL (Figure 24). The diagram of Figure 35 illustrates ON and OFF pairs of diffuse bipolar cells with contacts to ON and OFF parasol ganglion cells (also shown in Polyak's drawing of the foveal bipolar and ganglion cells in Figure 26 and see later drawings of wide-field bipolar cells). Parasol ganglion cells are thought to be achromatic (53) but motion sensitive (58). See more details of glutamate channels of the two ON and OFF bipolar connections (59) and types of bipolar cells in vertebrate retinas in the Webvision chapter on Bipolar Cell Pathways in the Vertebrate Retina by Nelson and Connaughton.

Counts of midget ganglion cells in the fovea

As we have seen above, the high acuity red and green channels in the retina are processed through parallel single-channel midget bipolar cells and midget ganglion cells to the brain. These high acuity circuits mean that every cone of the fovea will transmit an ON and an OFF signal via two midget bipolar cells and two midget ganglion cells. Every cone in the fovea must have at least two ganglion cells to contact. Are there enough ganglion cells in the foveal slope and foveal rim to ensure these parallel pathways in human retina? Curcio and Allen's (10) quantitative counts on human retinas indicate that there are.

Maps of the ganglion cell numbers counted at every 400 μm from the foveal pit (Figure 36, a, foveal pit is black) show the peak ring of ganglion cell (GC) bodies (Figure 36 orange patchy red ring) at about 800 μm to 1 mm from the central pit. There are large numbers of GCs up to this ring, consistent with the increasing piling up of GC bodies into 6 rows deep at maximum. This piling up of the GCs is clearly seen in the previous confocal images of the foveal rim of human retinas (Figure 24, Figure 28).

The cone densities are highest in the foveal pit and rod free area (Figure 36, b) and the Henle fiber lengths (cone axons) allow the foveal cones to reach the midget and other cone bipolar cells, which are also eccentrically directed to final connections with the midget and a few other GC types (see later section on blue or S-cone pathways). The counts reveal that between 2 and 3 GCs are present in the foveal area for each cone photoreceptor (10).

Things are different in peripheral retina where single cones have input to midget cone bipolar cells with several dendritic clusters for up to 3 cones per bipolar, and many midget bipolar cells converge onto a single midget ganglion cell with a wide dendritic tree (46). The one-cone-to-two-ganglion-cell channel is not available for high acuity vision in the periphery.

A demonstration of single cones mapping onto single midget ganglion cells with either ON or OFF light responses was elegantly demonstrated in the fovea of a **living** monkey retina by William's group (60). Using their signature methodology of adaptive optics to image the cones (as in Figure 17), spatial white noise stimulation of central foveal cones, and responses of ganglion cells with calcium signaling, this team of researchers was able to relate a single cone to its ON or OFF centered midget ganglion cell at the foveal rim 300-400 μm distance (Figure 37, ON mgcs circled in red and OFF mgcs in green).

In this way this team of researchers was able to map the distribution of the midget ganglion cells in a ring around the fovea at between 300 and 400 μm from the cones central to their receptive fields. Interestingly the

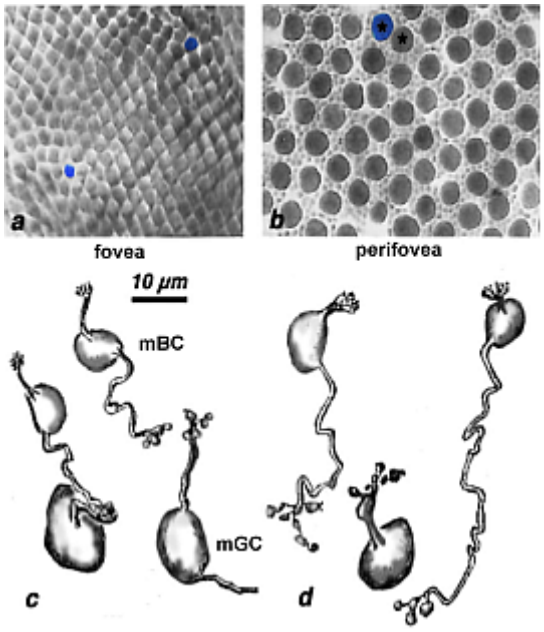

Figure 30. Midget ganglion cells and midget bipolar cells of the fovea (c), and of the perifovea (d) from Golgi-stained human retina. The photoreceptor mosaics (a, b) are above the Golgi-stained cells of (c) and (d). Blue cones are indicated in both mosaics. Midget ganglion cells (mGC), midget bipolar cells (mBC). From Kolb and Marshak, 2003 (46).

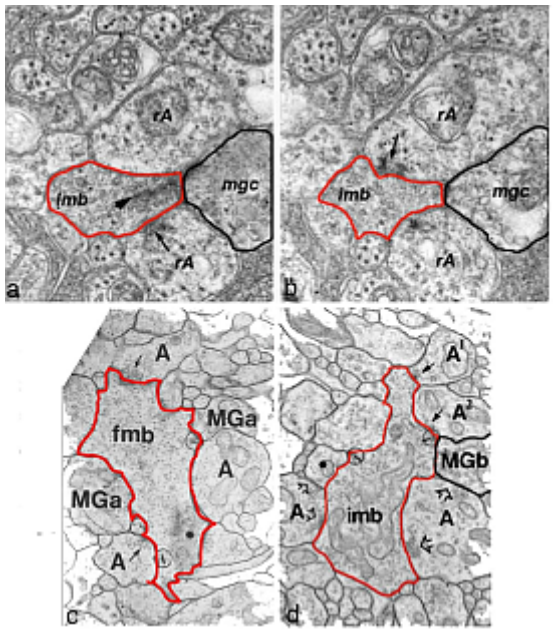

Figure 31. EM of flat (fmb) and invaginating (imb) midget bipolar cells making ribbon synapses on midget ganglion cells (mgc, MGa, MGb). (a) and (b) are from the human fovea and (c) and (d) from the parafovea. A: amacrine cells make synapses on the midget bipolar cell axon terminals. rA is a reciprocal amacrine cell synapse. From Kolb and Marshak, 2003 (46).

ganglion cells with deep cell bodies closer to the outer plexiform layer were closer to the central fovea i.e that 300 μm ring, whereas ganglion cells in the superficial ganglion cell layer were between 400 and 500 μm from the central cones, so that one point in space at the ganglion-cell layer represents more than one point in visual space. This all reflects the Henle axon layer and the pulling of the inner retinal cells obliquely away from the center with the superficial cells being pulled further out radially in development (see section of development of the fovea).

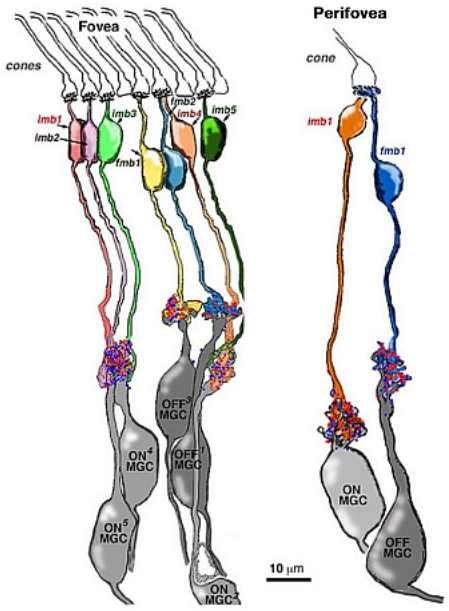

Figure 32. Drawing of reconstructed human midget ganglion cells with their cone input as routed through midget bipolar cells. Fovea: 5 midget ganglion cells get input from 7 midget bipolar cells. Perifovea: there is a strictly 1:1 relationship between ganglion cells and bipolar cells. One cone provides input to 2 mbcs and 2 MGCs in all areas of retina outside the fovea. From Kolb and Marshak, 2003 (46).

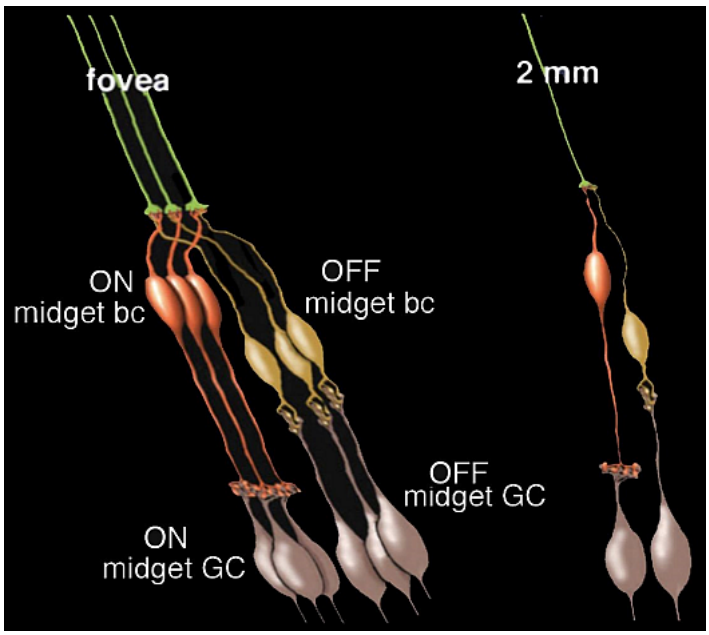

Figure 33. Diagrammatic scheme of the private wiring pattern of the midget system in the fovea and perifovea (at 2 mm). One cone – 2 midget bc's (one ON, one OFF) – 2 midget GC (one ON, one OFF).

Blue S-cone pathways in the fovea

So far, we have dealt with the architecture of the predominant cone spectral and high acuity pathways in the fovea namely the midget pathways for the green M-cones and red L-cones. What of the blue S-cone pathways? As we have seen above the S-cones have a small presence in the foveal cone mosaic (3% of cones generally) but

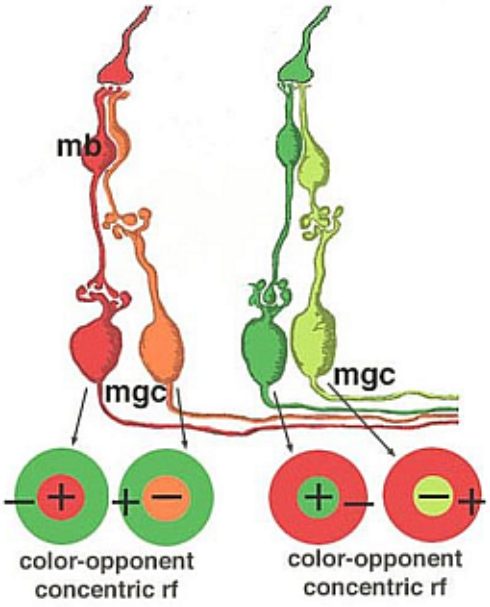

Figure 34. L/M midget ganglion cells have concentric and spectrally opponent receptive fields (rf). An L-cone (red cone) will feed an L-off and an L-on signal through its 2 midget bipolar cells (mb) to 2 midget ganglion cells (mgc). The mgcs will be either red ON center (+) or red OFF center (-) and have a green opponent surround either OFF (-) or ON (+). The M-cone (green cone) is similarly wired through mb cells and mgcs to generate spectrally opponent center surround organizations.

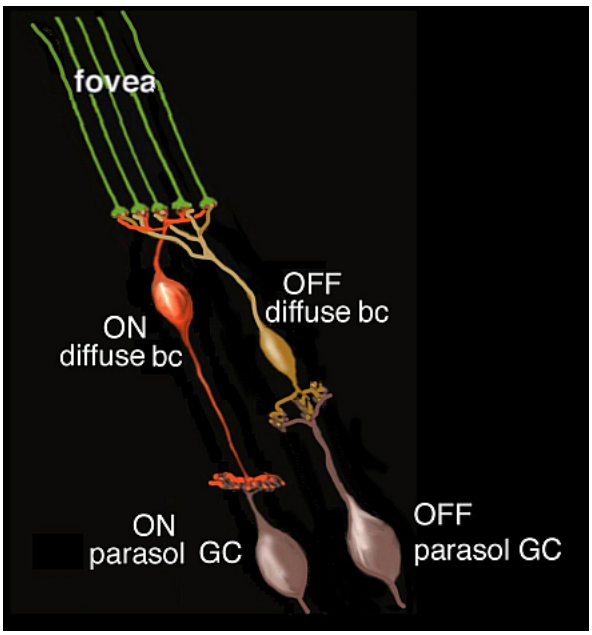

Figure 35. Diagrammatic scheme of the wiring pattern of the diffuse bipolar cell (bc) and parasol ganglion cell (GC) system in the fovea. Each cone (either L, M, or S type) will provide input to two diffuse bcs (ON and OFF types) and two parasol GCs (ON and OFF types).

reach their peak number for the whole retina at 12% of cones in foveal slope and rim at approximately 1 degree of eccentricity (Figure 13, Figure 14, Figure 15).

Mariani (61) described from a Golgi staining study of rhesus monkey retina, a bipolar cell that appeared to be selective for cone types that he proposed were the blue or S-cones. These cone bipolar cells were not midget per se. They appeared to be contacting 1-3 cones situated far apart and their axon terminals were always in the ON

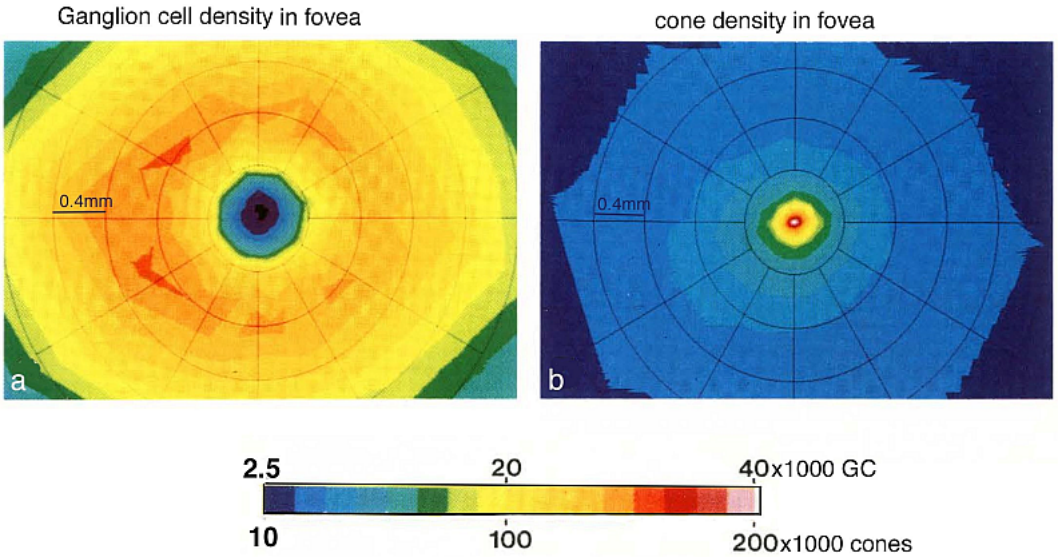

Figure 36. Computer generated heat maps of density counts of (a) ganglion cells, and (b) cones in a human fovea. Ganglion cells are at a minimum in the foveal center (black spot) and peak (red/orange) in a ring about 1 mm from the foveal center. (b) Cones peak at the highest numbers (white spot) in the foveal center and fall off to lower densities radiating out to the edge of the fovea. Color coding bar below gives cell density per mm^2 times a thousand. From Curcio and Allen, 1990 (10).

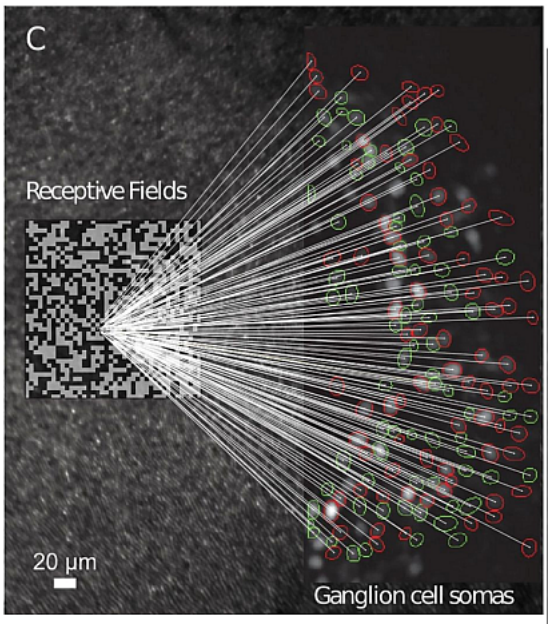

Figure 37. Using adaptive optics to image the cones in monkey fovea and stimulating with spatial white-noise checkerboards allows responses of ganglion cells to be seen by calcium signaling. Thus, a single cone can be followed to its ON- or OFF-center midget ganglion cell at the foveal rim 200-400 µm distant. ON, red and OFF, green. From MacGregor et al., 2018 (60).

layer deep in the IPL neuropil (Figure 38, A). Axon terminals were rather wide-spread compared with the restricted narrow axon terminals of M- or L-cone connecting midget bipolar cells of the central retina. Kouyama and Marshak (62) later confirmed that this type of bipolar was selective for S-cones by an immunostaining light microscope study. The cells were selectively immunoreactive for glycine-extended precursors of cholecystokinin. Later an electron microscope study of the fovea with serial sections and reconstructions (63) showed that this type of S-cone bipolar (Figure 38, A) was probably an ON center type due to its invaginating synapses with the

S-cone (not shown in Figure 38), and its axonal terminal ending deep in the IPL neuropil to contact the lower branches of a small bistratified ganglion cell (Figure 38, B-C, Figure, 39).

In the nineties Dacey and Lee (64) first described the morphology and the intracellular responses of the small bistratified ganglion cell as blue ON and yellow OFF. Figure 39 shows this blue-ON yellow-OFF bistratified ganglion cell stained with neurobiotin and recorded for light response and receptive field structure in the monkey peripheral retina (34). The bistratified cells of the fovea are presumed to have a similar dendritic tree but much smaller of course. The estimate from Calkins and coauthors (63) was that this ganglion cell type on the foveal rim, where they are at their highest numbers, forms 3% the ganglion cell population.

Apparently, humans can discriminate blue–yellow gratings of about 7–14 cycles/degree (16, 65-67). This limit corresponds to the Nyquist limit for the densest region of the S cone mosaic at 1° eccentricity (16, 68). The B–Y ganglion cell mosaic would support discrimination of the finest blue–yellow grating. These ON blue, yellow OFF GCs project to the koniocellular layers of the lateral geniculate body in the brain. It is now accepted that this blue-yellow ganglion cell circuit is the major pathway from blue S-cones to signal the brain about blue hue discrimination (34).

So far in this chapter only an ON center bipolar and ganglion cell for the S-cones have been described. Are there any OFF-center S-cone pathways? An OFF S-cone midget bipolar making basal junctions with the blue cone pedicle near the triad ribbon synapses, like in red and green midget bipolar cells, has been reconstructed by serial section electron microscopy in the monkey fovea (Figure 40; A, A) (69, 70). Its axon terminal contacts the small dendritic tree of a midget ganglion cell (69-71) (Figure 40; B, B).

Very recently S-cone OFF type of responses have been recorded from S-OFF midget ganglion cells (mgc) in the monkey macular area (70). This S-OFF mgc had a blue-OFF center and blue-ON surround organization. Its receptive field was interpreted by the authors to have a role in edge detection similar to L/M mgcs (70). Previously in monkey lateral geniculate nucleus, S-OFF responses had been recorded (72). To date there is no evidence for a matching S-ON **midget** ganglion cell in primate retina.

In 2005 Dacey and colleagues reported on "giant" ganglion cells that gave blue S-cone OFF responses in monkeys (73). These ganglion cells are intrinsically photoreceptive ON-types (iPRGCs) due to melanopsin photopigment in their membranes but also they are driven by both rod and L/M cone inputs in their ON responses (see Webvision chapter on Melanopsin-Expressing, Intrinsically Photosensitive Retinal Ganglion Cells). The overall cone input is S-cone OFF and M/L-cone ON, with a coextensive receptive field organization. In human retina multielectrode array studies also showed the ON responses of iPRGCs integrated rod and cone signals with intrinsic melanopsin photosensitivity. The human melanopsin signals came in at least three photoresponse variants (74). The morphologies of the "giant" melanopsin ganglion cells are shown in Figure 41.

These cell types are many times larger in both cell body size and dendritic field diameter than the bistratified S-ON, yellow-OFF ganglion cell described above (Figure 39). The giant cells have dendritic trees covering 1 mm in area (Figure 41, a, c). There are two stratification types of giant melanopsin ganglion cells. One of the giant melanopsin cell types (outer type) stratifies in stratum S1 right under the amacrine cell layer. The other (inner type) has dendrites running in S5 just above the ganglion cell layer (Figure 41, b) (73). The dendritic trees of "giant" melanopsin types are rather large in the fovea too (500-1000 μm diameter), forming a distinct ring of cells around the fovea (Figure 42). The "giant" S-OFF melanopsin GCs project to the parvo and magnocellular layers of the lateral geniculate nucleus (73). Furthermore, there is now thought to be to be a third type of ip-melanopsin cell in the human retina and all are densely distributed in perifoveal retina (74, 75).

The question arises as to what bipolar or amacrine cell would have input to S-cone-OFF, L/M-cone-ON melanopsin cells, particularly those that branch in the lower or inner IPL. The S-OFF midget bipolar cell could contact the outer giant melanopsin cell, but it is so far only known to contact the S-cone OFF midget ganglion cell. Most of the diffuse cone bipolar cells of the primate retina have contacts with an S-cone in their dendritic

coverage of the overlying cones, as summarized by Dacey (34) (Figure 43). These types of bipolar have not been recorded from to know how much OFF- S-cone signal would come through in their possible input to the outer type giant melanopsin ganglion cell dendritic trees (i.e. from DB1 and DB2 in Figure 43). Those bipolar cells with minority S-cone contacts that branch in the area of the inner types of giant melanopsin ganglion cells would potentially have minimal S-cone ON input but **not** S-cone OFF input (Figure 43). For these reasons the S-cone OFF signal in the giant melanopsin ganglion cells is now theorized to be via an intervening inhibitory amacrine cell circuit from the ON blue bipolar (B, B, Figure 43) to the dendrites of the melanopsin GCs (76, 77). An S-cone amacrine circuit from S-ON bipolar cells to M1 melanopsin iPRGCs has been found in dense reconstructions of monkey perifovea (77).

There is one last cone bipolar cell that has been all but ignored in the human retina. This is a giant bistratified bipolar cell that was described first by Mariani (78) in monkey retina and later by Kolb and coauthors (79) in a Golgi study of human retina. This bipolar type has the widest dendritic span of all cone bipolar cells, exceeding 50 µm in the central retina and as much as 100 µm in the periphery. The dendrites are searching for occasional cones to contact as would be expected if they were synapsing with the occasional S-cone in the dendritic field spread. The contacts are basal junctions, typically associated with OFF-bipolar physiology. The wide spreading axon terminal stratifies in both stratum 1 and stratum 5 of the IPL viz, right in the same strata of the dendritic spreads of the ON-layer and OFF-layer giant melanopsin ganglion cells (Figure 44). This giant bipolar has recently been mentioned in a paper on synaptic connectivity to melanopsin-containing ganglion cells in primate retinas (80). Putative and confirmed S-cone bipolar cells and their S-cone driven ganglion cells for the human fovea are illustrated in the summary diagram of Figure 44.

Amacrine cells of the fovea

There are about 30 different amacrine cell types in the human retina (79). All those with small dendritic spreads are known to use glycine as a neurotransmitter, while the larger field amacrine cells use GABA as a transmitter. It is assumed that all the medium to larger field GABAergic amacrine cells would be at their densest and form a ring around the fovea much like the larger field ganglion cell types as in Figure 42. Densities and distributions of amacrine cells are very difficult to assess, except with mixtures of immunostains for different putative amino-acid or peptide neurotransmitters, enzymes for pathways involved in catecholamine synthesis, or characteristic calcium-binding proteins. So, it has been a challenge to categorize the different amacrine cell populations particularly among the small-field amacrine cells that are crowded together in the fovea and tile the retinal IPL. Larger field amacrines are more widely spaced but have considerable overlap of their dendritic fields.

Data concerning amacrine cells in human retina, and fovea in particular, are very scarce. Golgi studies have revealed the different types of amacrine cell in the monkey and human retinas (79, 81) and immunostaining studies have given us details of acetylcholine containing amacrines (starburst cells) (82), dopamine containing amacrine cells (61), peptides (83) and AII amacrines (84-87) (see Webvision chapter on Roles of Amacrine Cells). The paper by Rodieck and Marshak (82) gives the only quantification we have for starburst amacrine cells which contain acetylcholine in the human retina (Figure 45). Clearly, they peak in density at the fovea between 0- and 2-mm eccentricity. The two types of starburst cells are plotted separately in Figure 45, i.e. amacrine cells in the ganglion cell layer (GCL) and those in the amacrine cell layer (ACL). The ACL starburst cells are not counted any closer than 1.5 mm eccentricity. However, the ACL cells are always lower in number compared with the GCL-occurring cells in all areas of retina, i.e. foveal, temporal, nasal, upper and lower quadrants (Figure 45).

Amacrine cells with small dendritic fields are well characterized and classified into different types in human retina (79). As mentioned above all these different small field cells are glycinergic. Although they haven't been so demonstrated in human retina, they have in mouse retina by immunostaining in the thy1-GFP-O mouse retina (88, 89) (Figure 46). These cells are clearly recognizable across species and are seen in human and monkey retina

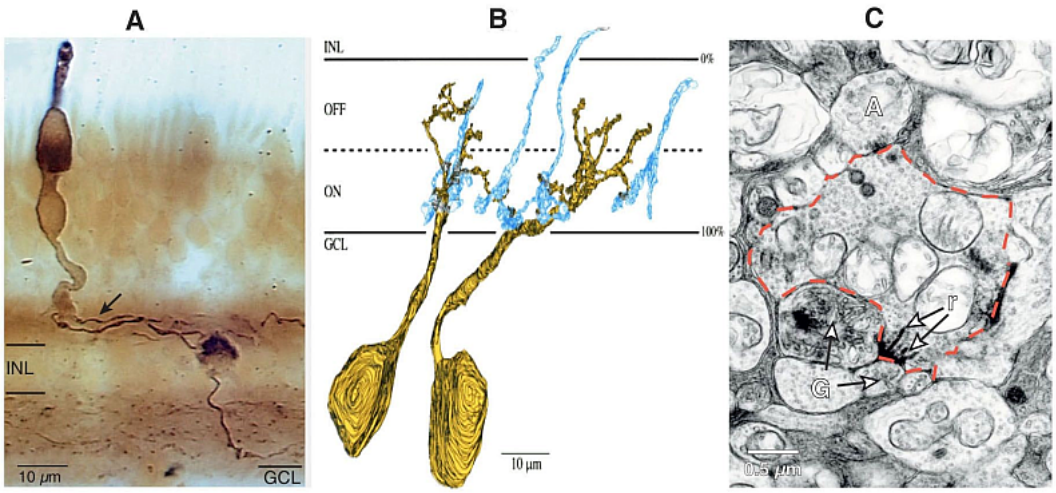

Figure 38. (A) A blue cone bipolar stained with anti-cholecystokinin contacts a blue cone, immunostained with an antibody to S-opsin. (B) A pair of small bistratified ganglion cells (yellow) are contacted at their lower dendrites in the ON layer of the IPL by blue cone bipolar cell axons (blue profiles). Reconstructions of serial sections in EM of the fovea in monkey retina. (C) EM of a section of the blue cone bipolar cell axon (red dashed outline) in the series to show its ribbon contacts (arrows) to the dendrites of the small bistratified ganglion cell (G). From Calkins et al. (63), 1998; and Dacey et al., 2014 (34).

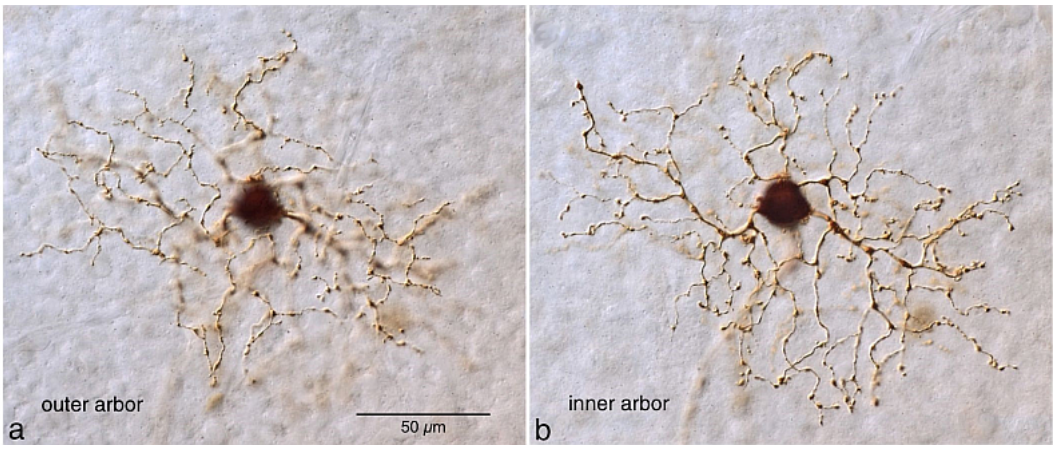

Figure 39. Neurobiotin, intracellularly filled, small bistratified ganglion cell in monkey retina. (a) The outer dendritic tree is in focus while (b) the inner dendritic tree is in focus. The cell responded to blue S-cone stimulation with an ON response and to yellow stimulation of L and M cones with an OFF response. Both receptive fields were coextensive. From Dacey et al., 2014 (34).

too. We are presuming and have evidence on some of these small field cells that they are most frequent in and near the fovea.

Kolb and coauthors Golgi study of small field amacrine cells (79) was done on whole mount preparations so a vertical section view of some of these small field amacrines has to come from Polyak's book (90). See Webvision chapter on Roles of Amacrine Cells to see more details of Polyak's Golgi staining of amacrine cells. In Figure 46 he shows a small-field amacrine that stratifies in the top strata (number P8), another type in the middle strata (number P9) and third type in the lower strata (number P10) of the IPL neuropil. These are quite possibly the same as the glycinergic amacrine cells seen in mouse retina (89) (Figure 46 C, D and E). Cells A and B and F (Figure 46) were not described by Polyak but one or more were described by more recent authors (79, 84, 85, 91-94). See more details in the Webvision chapter on Roles of Amacrine Cells.

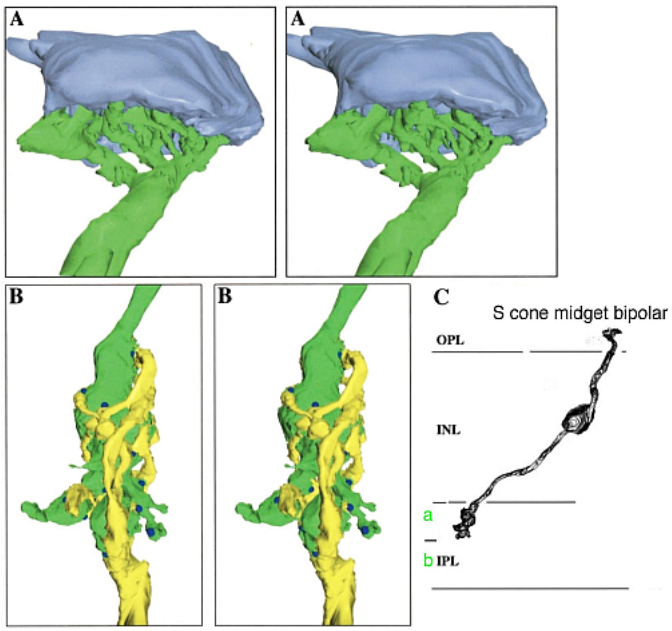

Figure 40. Reconstruction picture from EM series of a midget bipolar cell in monkey fovea. The dendritic top (green) contacts a single S-cone pedicle (blue) with many flat contacts (A, A), while its axon terminal in sublamina ***a*** of the IPL is synaptic upon a midget ganglion cell's dendritic tree (B, B) (yellow). A drawing of the complete S-cone midget is seen in (C). A, A and B, B are stereo pairs. If you can fuse the images, they appear 3-dimensional. From Klug et al., 2003 (69).

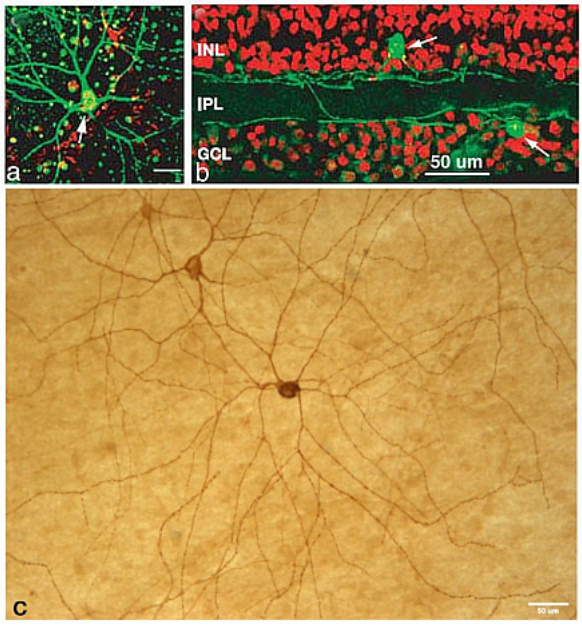

Figure 41. (a) A giant melanopsin-IR ganglion cell of peripheral human retina (green). (b) inner and outer melanopsin-IR ganglion cells in vertical section with dendrites in S5 and S1 of the IPL respectively. From Dacey et al., 2005 (73). (c) Giant melanopsin cells immunostained with melanopsin antibody in peripheral human retina. Their dendritic trees cover one mm area of retina.

A great many small field amacrine cells are stained with calbindin from the foveal rim into the foveal slope, as we have seen in Figure 24. Figure 47 (a) shows calbindin immunoreative (CB-IR) cells close to the fovea and in the foveal pit (Figure 47; a, c; green and orange cells). The orange amacrine cells co-label mixed calbindin and calretinin (CR) immunoreactivity. Some calbindin cells do not co-label with calretinin (green cells) and some calretinin cells do not co-label with calbindin (red cells). Thus, there are at least 3 different types of small field

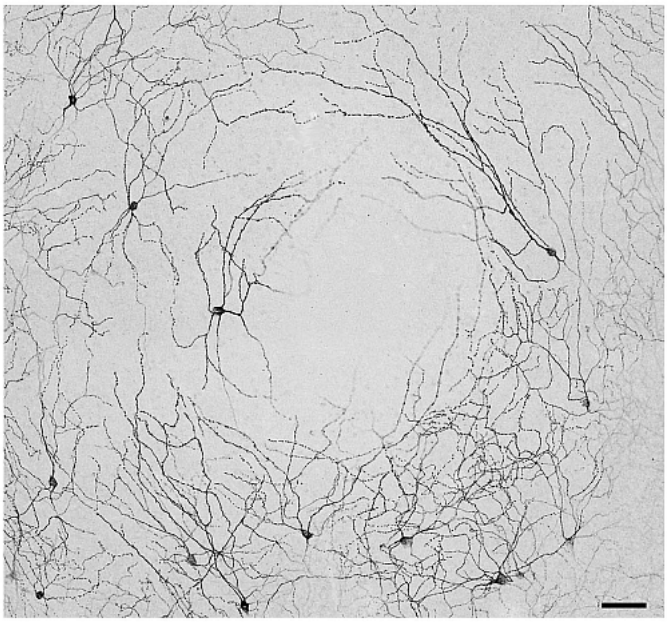

Figure 42. Melanopsin-expressing cells in the human foveal region. A single image from a stack of images is shown. The dendritic processes of the foveal cells wrap around the foveal pit. Scale bar = 100 µm. From Nasir-Ahmad et al., 2019 (114).

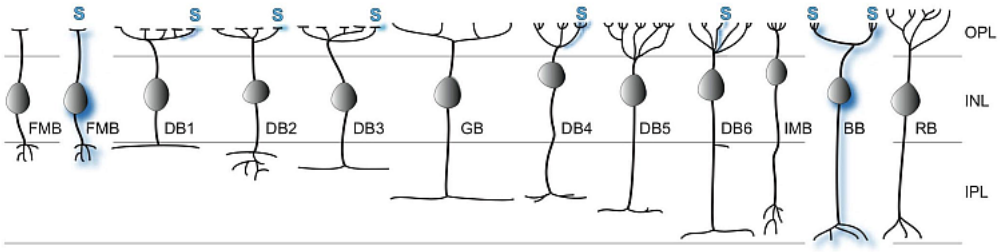

Figure 43. Schematic that illustrates the bipolar cell types of the primate retina currently known to have S-cone connectivity, indicated by S and blue shading. A subset of flat midget bipolar cells (FMB), and the blue cone bipolar (BB) make selective connections with S-cones. DB1, DB2, DB3, DB4, and DB6 bipolar cells, like other diffuse types, receive input primarily from L- and M-cones, but also make consistent but sparse S-cone connections. From Dacey et al. 2014 (34).

cell in the fovea. Probably they are equivalent to cells A, E and F in Figure 46. In addition, there are 2 cell types in Figure 47, in the monkey fovea, viz. one that colocalizes parvalbumin (PV) and calretinin (CR) (white arrows, Figure 47, b) and one solely PV-IR (green cells; Fig. 47, b). We know that A in Figure 46 is the well-known AII amacrine cell that is a cross over bistratified cell well documented to receive rod bipolar cell input and transmit rod signals to ON cone bipolar cells via gap junctions and to OFF cone bipolar cells and OFF ganglion cells via glycinergic synapses (84, 95-97) (see Webvision chapter on AII Amacrine Cells).

AII cells would not be expected to occur right in the rod-free fovea of the human retina but only to occur as the rods and rod bipolar cells appear on the foveal slope. AII amacrines are well known to be calbindin-IR, calretinin-IR and glycine-IR (85-87). AII amacrine cells reach their peak density of 10,500 cells/mm^2 at 1 mm from the foveal center. The cells of Figure 47 (c) right in the foveal pit and immediate foveal slope are CR –IR but not CR/CB-IR and therefore we suggest they are not the AII amacrine cells (Figure 47, arrow head points to a cell body, and small double arrows point to many CR dendrites) (85). The same conclusion can be drawn from a recent immunostained human retina shown in Figure 48.

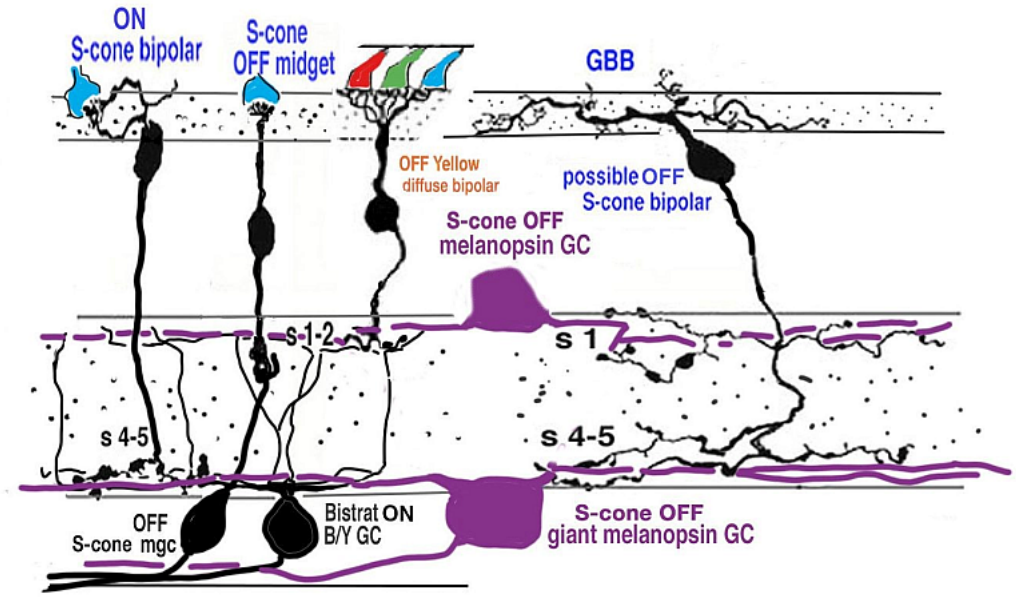

Figure 44. Drawing of the neurons involved in transmitting S-cone signals through the retina. The ON S-cone bipolar cell and the S-cone OFF midget bipolar cell are known to contact bistratified ON blue/yellow ganglion cells (Bistrat ON B/Y GC) and OFF S-cone midget ganglion cells (OFF S-cone mgc) respectively. The OFF yellow diffuse bipolar cells (dfb) contact all spectral cone types, and possibly contact the bistratified ON B/Y GC to provide OFF yellow opponency. The inner giant melanopsin GC could receive some ON input from the S-cone bipolar cells, but a dominant OFF S-cone input is not fully explained yet. An S-cone amacrine cell selective for ON-S-cone bipolar cells (not shown) likely provides S-cone OFF input to the outer giant melanopsin M1 GC. A giant bistratified bipolar cell (GBB, possible OFF S-cone bipolar) is theorized by us to be available to both inner and outer giant intrinsically photosensitive melanopsin ganglion cells.

The foveal retina (Figures 48, a-b) is compared to peripheral retina (Figure 48, c) in this double stained section for glycine (green cells) and CR (red cells). CR-IR amacrine cells are in the foveal pit area but are not double stained AII cells. AII cells are seen on the foveal slope (Figure 48, a-b) as double stained cells (yellow cells). They are very common in the peripheral retina (Figure 48, c, yellow cells). In all areas of retina there are still some pure CR-IR amacrine cells that are not AII cells (Figure 48, c, red cell bodies). These CR-IR amacrines do not appear to stain for glycine (probably for some technical staining reasons) in our human material. Green cells in the foveal pit and periphery that immunostain for glycine are mostly cone bipolar cells in Figure 48 a-c.

Our detailed EM study (85) showed that the CR-IR amacrine cells of the foveal slope closest to the foveal pit occurred internal to the first rod spherule and rod bipolar (Figure 49, a, arrow 4, 350 µm from the foveal pit). Cells at position arrows 3 and 1, 2 were amacrine cells that occurred at the same position that the first rod bipolar cells entered the IPL neuropil. They were a mixed group of CA-IR amacrine cells, many with AII characteristics i.e. input from rod bipolar axons and gap junctions with diffuse ON center bipolar cell types. In the foveal region we and others have never seen invaginating midget cone bipolar cells getting gap junction contacts from an amacrine cell (44, 46, 63, 69). Thus, we conclude that AII amacrine cells have nothing to do with the midget system in the foveal retina at least. We also conclude a different small field amacrine cell from AII cells, that is CR-IR, occurs in central, rod-free fovea. Recent studies by Lee and coauthors (86) and Strettoi et al. (98) come to a different conclusion.

The question is what type of amacrine cell is the CR-IR cell of our foveal study (Figure 49, cell 4 at 350 µm from the foveal center). Light microscopy suggest this CR-IR cell has a tristratified or diffuse dendritic tree with fine dendrites throughout the IPL (Figure 49 b, A curved arrow). The electron microscope study of the cells at 350 µm from the foveal center indicated that the CR-IR processes were receiving ribbon input from OFF midget bipolar cells and fed reciprocal synapses to the same bipolar terminal (Figure 50, a-b). The CR-IR amacrine

received input from a bipolar cell's axon terminal in the lower IPL neuropil, therefore from an ON center bipolar (Figure 50, c). This was likely an ON midget bipolar but an ON diffuse bipolar axon terminal could not be ruled out (Figure 50, d), because this study is looking at neuropil with many stained processes from multiple stained cells. The CR-IR amacrines also made clear synapses upon a large ganglion cell process that was almost certainly an ON-center midget ganglion cell (Figure 50, c and d). In the fovea the CR-IR amacrine cell seems to be driven by OFF and ON midget bipolar cells and make reciprocal synapses upon the OFF bipolar type at least, and crossover inhibitory synapses upon ON midget ganglion cells (Figure 50 a, b, c, d, and summarized in e).

Besides the CR-IR putative small field diffuse amacrine cell, there are at least two other small field, glycinergic amacrine cells that are probably part of the foveal and midget bipolar-midget ganglion cell system of transmission of cone specific pathways. These are the A8 bistratified cell (79, 92) which can be stained with synuclein antibodies (93, 94) and a small field glycinergic amacrine equivalent to Figure 46, E, A3 or knotty type 2 cells, which can be marked with Parvalbumen immunoreactivity (91, 99) (see Webvision chapter on Roles of Amacrine Cells). An additional small field glycinergic cell described in rat, mouse and macaque monkey retina is immunoreactive to the vesicular glutamate transporter 3 (100). This vGluT3 cell is likely found in human retina too. Its dendritic tree lies between the two cholinergic amacrine types' branching levels, where it receives input from bipolar cells and from other amacrine cells. The axon terminals of OFF diffuse cone bipolar types DB3 and ON diffuse cone bipolar DB5 (see Figure 43) run within the vGluT3 dendritic tree, so it is possible that vGluT3 cells are driven by both ON and OFF light responses and that they transmit this response to (at least) OFF ganglion cells (100, 101). In mouse retina, this amacrine cell selectively targets suppressed-by-contrast ganglion cells (102). It remains to be seen whether a glutamatergic amacrine cell is present in human fovea.

Furthermore there is at least one wide-field CR immunoreactive GABAergic amacrine that has dendrites coursing through the IPL on the foveal slope and even crossing the foveal pit floor (85, 86). This wide field A19 cell, immunostains for GABA, CB and CR (85). There is indirect evidence that the perifoveal blue-cone amacrine, perhaps the human A12, is GABAergic (77, 79).

Other wide-field amacrine cells are certainly present around the fovea at high density, as are all amacrine and ganglion cell types. Figure 51 shows the distribution of dopaminergic amacrine cells immunostained with tyrosine hydroxylase at the human fovea. These cells are at quite high concentration here and have a meshwork of dendrites forming a nest of processes around the foveal rim (Figure 51). The few dopaminergic synaptic beads in the foveal slope and pit (Figure 51, green spots) are probably synapsing upon small field A8 cell types, the CR immunoreactive small, diffuse amacrine. These are the same CR-IR amacrines we immunostain in the foveal center (Figure 48, Figure 49) (85). Dopaminergic amacrine cells synapse on AII amacrine cells in perifovea and peripheral retina (Figure 52) and on the stratum 1 melanopsin ganglion cell (103). Dopamine amacrine cells are also GABAergic and reach their highest concentration at the 4 mm ring around the foveal center where the highest concentration of rods is found (Figure 51) (104).

Summary

The diagram in Figure 53 summarizes the different neural types and their circuitry in the human fovea. The central foveal pit is devoid of second and third order neurons because of the close packing of the cone photoreceptors and the pushing out radially of these circuits to drive ganglion cells piled up at the outer edge of the foveal slope and thence passing visual messages to the visual centers in the brain. The cone mosaic in the foveal pit and throughout the rod free zone through the foveal slope is the basis of our visual acuity. We know that the human visual system is capable of acuity of 1 min of arc or 60 cycles/degree of visual angle. One degree of visual angle is thought to cover approximately 280-300 μm of retinal distance. The center of the fovea is about one degree across thus allowing visual discrimination of 1 min of arc i.e. the center to center spacing (3 μm) of the cones of the central mosaic in the foveal pit.

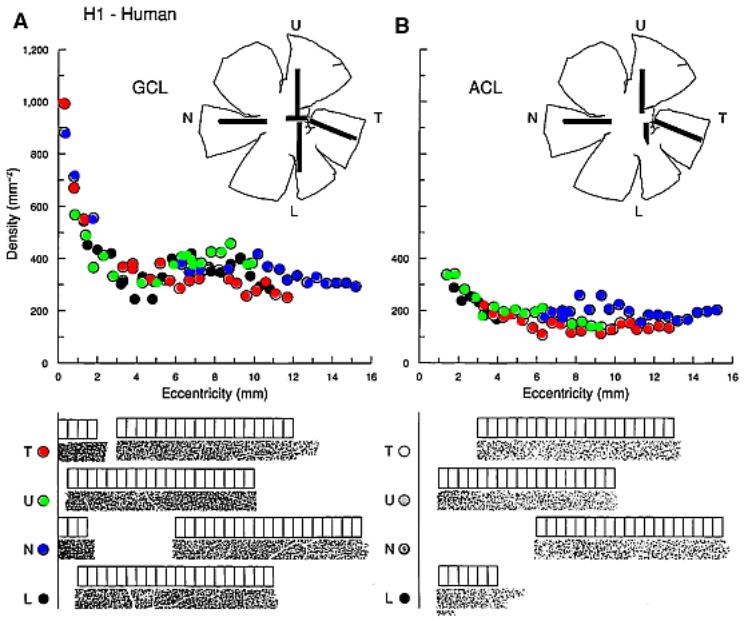

Figure 45. The counts of acetylcholine containing amacrine cells (starburst cells) in the human retina with eccentricity from the fovea. Strips counted for stained cells in nasal (N), temporal (T), upper (U) and lower (L) retina are shown for starburst cells in the ganglion cell layer (GCL) (A), and in the amacrine cell layer (ACL) (B). More cells lie in the GCL. Actual cell counts (dots) are shown in the lower panels. Clearly GCL starburst cells are at a peak density at the fovea. From Rodieck and Marshak, 1992 (82).

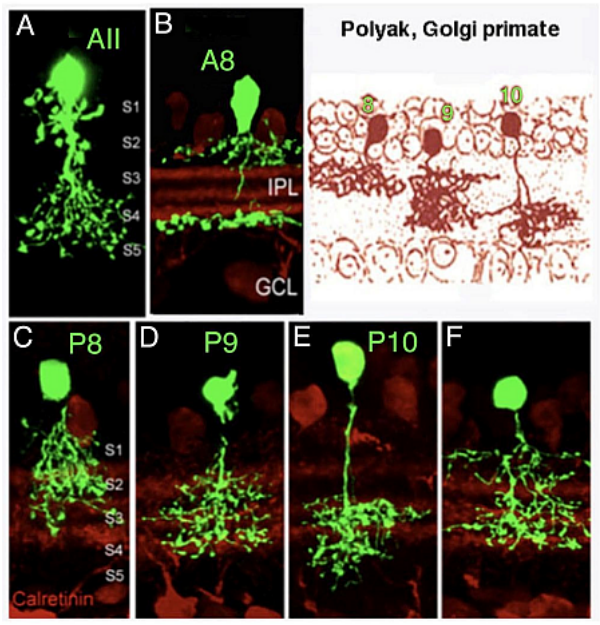

Figure 46. Glycine staining of amacrine cells expressing GFP (green fluorescent protein) in the thy1-GFP-O mouse (88). AII (A) and A8 (B) cells are well known crossover glycinergic amacrine cells in mammalian retina. Other small field amacrine cells (C-F) branch at different strata of the IPL, and all have been described in the human retina. Polyak's (#8, #9, #10) drawings are shown in the right inset drawing and compared to counterparts in mouse retina (C-E, P8, P9, P10). From Wässle et al., 2009 (89); Polyak, 1941 (90).

The central fovea with no superficial cell bodies and neural circuitry allows light to directly stimulate cones and give us this maximal visual acuity, but the circuitry underlying the transmission of this acuity to the brain must occur at the rim of the fovea. The rim of the fovea is where the ganglion cells are piled 6 to 7 deep (Figure 53) and is the foveal area containing all the intervening cells and connectivity to drive those ganglion cells. The

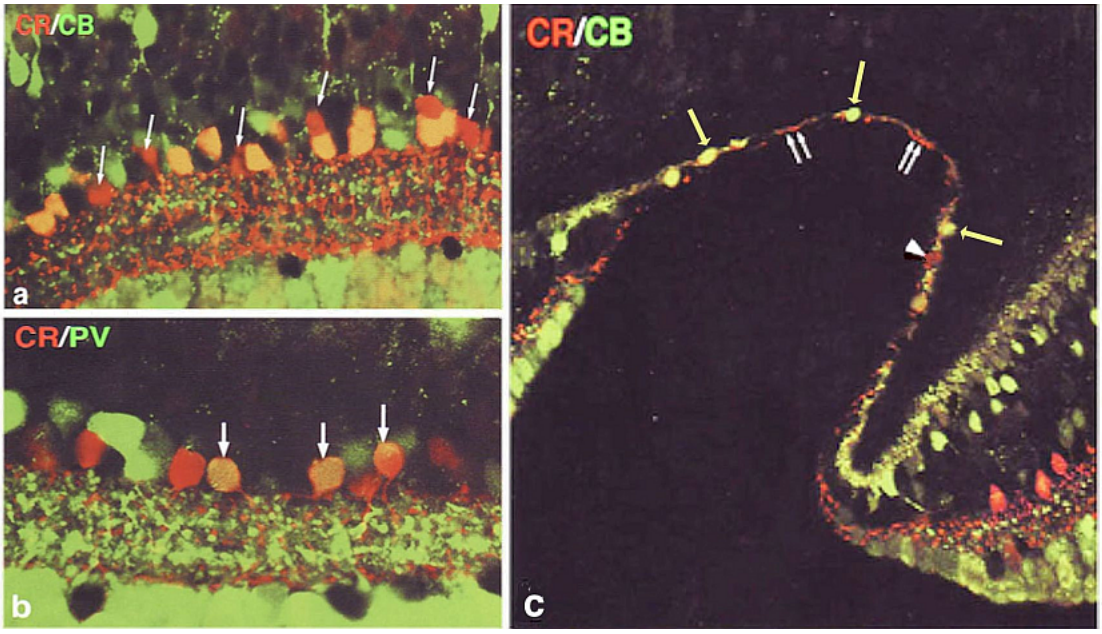

Figure 47. Immunostained central monkey retina, double staining with calretinin (CR, red) and calbindin (CB, green) or parvalbumin (PV, green). (a) Many amacrines double stain (yellow) with CR and CB (AII cells) but some are CR alone (white arrows). (b) Many amacrine cells double stain with CR and PV (arrows, yellow) but some are PV alone or CR alone. (c) In the foveal slope and pit, some amacrine cells are CR alone (red cell bodies and processes, double arrows and arrowhead). CR cells are on the foveal slope (right hand side). CB cells (green) are also in the foveal pit (green arrows), but they could be CB bipolar cells. From Kolb et al., 2002 (85).

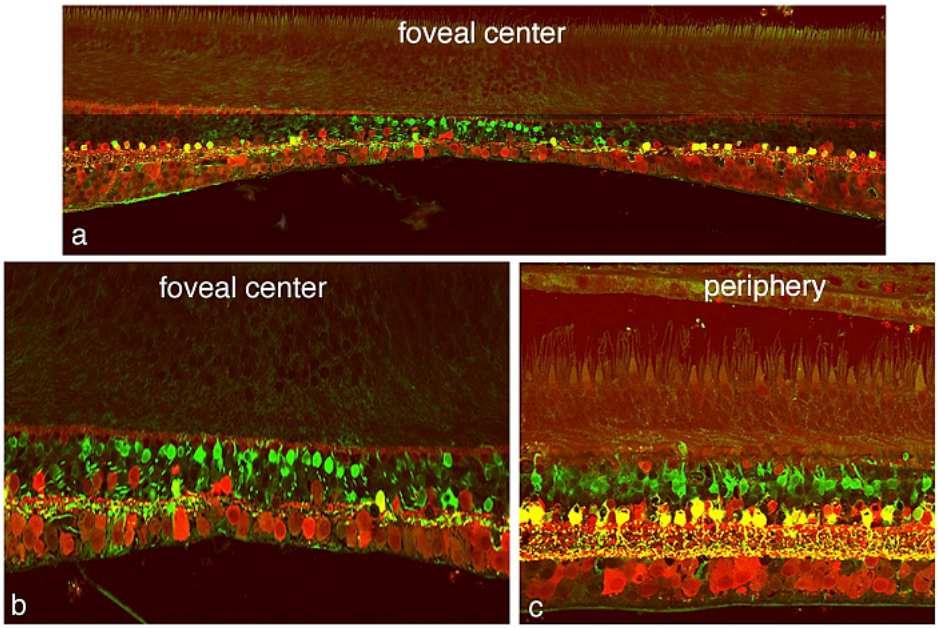

Figure 48. Fovea of the human retina immunostained for calretinin (CR red) and glycine (green). (a) Just at the beginning of the foveal slope, the amacrine cells and ganglion cells are labeled solely with CR, while bipolar cells label for glycine. Some double labeled (yellow) amacrine cells begin to appear on the outer foveal slope. (b) is an enlargement of the foveal center. (c) Shows that many amacrine cells in peripheral retina double label for CR and glycine (yellow). They are probably AII amacrine cells. Some bipolar cells label for glycine, while ganglion cells label for CR solely.

predominant circuitry is concerned with the private cone to midget bipolar and midget ganglion cells. Every cone drives two midget bipolar cells and two midget ganglion cells so that the message from a single cone is provided to the brain as a contrast between lighter signals (ON pathways) or darker signals (OFF pathways)

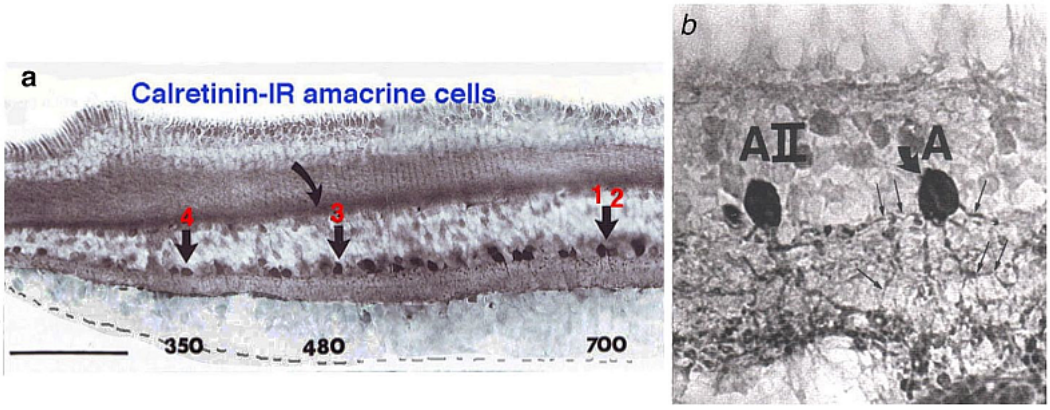

Figure 49. (a) Vibratome section of half a fovea of monkey retina immunostained for calretinin (CR-IR). The distance from the fovea is expressed in µm. At 480 µm the first rod spherules appear (curved arrow). At 350 µm there are no rod spherules or rod bipolar cells. (b) Cryostat of the CR-IR material outside of the fovea where it is clear that one CR-IR cell is an AII amacrine cell (lobular appendages and distal dendrites in lower IPL), while the other amacrine (A, curved large arrow) has an array of fine dendrites with synaptic boutons passing down through the entire IPL (fine arrow) either in a tristratified or diffuse branching pattern. From Kolb et al., 2002 (85).

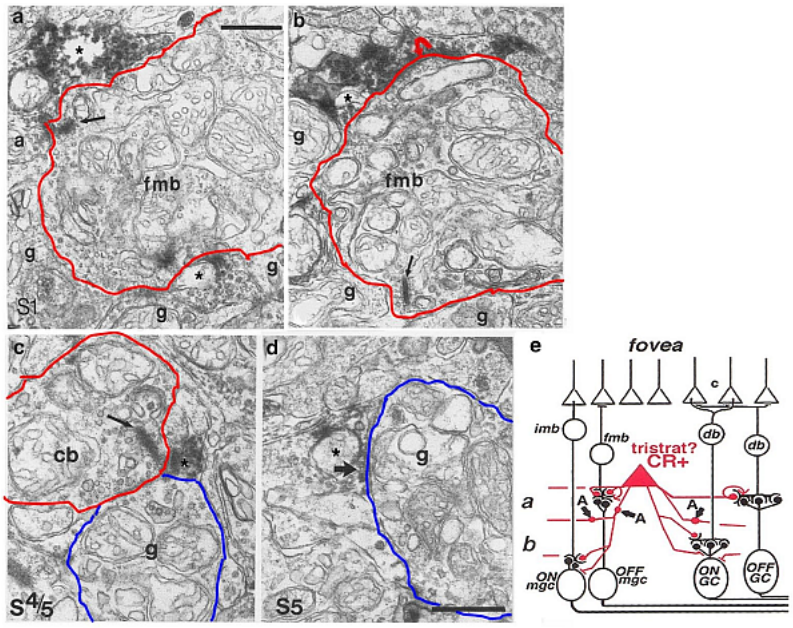

Figure 50. EM of CR-IR profiles (black, asterisk) in stratum 1 (a, b) and deep in the IPL in stratum 4/5 (c, d). The CR-IR profiles are postsynaptic to ribbons of flat bipolar cells, most of which are flat midget bipolar cells (fmb) and make reciprocal synapses (red arrow). In (c, d) CR-IR profiles are post-synaptic to bipolar cells, most of which are invaginating midget bipolar cells (imb) and presynaptic to ganglion cells, most of which are ON center midget ganglion cells (mgcs). Scale bar = 0.5 µm. (e) Summary diagram of the circuitry of the CR-IR amacrine cell of the fovea. From Kolb et al., 2002 (85).

(Figure 53). The sharpening of this contrast message is provided by horizontal-cell feedback circuits and, in some pathways by amacrine circuitry. The human retina with 3 spectral types of cone means that many of these midget pathways will carry a concentric color opponent message (Figure 53). For example, a red cone will transmit to a midget bipolar cell and a midget ganglion cell a red ON center, green OFF surround or a red OFF center and a green ON surround. The same occurs for the green cone message to midget bipolar cells and midget ganglion cells (Figure 53, red and green neurons). In these red and green color pathways, the H1 horizontal cell is thought to play a role via feedback mechanisms to give the midget bipolar and midget ganglion cells the concentric opponent message (Figure 53). A current model of color vision channels in the human fovea,

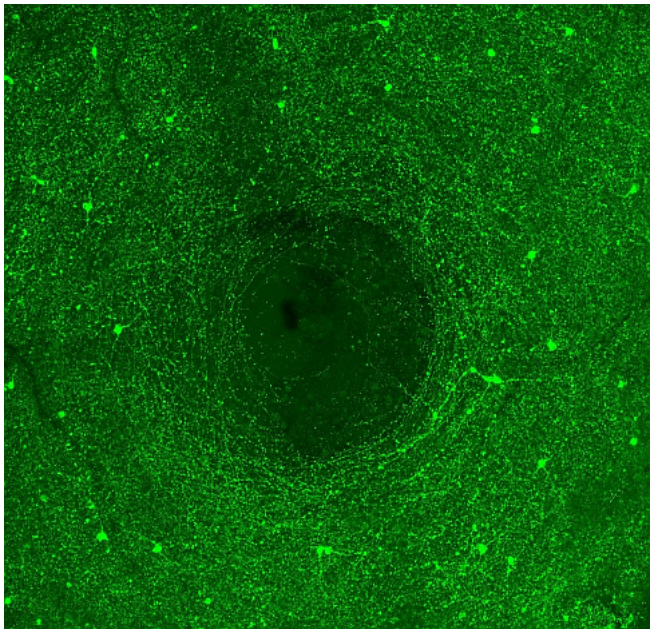

Figure 51. Wholemount of the fovea in a human retina that is immunostained for tyrosine hydroxylase. The stained dopaminergic amacrine cells are numerous and have a meshwork of dendrites surrounding the fovea. Some fine dendrites penetrate the foveal slope and surround the foveal pit.

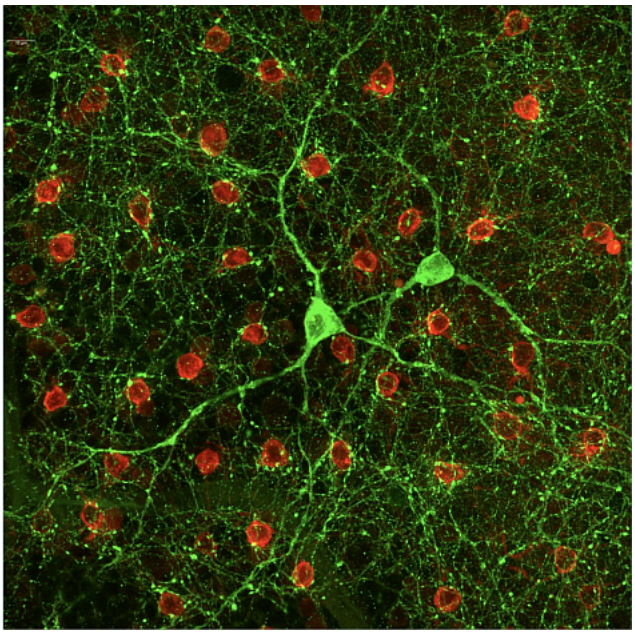

Figure 52. Wholemount human retina immunostained for tyrosine hydroxylase (Th, green) and Calretinin (CR, red). The Th-IR cells are dopamine cells and exhibit rings of synaptic profiles around the CR-IR cell bodies of AII amacrine cells in this case.

however, suggests that the red and green cone midget systems are not channels for color hue, but are primarily chromatic edge and visual acuity channels (70).

Signals from blue cones in the foveal slope have different pathways, in the case of ON center blue signals, to a non midget small bistratified ganglion cell (Figure 53) via the lower tier of dendrites. The upper tier of dendrites receives red and green cone OFF input from a diffuse cone bipolar type (Figure 53, yellow/orange cells). An OFF-center blue midget bipolar cell is known to be present in the fovea and connect to a blue-OFF midget

ganglion cell (Figure 53). Another OFF blue message is sent to giant melanopsin ganglion cells that are present in the foveal ring area, but the circuitry driving these is uncertain and possibly involves an intermediate amacrine cell (not drawn in Figure 53). The H2 horizontal cells are thought to be feedback neurons of the blue cone system providing a concentric color-opponent organization of blue cones (35), nonetheless there is no concentric opponent visual message for the bistratified blue-driven ganglion cell types (Figure 53, blue and yellow opponent fields are coextensive), unlike the red and green cone midget ganglion cells.

Apart from the midget system that dominates the fovea, there is a presumed non-color channel (i.e. luminosity channel) in the fovea via the diffuse bipolar cells that get input from several cones of different spectral type and carry that non-color-specific message about light to a large field ganglion cell type known as a parasol ganglion cell (Figure 53, grey cells with receptive field structure in grey). Parasols also come in ON center and OFF center varieties, and are thought to have a center–surround organization concerning light and dark although they may have an imbalance of the strength of spectral mechanisms in center and surround (51, 105). These cells respond strongly to a sequence of slits consecutively displaced along a fixed direction, but much more poorly to a sequence of randomly positioned slits. This is evidence of tuning for motion (58).

Amacrine cells of the fovea are mostly small field and glycinergic. The larger field amacrines are present but more typically surround the fovea in a ring of processes, with little or no penetration into the foveal center (Figure 53). Thus, the small field glycinergic amacrines are important in some sort of interplay with the midget bipolar cell – midget ganglion cell channels (Figure 53, A8, CR and PV cells). We have anatomical descriptions of their synaptology but only the A8, P8 (called A2 in cat retina) (106) and PV cells have been recorded from. All have cone driven responses. Some are OFF center (A2, A8), and some are ON center (PV cells). All have been hypothesized to have a role in the generation of antagonistic surrounds of ganglion cells, but this remains to be proven. Foveal midget ganglion cells appear to receive little direct synaptic inhibition (107).

In sum, the fovea is a small but vital area of the central retina, unique in neural circuits, and molecular expression (108). The foveal cones themselves have evolved a sustained response characteristic, suited to standing contrast, that differs from peripheral cones (107). Foveal midget ganglion cells show virtually no synaptic inhibition, as compared to peripheral midgets (107). The fovea appears to have evolved in development from a central mound of cells as seen, for instance, in cat area centralis, to a virtually neuron-free pit, to concentrate cone photoreceptors into a dense array to be maximally sensitive to the smallest stimuli, and further, displace all ensuing circuitry into an exquisitely organized small surrounding rim of real estate in the retina foveal slope. If this small area is damaged by looking at the sun, by inherited cone atrophies or degenerated by age related macular degeneration (AMD), or even underdeveloped, as happens in albino people (see Webvision chapter on albinism), our eyesight becomes very poor.

Acknowledgements

P.A., N.C., I.O.-L. and R.F.N. thank H.K. for initiating and organizing this project, in part arising from long and fruitful collaboration among our laboratories. P.A thanks collaborators at the Medical University of Vienna and elsewhere, in particular Christian Schubert, Martin Glösmann and Dietmar Pum. Eduardo Fernandez obtained part of the human donor tissue. P.A work was supported by grants from the Austrian Science Fund (FWF)and EC-grant QLK6-CT-2001-00279. N.C. work was supported by the Spanish government, MINECO-FEDER-BFU2015-67139-R, RETICS-FEDER-RD16/0008/0016 and FPU14/03166. Generalitat Valenciana-FEDER, IDIFEDER/2017/064 and Prometeo-2016/158. R.F.N. work was supported by the Intramural Research Program of the National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda MD.

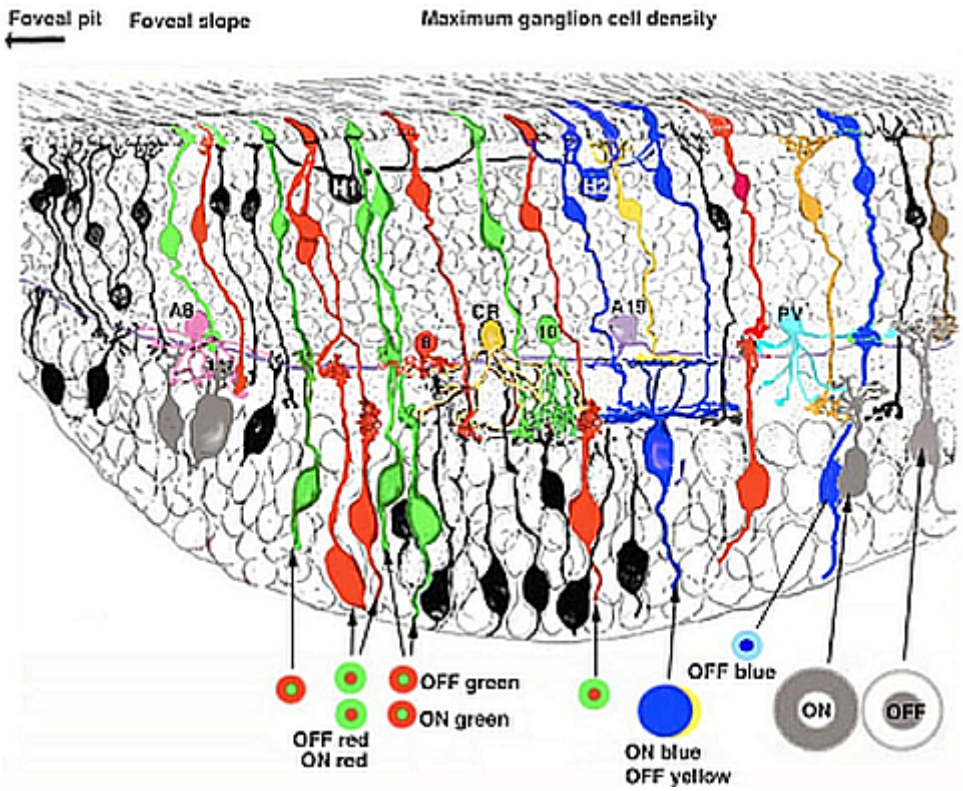

Figure 53. Summary diagram of the neural architecture of the human fovea, adapted from an original drawing of Polyak (1941) (90). The cone pedicles are closely abutting in the foveal OPL where ON and OFF midget cone bipolar cell dendrites contact them. ON and OFF midget bipolar cells contact ON and OFF midget ganglion cells in the inner retina providing M- and L-cone-connected private channels (red and green cells). The S-cone midget system (small blue cells) is only an OFF midget bipolar-ganglion cell channel, but the S-ON channel is via a blue-selective bipolar cell and a bistratified B/Y ganglion cell chain. A diffuse bipolar cell (yellow) provides OFF L/M cone input. Diffuse cone bipolar cells (brown and orange cells) contact the parasol ganglion cells (grey cells). Various small field amacrine cells are indicated as A8, P8, CR, P10, A19 and PV. H1 and H2 horizontal cells are indicated as feedback neurons for the M and L-cone (H1) and for the S-cone (H2) pathways.

About the authors

Helga Kolb, **Ph.D.** is the originator and chief editor of Webvision. She was born in England and educated with degrees from Bristol University. Helga has been in eye research since 1961, at first doing electrophysiology at the Institute of Ophthalmology, Moorfields Eye Hospital, and then emigrating to the USA. At the Wilmer Institute, Baltimore, in John Dowling's lab, along with Brian Boycott she continued work in anatomy of the retina concentrating on understanding the neurons and wiring of the monkey retina. Later at the NEI, and the NINDS, Bethesda**,** she collaborated with Peter Gouras and Ralph Nelson on joint physiology and electron microscopy of retinal neurons to understand the connections of cell types involved in light, dark and color pathways in cat and monkey retinas. On moving to Utah, Helga continued collaborative projects with Ralph Nelson and started new collaborations with various postdocs in her lab from Europe and China mainly. Thus, Peter Ahnelt and Nicolas Cuenca aided and abetted studies of the monkey and human retina, before going on to their stellar careers in Austria and Spain respectively. All of us have been fascinated with the organization of the human fovea and this chapter represents our collaboration over the years.

Ralph F. Nelson, **Ph.D.** received his B.A. in Biophysics from Amherst College and his Ph. D. in Biophysics from Johns Hopkins University. At Johns Hopkins, under the preceptorship of John Dowling, he studied conductance

mechanisms responsible for light responses of retinal bipolar cells. In his postdoctoral studies at the National Institutes of Health in Dr. Peter Gouras' lab, he formed a close collaboration with Helga Kolb in pioneering a type of study in which the light responses of retinal neurons were tightly interpreted in terms of synaptic connectivity. This group was the first to show that separation of bipolar/ganglion cell connections into two layers within the IPL underlaid the ON-center and OFF-center responses of the retina and whole visual system. Ralph Nelson's laboratory is the Neural circuitry Unit of the Basic Neurosciences Program at the National Institute of Neurological Diseases and Stroke, NIH, Bethesda. His recent studies are on the neural circuitry for image processing in zebrafish retina.

Dr. Peter Ahnelt, Ph.D. was born in Bernstein, Austria. He received his Ph.D. in Biology at the University of Vienna in 1980. His foremost interest was the identification of color specific cone photoreceptors in ground squirrel retinas at the Dept. of General and Comparative Physiology, Medical University of Vienna (MUW). In 1984/85 he worked as a post-doc in Helga Kolb's lab at the University of Utah, identifying two spectral subtypes of human cone photoreceptors based on morphological and topographic criteria. Further studies at the U of U, revealed patterns of color-specific connections between human cone and horizontal cell subtypes. As associate professor at the MUW, in collaboration with Jan Nora Hokoc, Eduardo Fernandez, and Martin Glösmann he worked on understanding the various evolutionary and ecological trends underlying mammalian/primate photoreceptor mosaic organization. When retinal OCT imaging was advancing in labs such as Wolfgang Drexler's, Peter made correlations of OCT signal profiles with retinal sublayers. More recently, Peter is interested in the role of Fractalkine in microglial activation in a retinitis pigmentosa mouse model.

Isabel Ortuño-Lizarán, Ph.D. is from Elda, Alicante, Spain and studied for a Biotechnology degree in the Polytechnic University of Valencia, Spain. After, she received a master's degree in Neurosciences at the University of Valencia, she recently finished a doctorate degree (2019) at the University of Alicante, under the supervision of Dr. Nicolás Cuenca. Her research has been mainly focused on studying the human retina and foveal organization in Cuenca's lab. She has also been working on understanding the visual impairment in Parkinson's disease using human retinas and examining the melanopsin ganglion cell density and degeneration rates with the disease progress.

Nicolás Cuenca, Ph.D. was born in Elda, Alicante, Spain. He has a B.Sc. Degree in Biological Sciences from the University of Valencia, Spain and a Ph.D. Degree from the University of Alicante, Spain. He carried out postdoctoral studies at the Department of Physiology, University of Utah (USA) in Helga Kolb's laboratory. Currently, Nicolas is Full Professor in the Department of Physiology, Genetics and Microbiology at the University of Alicante. His research is dedicated to the understanding the functional organization of the mammalian retina. He has extensive expertise in the field of retinal connectivity, morphology and functional correlations, and is an expert in confocal microscopy of immunostained retinas. Nicolas has won many awards

throughout Europe for his photography of immunostained retinas. Presently he is studying the disruption of the retinal architecture including blood vessels and glial cells in inherited retinal degenerations. He is concentrated on therapeutic treatments using animal models for retinitis pigmentosa, glaucoma and macular degeneration. His team is aiming to slow down the progression of neurodegenerative diseases, through the use of cell transplant, antiapoptotics, gene therapy and antioxidant drugs. All are welcome to visit his imaging website at www.retinalmicroscopy.com.

Retinal Circuits

Circuitry for Rod Signals through the Retina

Helga Kolb

Created: May 1, 2001; Updated: September 1, 2009.

Rods

Rod photoreceptors and rod-connected nerve cells through the retina are responsible for pathways concerned with night vision and increased sensitivity of our visual system under what is called scotopic conditions (conditions of very little ambient light). Most vertebrates have a preponderance of rod photoreceptors in their retinas and such animals are very good at hunting and movement at night because of their very sensitive scotopic visual systems. Some animals are even completely nocturnal and have lost some of their cone types and their cone system neurons.

Humans, of course, are highly visual vertebrates and function mostly with their cone systems for color and high acuity form vision. However, the rod system is also important for our capacity to move around and function in scotopic conditions. If our rods or rod system neurons become diseased and degenerated we become night blind as happens to unfortunate people who have a disease called retinitis pigmentosa.

When looking at the mosaic of human photoreceptors it becomes apparent that the human retina is actually rod-dominated numerically. That is, rod photoreceptors out-number cone photoreceptors by orders of magnitude and the consequent second- and third-order neurons recruited for processing rod-driven vision outnumber the cone pathways neurons everywhere but in the central fovea (Fig. 1).

Rods peak in density in a ring approximately 5mm (18o) from the center of the fovea (human (1); rhesus monkey (2)). Rods are present in greater numbers than cones from 2 mm from the fovea to the far periphery. As can be seen in Fig. 2, the rods always form a nice hexagonal packing around the cones and separate the cones from each other.

Rod Bipolar Cells

As was pointed out in a previous section, only one morphological type of bipolar cell has been found to make connections with the rod photoreceptors. The rod bipolar collects input from between 15 and 30 rod spherules in the outer plexiform layer (Fig. 3).

Electron microscope investigation of Golgi-impregnated rod bipolar cells first showed that the rod bipolar dendrite penetrates into the rod spherule to make an invaginating ribbon related type of contact (3) (Fig. 4). This invaginating contact is known to bear metabotropic glutamate receptors in the bipolar dendrite membrane (Fig. 5). The receptor was proved to be mGluR6 by Numura and coauthors (4) and Vardi and Morigawa (5) using immunocytochemistry against the cloned mGluR6 receptor. Since then the mGluR6 receptor is thought to trigger a second messenger cascade involving GalphaO, transducin molecules, to act on voltage gated Ca channels (6, 7).

Both Golgi impregnation of single rod bipolar cells (Fig. 6) and immunocytochemical staining of rod bipolar cell populations with protein kinase C (PKC) (Fig. 7) show the characteristic morphology of the rod bipolar cell type in mammalian retina (8, 9). The immunocytochemical staining and confocal microscopy is now the most illustrative way of seeing the rod bipolar cells in mammalian retinas (Cuenca personal communication) (Fig. 7). As can be seen in this stunning micrograph (which incidentally won the first place award in science photos at the Spanish Congress of Neuroscience, 2009) rod bipolar cells (red) send dendrites to the rod spherules in the outer plexiform layer (green) to end at synaptic ribbons therein (blue) and axons to the inner plexiform layer where they terminate deep, close to the ganglion cell bodies, as narrow-field, clumpy axon terminals (red).

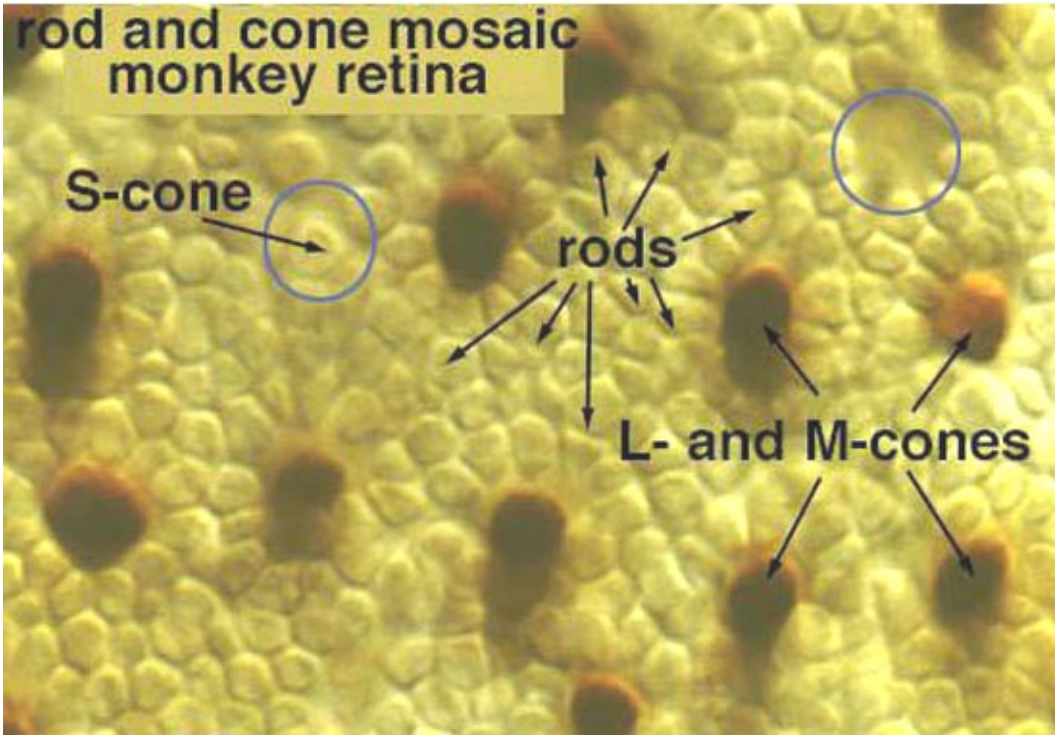

Figure 1. Light micrograph of the primate photoreceptors.

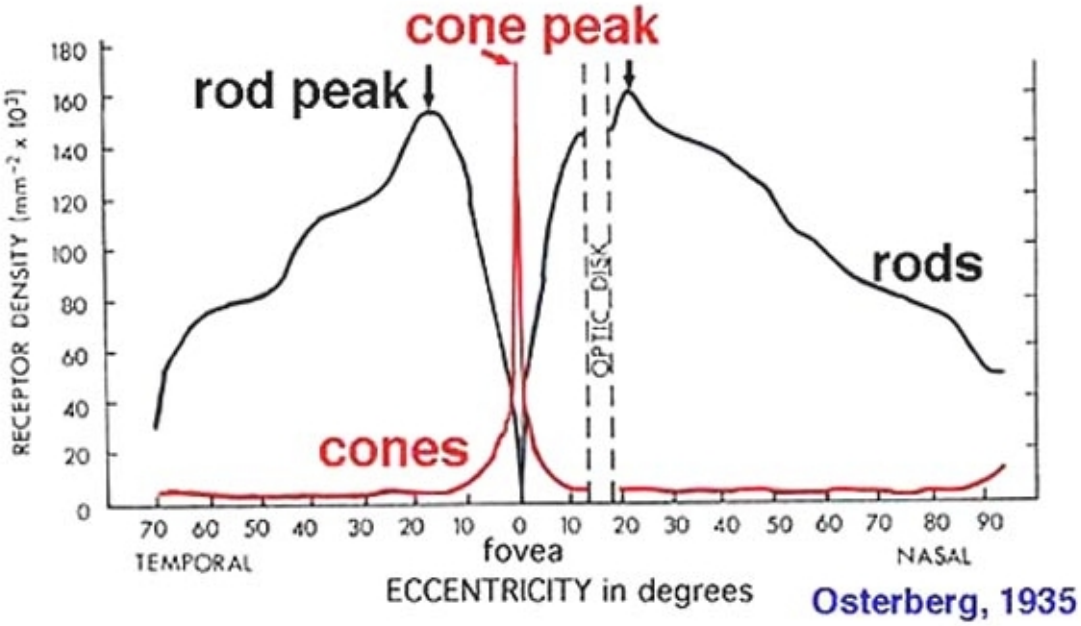

Figure 2. Graph to show rod and cone densities along the horizontal median.

Electron microscopy of the rod bipolar cell axons in the inner plexiform layer shows that they make ribbon synapses only upon amacrine cell profiles. A ganglion cell dendrite is not seen to be postsynaptic to rod bipolar cell axons (10, 11). This allows for both divergence of the rod signal and collection (convergence) of signals from many rods and rod bipolars, by means of these amacrine cells, before synaptic output to ganglion cells. Most commonly the output of the rod bipolar ribbon is to a dyad of amacrine cell processes, one of which is known as

AII and the other as A17, a reciprocal amacrine (see below). The AII is characterized by making gap junctions with neigboring cone bipolar or other AII profiles. The A17 is characterized by always making a return synapse known as a reciprocal synapse to the rod bipolar axon terminal (Fig. 8 and Fig. 9).

Rod Amacrine Cells

Two amacrine cells are key in the rod pathway circuitry through the mammalian retina (see above). The one is a small-field, bistratified cell given the name AII in its original description, to compare with the other amacrine common at the rod bipolar ribbon dyad, known as AI (10). Since then the AII label has stuck to the rod amacrine but the AI label has been dropped in favor of calling the cell the A17 or reciprocal amacrine. The small AII amacrine is probably the commonest amacrine cell in the mammalian retina (512,000 total in cat retina) followed by the A17 cell (between 170,000 and 230,000 cells in rabbit) (12) (Fig. 10).

Two other amacrine cells are known to be involved in the rod pathways but to a lesser extent that AII and A17. These cells are A8 and A13 (above). But they are more strongly driven by the cone system in that greater numbers of cone bipolar cells have synapses upon them than rod bipolar cells. We shall, therefore, consider them in great detail in the chapter on cone driven pathways through the retina. However one amacrine cell, A18, is definitely involved in the pathways of the rod system by virtue of influencing both AII and A17 amacrine cells. So we will describe A18 cells in detail in this chapter.

AII Amacrine Cells

AII amacrines are fascinating, small-field amacrines that have a seminal role in the rod pathways, and in linking the rod and cone pathways so that the rod signals can also use the cone bipolar pathways to ganglion cells. The narrow-field bistratified rod amacrine cell, AII, is primarily postsynaptic to rod bipolar axon terminals in lower sublamina **b** of the IPL (30% of its input (13)). Its major output is from its lobular appendages upon ganglion cells that have dendrites only in sublamina **a** (8, 14) (Fig. 11).

The AII also passes rod-driven information to a cone bipolar cell that makes contact with ganglion cells of sublamina **b**. It does so through large gap junctions with these cone bipolar axons before they in turn make their ribbon synapses to those ganglion cells (black spots on AII primary dendrites to pink cb axon). A little OFF-center cone bipolar input is provided to the AII lobular appendages by cb1 and cb2 cone bipolar cells in sublamina **a** (19% of input (13)) (yellow cb profiles). AII amacrine cells are also coupled across the retina in a weak electrical syncytium by virtue of their gap junctions between their dendrites in sublamina **b** (gj, lower right) (14-16) (Fig. 12).

We know from the intracellular recordings done in cat retina that ganglion cells with dendrites in sublamina **a** respond to light with a hyperpolarizing or OFF-center response and that ganglion cells with dendrites in sublamina **b** respond with a depolarizing or ON-center response (17).

We also know that rod bipolar cells respond to light with a center-depolarizing (ON-center) responses (18), and by virtue of their deep penetrating axon terminals to sublamina **b** we expect them to carry rod ON-center signals to the next order neurons i.e. either ganglion cell or amacrine cell of that neuropil. Since rod bipolar cells do not synapses directly with ganglion cells we expect the rod bipolar cell to have output at ribbon synapses instead to center depolarizing (ON-center) amacrine cells. And this is in fact what has been discovered from intracellular recordings in cat and rabbit retinas. AII amacrine cells respond to light with a depolarizing response (ON center response) in their centers (18) (Fig. 13).

Thus the center-depolarizing (ON-center) AII cell make a sign-inverting synapse upon the center-hyperpolarizing (OFF-center) type of ganglion cell to contribute rod signals to the center response of the receptive field of that ganglion cell. (Amacrine cells in general are known to be inhibitory neurons using

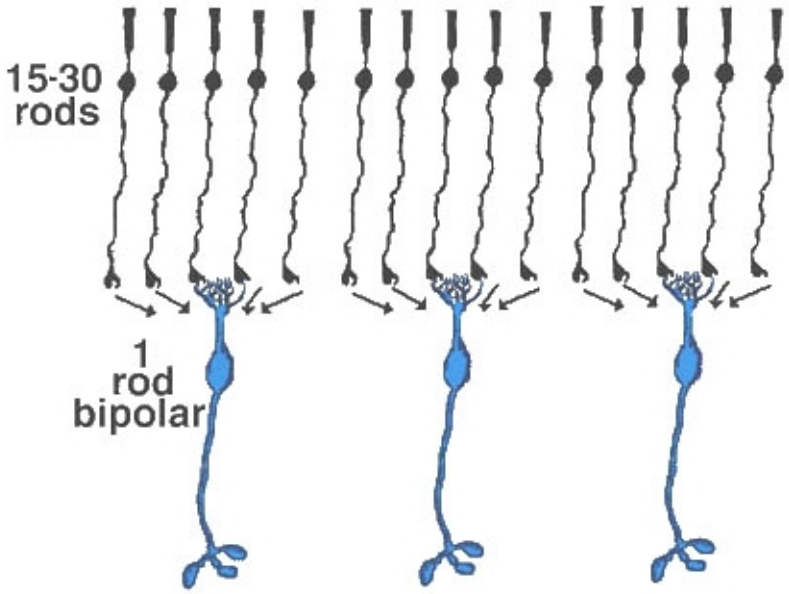

Figure 3. Convergence of rod pathways.

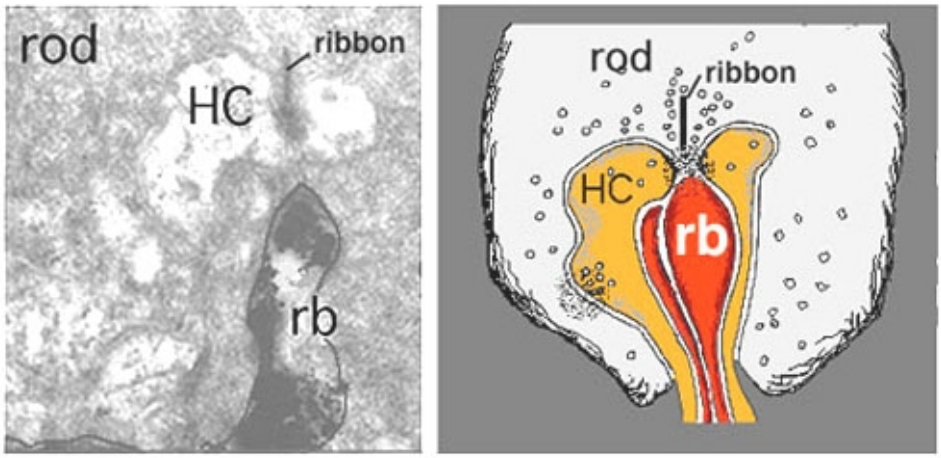

Figure 4. Electron micrograph and drawing of a rod spherule.

common inhibitory neurotransmitters of the CNS like glycine and GABA). AII amacrine cells are glycinergic (19). The AII uses the gap junction with the sublamina **b** type of cone bipolar (cb5 in Fig. 13) to pass center-depolarizing (excitatory) input to the center-depolarizing ganglion cell with which the cone bipolar has synapses (cb5 to ON-center beta GC, Fig. 13). By this division of function within the small dendritic field of the AII amacrine cell, rod signals can be ensured of reaching both ON- and OFF-center types of ganglion cells (Fig. 14).

A17 Amacrine Cells

A17 cells are very wide-field diffusely branching amacrine cells types. Their fine dendrites pass through the IPL to end running in the lower sublamina **b**, receiving synapses at intervals denoted by their beads from rod bipolar axon terminals (Fig. 15).

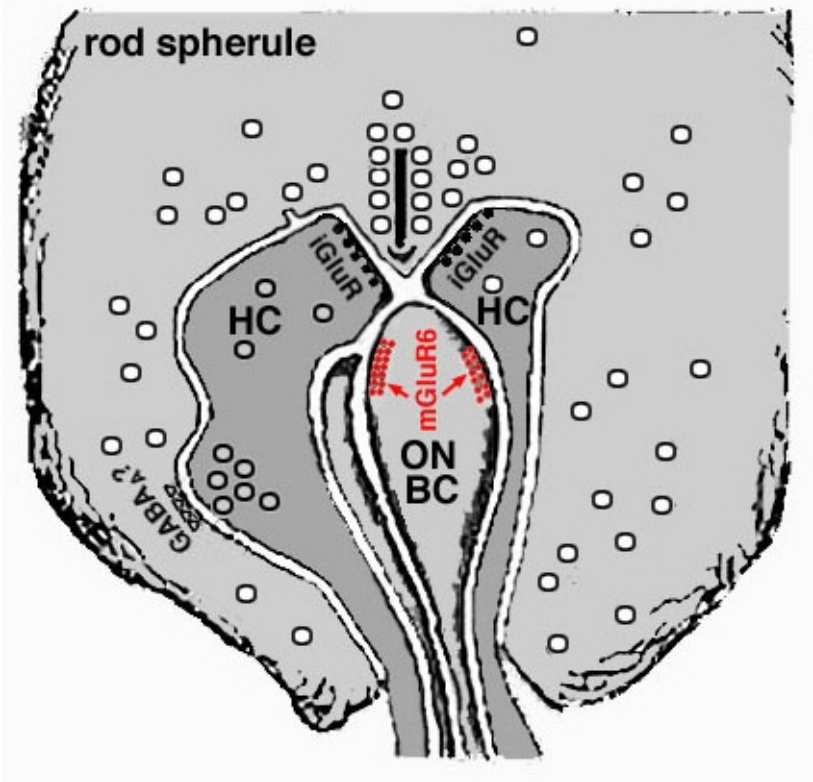

Figure 5. The present understanding of the receptor molecules thought to be present at the rod to bipolar and horizontal cell dendrites in the mammalian retina.

A single A17 amacrine cell receives synaptic input from approximately 1000 rod bipolar cells. Interestingly A17 cells do not appear to make synapses upon other amacrine or ganglion cells, instead they merely interconnect rod bipolar cells by reciprocal synapses. The A17 thus has a completely different receptive field area over which it collects rod signals than its narrow-field partner at the dyad, the AII amacrine cell. Presumably the A17 is an integrating unit that helps set sensitivity levels over a very large area of rod photoreceptors and rod bipolar cells (20).

Like the AII amacrine cell A17 cells respond to light flashes with a center depolarizing response (20). Its ON-center response reflects the rod generated ON-center message (18). But unlike the AII, the A17 cell's output is only known to be reciprocal synapses to the rod bipolar from which it receives input (20) (Fig. 16).

A17 cells are very sensitive at low light intensities and may play a role in converging and amplifying rod signals from large areas of retina. A17 is known to accumulate serotonin in rabbit retina (12) but is thought to be a GABAergic neuron in terms of neurotransmission, in all mammalian retinas (21).

Dopamine Containing (A18) Cells of the Retina

A18 is a wide-field amacrine with extensive dendritic branching in the stratum next to the amacrine cell bodies, i.e. S1 of sublamina **a**. The A18 is known to be a dopaminergic amacrine cell and the whole population of these cells in the retina can be revealed by immunostaining to the synthesizing enzyme of dopamine, tyrosine hydroxylase (above). A18 has thin dendrites and axon like processes that run for hundreds of microns (Fig. 17).

The fine terminals of these processes surround cell bodies and dendrites of amacrine cells AII, A8, A17 and possibly A13 cells (22-24). The A18 thereby synapses in profusion upon the two major and some of the minor amacrines of the rod pathways. In addition, the A18 receives many synapses from other amacrine cells and some few synapses from a cone bipolar cell type, as yet not positively identified, but possibly the type known as a giant

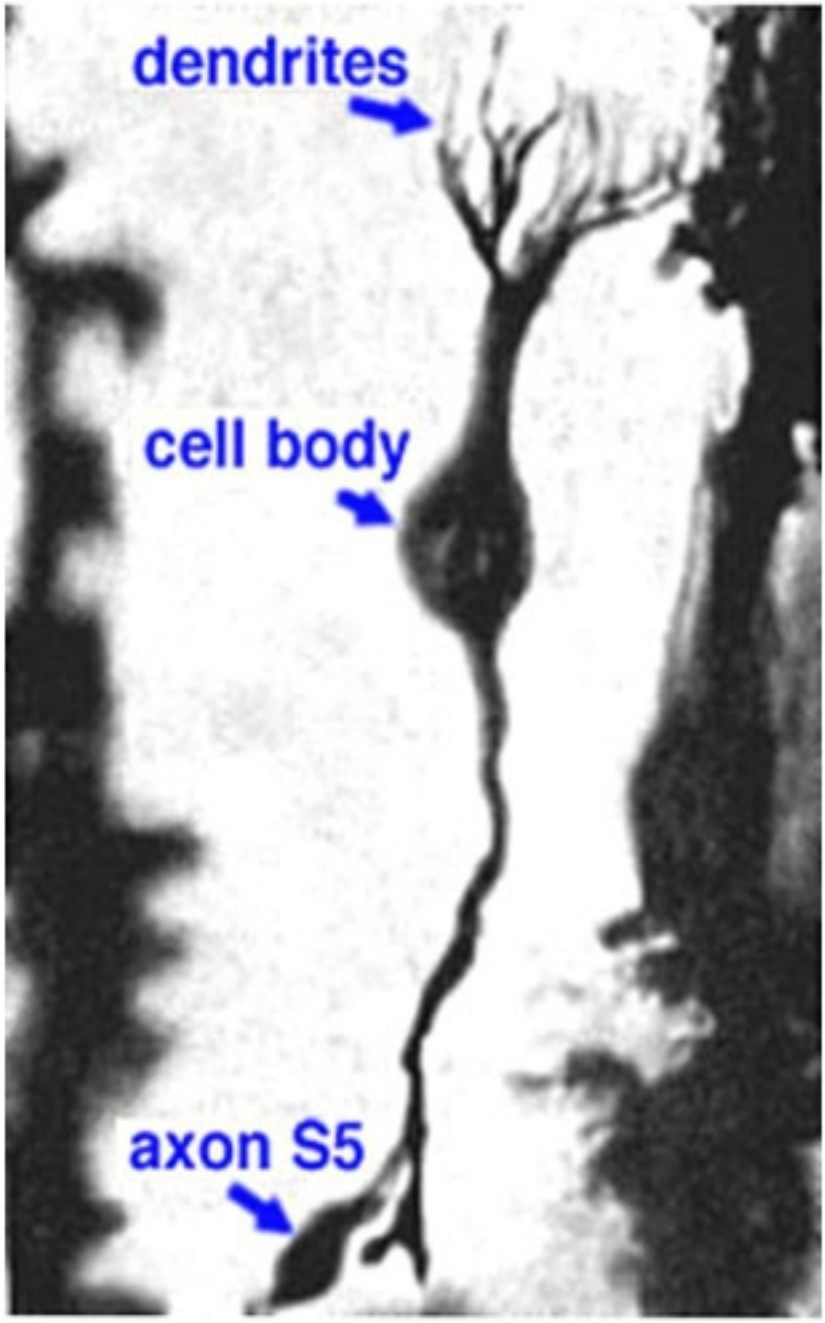

Figure 6. Golgi impregnation of rod bipolar cells.

bistratified cone bipolar cell (25). Recently it has also been discovered that deep axon-like processes of the A18 amacrine passing in S5 of sublamina **b** make synapses directly upon rod bipolar axon terminals (23). A18 has not yet been studied by intracellular recordings, but equivalent dopaminergic amacrine cells in other species are known to be transient-sustained, center-depolarizing in response type (26) (Fig. 18).

It is thought that the dopaminergic A18 cell has an effect upon the rod AII amacrine to uncouple the syncytium of AIIs across the retina and to uncouple the AII amacrine from the cone bipolar cell of sublamina **b** (27, 28). This could have the effect of increasing receptive field sizes of ganglion cells under scotopic conditions, providing added sensitivity to the rod system messages in the ganglion cells. Dopaminergic amacrine cells are also thought to function in the circadian cycle of the shift from dark to light conditions, and in modulating the adaptational state of the whole retina.

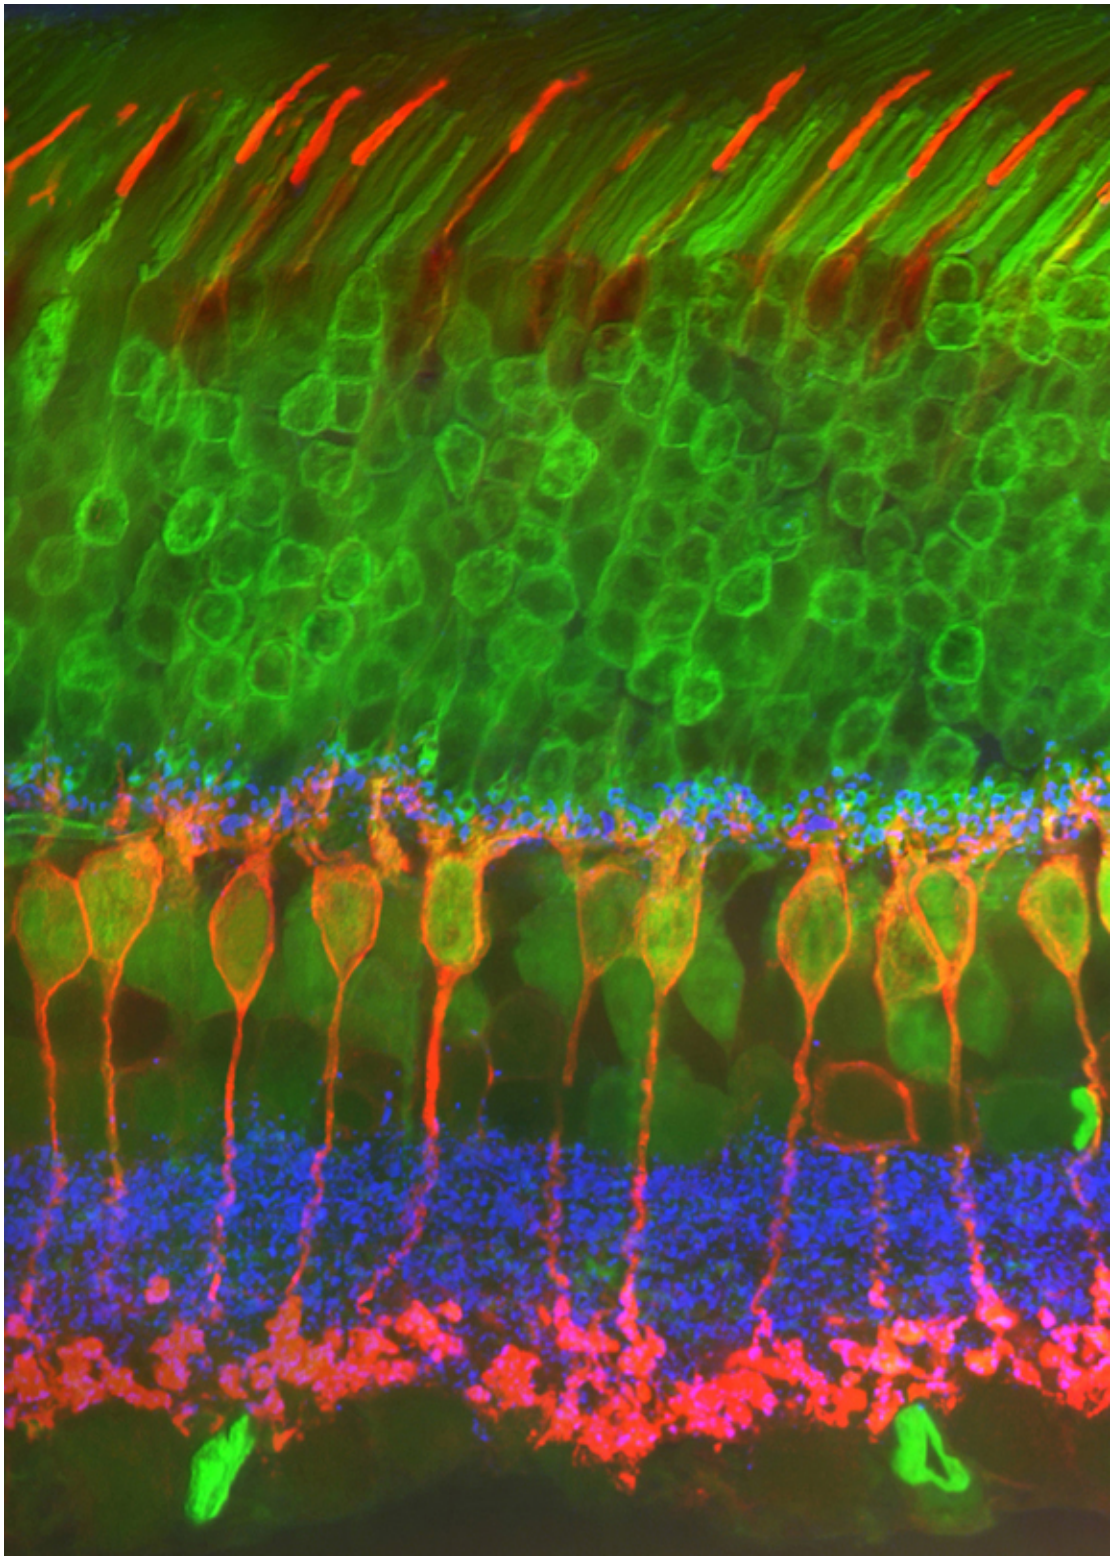

Figure 7. PKC immunostaining of rod bipolar cells (orange/red) in transgenic GFP mouse (green). Other immunostaining is bassoon for synaptic ribbons (blue) in the OPL and for GABA in the terminals packing the IPL (blue). Cone outer segments are stained for transducin (red). (From Nicolas Cuenca personal communication).

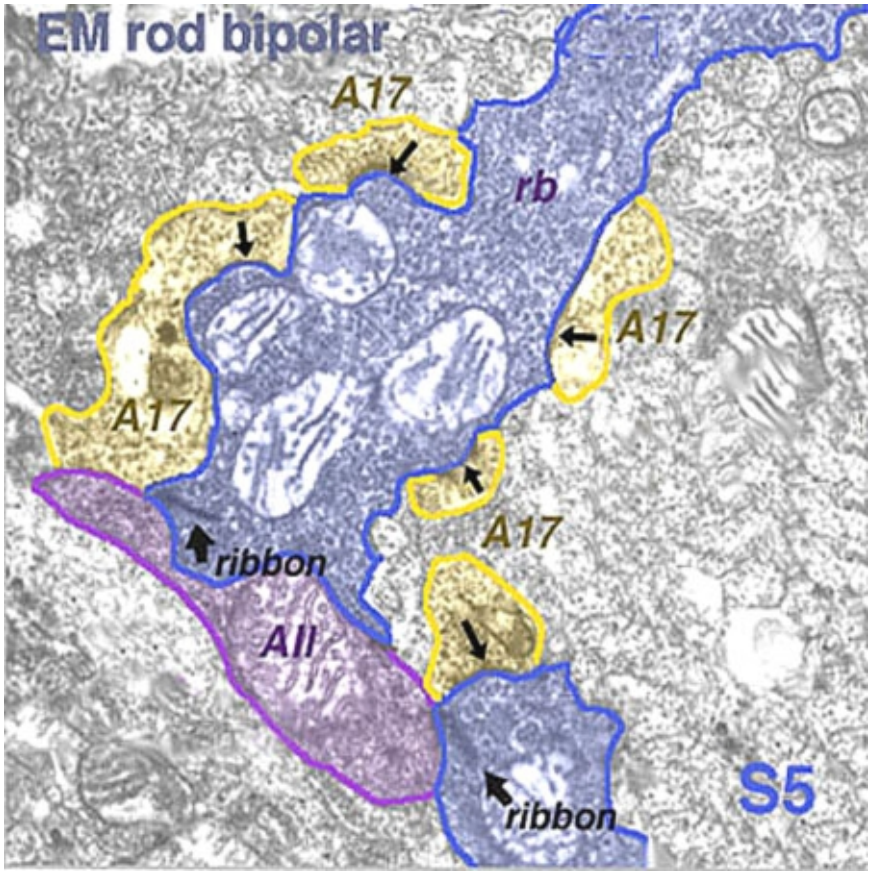

Figure 8. Electron micrograph of a rod bipolar axons.

The Rod Pathway Is Convergent to Increase Sensitivity

Rod pathways involve huge convergences and divergences of cell contacts. The pathway starts with many rods converging information to the rod bipolar cell in the OPL. Rod responses are carried to the next stage of processing in the IPL where divergence occurs to several different amacrine cell types, the most important of which are the AII and the A17 cells. Rod bipolar cells do not contact ganglion cells directly. Instead they contact amacrine cells which spread out the rod information before converging on ganglion cells. One other cell type is also influential upon the rod pathways. This is the dopaminergic amacrine, A18.

The huge convergence of the rod system in the cat retina has been calculated by Sterling and coauthors (29, 30) and Kolb and Nelson (8). Thus about 1500 rods have input to a single small-field ON-beta ganglion cell via 100 rod bipolars, 5 AII amacrine cells and 4 cone bipolar axons. In the case of a large-field OFF-alpha ganglion cell, 75,000 rods drive 5000 rod bipolars and 250 AII amacrine cells before converging on the ganglion cell (Fig. 19).

In terms of divergence of the rod system, we know that a single rod photoreceptor passes information to 2 rod bipolar cells, thence through 5 AII amacrines to 8 cone bipolar cell axons to drive 2 ON-beta cells (29, 30). So it is, that divergent and then convergent circuitry provides pooling and amplification of the rod signal in very low light levels to allow our visual system to be sensitive to a single quantum of light (31).

Summary Diagram of the Rod System of the Mammalian Retina

Combining the physiological responses we now understand for the neurons of the rod system in the cat retina, with their anatomical connections, we can construct a summary diagram of the likely pathway for scotopic vision though the human retina (Fig. 20) (see the animation of the rod circuits).

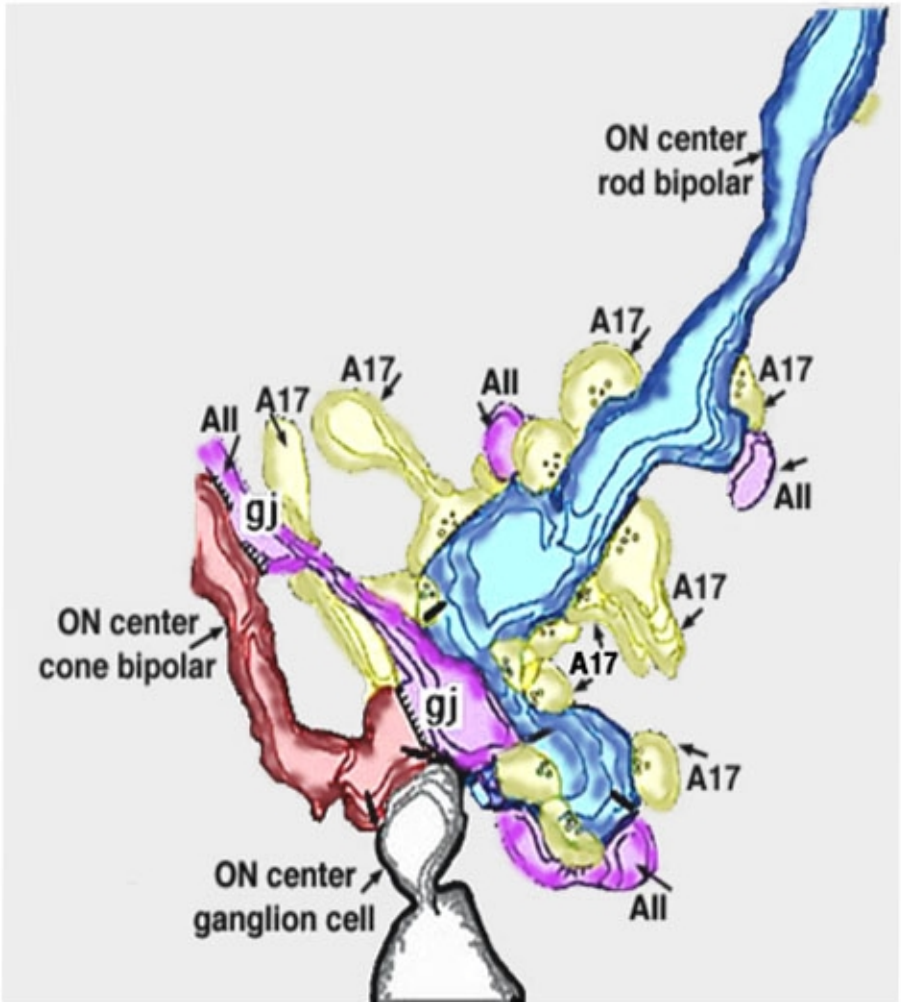

Figure 9. 3-D view of a rod bipolar axon terminal.

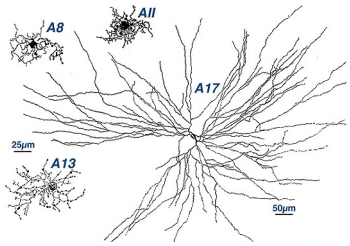

Figure 10. Rod amacrine cells of human retina.

Signals from hyperpolarizing rod photoreceptors depolarize rod bipolar cells. Rod bipolar cells synapse upon two depolarizing amacrine cells, the wide-field A17 and the small bistratified AII amacrine cells. Rod signals reach OFF-center ganglion cells (a-type beta GC) via chemical synaptic input from the AII amacrine cell lobular appendages (boxed region a). ON-center ganglion cells (b-type beta GC) receive rod signals, via AII amacrine cell electrical synapses at gap junctions to cone bipolar cells (ibc, boxed region b). The latter cone bipolars stimulate the ON-center ganglion cells by excitatory chemical synapses. Dopaminergic amacrine cells (Fig. 20, *DA*) influence the rod pathways by chemical synapses in the IPL upon AII and A17 amacrine cells and via an internuncial GABA-ergic interplexiform cell (see later section for more details on interplexiform cells), which in turn synapses upon rod bipolar cells in the OPL.

Cone Pathways through the Retina

Helga Kolb

Created: May 1, 2001; Updated: July 1, 2009.

Circuitry for Cone Signals

Cone photoreceptors are the sensors of bright light and different wavelengths of light in the retina. They are sensitive in photopic (bright light) conditions and come in several types according to the structure of the visual pigments or opsins in their outer segment regions. In dichromatic animal species there are two types of visual pigments in two types of cone (most mammals): cones sensitive to blue light and cones sensitive to red-green light. In trichromatic animal species (some primates and man) there are three types of cone according to their visual pigments (see chapter on photoreceptors). These are long wavelength (red), medium wavelength (green) and short wavelength (blue) sensitive cones (Fig. 1).

The circuitry whereby cone signals pass through the retina to the ganglion cells is rather different from that of the rod pathways. The first difference is at the outer plexiform layer. The cones synapse upon **various** cone bipolar types rather than on a single type like the rod system. Thus at the outer plexiform layer a choice of pathways is already installed for the cone system. As we have already mentioned (section on the OPL), cone bipolars come in varieties distinguished by the size of their dendritic field (midget, diffuse, and large-field diffuse) and by their different types of synaptic contact with the cone pedicles i.e. invaginating-ribbon synapses, semi-invaginating basal junctions or non-ribbon related basal junctions (see section on OPL).

Vertebrate photoreceptors are in a depolarized state in darkness and are hyperpolarized by light (1). Thus it is thought that the neurotransmitter glutamate is released continuously in the dark and is suppressed by light (Fig. 2).

Different glutamate receptor types appear on depolarizing ON- and hyperpolarizing OFF-center bipolar cells (2). The OFF-bipolar receptor appears to be related to the AMPA-kainate type and so is a common, excitatory, ionotropic glutamate receptor (iGluR). In contrast the ON-type bipolar cells have metabotropic receptors (mGluR) that bind selectively the glutamate agonist APB (or AP4, 2-amino-4-phosphonobutyrate), and are insensitive to AMPA-kainate ligands. Application of APB selectively hyperpolarizes their membrane potentials and suppress the light-responses of ON-center bipolar cells (3, 4). The receptor at the ON-bipolar cell is now thought to be mGluR6 (5, 6). Receptor-activated G-proteins, originally thought to mimic the cyclic-GMP cascade occurring in photoreceptors are the underlying mechanism of transduction in ON-center bipolar cells (7, 8). Most recently, good evidence has been provided for a subunit of the transducin molecule, GalphaO, to be the second messenger in the ON-center bipolar cell activation pathway (9, 10).

Thus, we know that the cone bipolar types that make central ribbon contacts or narrow-cleft, semi-invaginated contacts have the metabotropic glutamate receptors (Fig. 3) and will be ON-center (center-depolarizing) types (ON BC), while cone bipolar cells that make wide-cleft basal junctions (OFF BC) will have the ionotropic glutamate receptors (Fig. 3) and will respond to light like the photoreceptor itself, i.e. will be OFF-center (centre-hyperpolarizing) types (11) (see movie of the intracellular recordings).

Some years ago it was demonstrated by electron microscopy and 3-D reconstruction of cone bipolar profiles in the inner plexiform layer of the cat retina, that these bipolar axons make most of their ribbon output synapses to ganglion cell dendrites (12) (Fig. 4 and Fig. 5).

Bipolar cell axons that terminated in sublamina **a** of the inner plexiform layer (closer to the amacrine cell bodies) made ribbon synapses exclusively with dendrites of ganglion cells that had dendrites in this sublamina. In fact, such bipolar cell axons did not even reach down far enough to contact ganglion cells in sublamina **b** of

the IPL. The ganglion cells branching in sublamina **a** were known from Nelson and coworkers findings (13) to give OFF-center responses to light flashes.

Conversely the cone bipolar cells with axons in sublamina **b** of the inner plexiform layer (closer to the ganglion cell bodies) made ribbon synapses only upon the dendrites of ganglion cells that branch in sublamina **b**. Again, Nelson et al. (13) had shown that such ganglion cells were ON-center in response to light flashes (Fig. 6) (see the movie of the intracellular recordings).

In the human retina the common cone bipolar cells are, like the cat, classified not only by the nature of their synapses with cone pedicles, but also by which sublamina of the IPL their axons terminate in. Thus, some of the cone bipolar types send axons to sublamina **a** (fb types) and others to sublamina **b** (ib types) of the IPL.

We expect that like the cat, human cone bipolar cells with axons in sublamina **a** will connect to OFF-center (center-hyperpolarizing) ganglion cells and bipolar cells with axons in sublamina **b** will connect to ON-center (center-depolarizing) ganglion cells (Fig. 7).

Thus a major difference in the circuitry of the cone compared the rod pathways in the mammalian retina is that cone bipolar cells make direct synapses with ganglion cell dendrites, without the need for intermediate amacrine cell circuitry as occurs in the rod pathway (see previous chapter). The cone pathways are, therefore, both more direct and more narrow-field and convergent than the rod pathways. Fewer cones converge onto cone bipolars than rod to rod bipolars and then only a relatively small number of cone bipolar cells converge onto their ganglion cells. The ultimate in low convergence ratio is the midget system in the human and primate retina, which we shall deal with separately in another section (Fig. 8).

Cone Pathways Mediate Successive Contrast (ON and OFF Pathways)

Cone pathways in mammalian and human retinas run as two parallel streams of information directly from the cone photoreceptor to the ganglion cell through the straight pipe-line, the cone bipolar cell. What is the reason for two parallel channels for the cone system when the rod system had only one? The answer is that this organization allows one channel to provide information to the ganglion cell concerning brighter than background stimuli (the ON-center channel) and the other, darker than background stimuli (the OFF-center channel) as first demonstrated by Kuffler (14) in 1953 from recordings of ganglion cells in the cat retina.

As we have seen above the anatomical substrate for the origins of these two important ON-center and OFF-center channels in the bipolar cell is in the types of synaptic contacts cone bipolar cells make with cone pedicles in the mammalian retina (see above) (11, 12, 15). The hyperpolarizing bipolar types are the start of OFF-center channels and the depolarizing types are the start of ON-center channels through the retina (Fig. 9.).

The ribbon synapse of the cone bipolar cells to the ganglion cell dendrites in the IPL, is considered to be an excitatory synapse and so, the type of signal in the ganglion cell, (either ON- or OFF-center) is essentially determined by the nature of the cone bipolar cells contacting it. Thus the complete circuit to carry the message concerning brightness and darkness through the retina in the cat is shown below (Fig. 10) (see an animation of the cone circuits.).

Cones hyperpolarize to light but two bipolar channels, one carried by a depolarizing bipolar (orange cell and light response) and the other by a hyperpolarizing bipolar (yellow cell and light response), split the original cone signal into lightness or ON-center and darkness or OFF-center. These bipolar responses are transmitted directly to ganglion cells architecturally separated to the different sublaminae of the inner plexiform layer, resulting in one channel of ganglion cells with dendrites in proximal retina (sublamina **b**) becoming ON-center and the other types with dendrites only in distal retina (sublamina **a**) becoming OFF-center.

Cone Pathway Circuits Mediate Simultaneous Contrast (Center-Surround Receptive Fields)

Information concerning the overall brightness or darkness of the image is of primary importance for visual sensation, but putting these two informations in simultaneous contrast to each other greatly improves the resolution of the image.

Simultaneous contrast is achieved by lateral inhibition where a dark boundary inhibits a light area or vice versa. In the retina, an important finding by Hartline (16) from frog optic nerve recordings first described retinal ganglion cell receptive fields as concentric with a response of opposite sign to the center found in a surround of the receptive field (Fig. 11).

It is thought that horizontal cells at the OPL provide, through a mechanism of lateral inhibition, a surround arranged around the receptive field center of firstly the photoreceptor itself and then the bipolar cell contacting the photoreceptor (17-19). The wiring responsible appears to start at the small local circuit we saw in the cone triads at the ribbon synapses (see the chapter on the outer plexiform layer) (Fig. 12).

Thus, the negative feedback synapse of the horizontal cell to the cone photoreceptor at the ribbon triad synapse allows the larger receptive field of the horizontal cell network (horizontal cells are coupled in a syncytium across the retina by electrical synapses between neighboring cells. Like horizontal cells are coupled to each other) to provide a surround to the narrow central cone response (20). This concentric organization is then transmitted to the bipolar cells making contact with the cone (21) and thence to the ganglion cell that the cone bipolar cell contacts (see the movie of the mechanism of lateral inhibition on a stimulated cone).

The diagram in Fig. 13 summarizes the architecture for center surround organization by means of horizontal cell to cone bipolar cell circuits in the cone bipolar system of the mammalian retina. The center pathway is created by the cone to bipolar to ganglion cell through-channel, while the injection of horizontal cell information provides an antagonistic surround to the center: an OFF-surround for the ON-center channel (horizontal cell and orange bipolar, left hand pathway) and an ON-surround for the OFF-center channel (horizontal cell and yellow bipolar, right hand pathway (19, 22) (see the animation of the formation of surrounds for cone bipolar and ganglion cells).

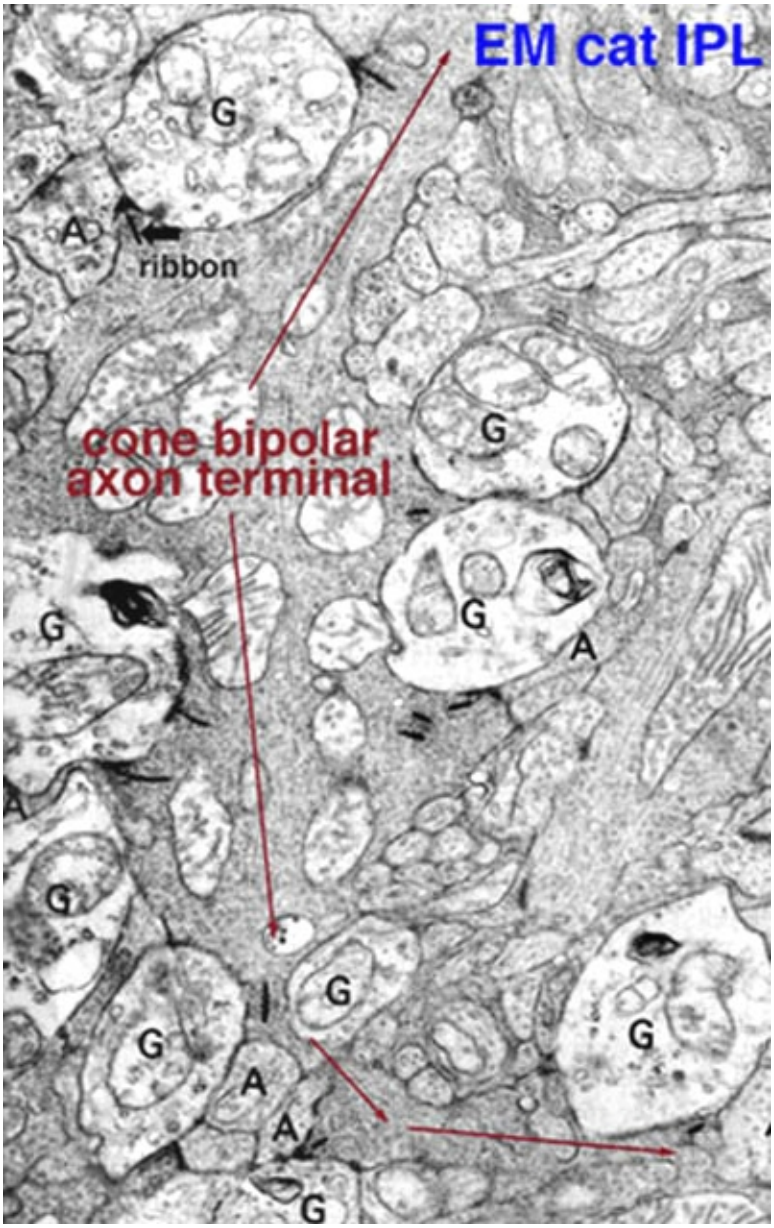

Figure 4. Electron micrograph of a cone bipolar axon terminal

In mammalian retinas, surround responses are not as strong a component of bipolar cell receptive field as they are in cold-blooded vertebrate bipolars (11). Compare for instance the bipolar responses from a Turtle retina (23) with those of a cat retina (11) in Fig. 14 and Fig. 15.

We know from intracellular and extracellular recordings of cat and monkey ganglion cells (14, 24-27) that the commonest mammalian ganglion cells have a strong center surround organization. Thus, it is possible that additional surround antagonism to the bipolar driven center response of a ganglion cell, is constructed by certain, as yet not fully understood, amacrine cell networks in the inner plexiform layer (Fig. 16).

Roles of Amacrine Cells

Helga Kolb

Created: May 1, 2005; Updated: April 30, 2007.

General Characteristics

Amacrine cells of the vertebrate retina are interneurons that interact at the second synaptic level of the vertically direct pathways consisting of the photoreceptor-bipolar-ganglion cell chain. They are synaptically active in the inner plexiform layer (IPL) and serve to integrate, modulate, and interpose a temporal domain to the visual message presented to the ganglion cell. Amacrine cells are so named because they are nerve cells thought to lack an axon (1). Today, we know that certain large-field amacrine cells of the vertebrate retina can have long "axon-like" processes, which probably function as true axons in the sense that they are output fibers of the cell (see a later section on dopaminergic amacrine cells). However, these amacrine axons remain within the retina and do not leave the retina in the optic nerve, as do the ganglion cell axons (Fig. 1).

Since the time of Cajal, we have known that amacrine cells come in all shapes, sizes, and stratification patterns. Since those days, many more morphological subtypes have and continue to be described from additional Golgi studies, intracellular recordings, and immunocytochemical staining. Thus, we presently have a classification of amacrine cells consisting of about 40 different morphological subtypes (Fig. 2).

It is useful and most easily understandable to group the amacrine cell types into the general descriptors of narrow-field (30-150 µm), small-field (150-300 µm), medium-field (300-500 µm) and wide-field (>500 µm) based on a measurement of their dendritic field diameters (2). Then, the next most important criterion of classification involves knowing the stratification of the cells. It is generally agreed now that the IPL can be subdivided into five equi-thickness strata or sublayers (1) into which amacrine, bipolar, and ganglion cell processes can be assigned. All of these cell types are now classified primarily on the stratum or strata of the IPL in which their dendrites or axons are located. This is because, as mentioned in previous chapters, the IPL of vertebrate retinas can be divided into areas of neuropil, where specific cells are put into synaptic contacts and form circuits only with cells earmarked for a particular functional role.

Many varieties of amacrine cell are monostratified (restricted to a single stratum), whereas others are bi- or tri-stratified. When amacrine or ganglion cell processes pass through all the strata of the IPL from distal to proximal or *vice versa*, they are called diffuse cells. Superimposed upon Cajal's five strata subdivision of the IPL is a sublaminar division of the IPL. The first two strata, 1-2, are known as sublamina **a** of the IPL, whereas strata 3-5 are known as sublamina **b** by this scheme (3). It will be remembered from previous chapters that sublamina **a** contains bipolar axons and ganglion cell connections that lead to OFF-center ganglion cell physiology, whereas sublamina **b** contains bipolar to ganglion cell connections resulting in ON-center ganglion cell physiology (4).

Fig. 3 shows drawings of some small field amacrine cells of the monkey retina as seen in vertical sections. Small-field cells like these can be well visualized in section because their dendritic trees are contained within the depth of the section. However, large-field cells are not so well described in the section where their dendrites get cut off.

It was only when whole-mount preparations, from Golgi staining (5, 6) or immunocytochemical staining (7), were attempted that we could classify such cells. Then the full extent of their dendritic trees, which can be up to 1 mm in spread, could be visualized (see Fig. 4a) and a whole new understanding of amacrine cells became available.

A new technique of intracellular staining by a photochemical method has been developed In Richard Masland's group as an alternative to the unreliable Golgi technique (8). Amacrine cells of the rabbit retina are labeled with the nuclear stain DAPI and then selected, single-nuclei are irradiated by a narrow beam of light to drive DAPI to the oxidation of non-fluorescent dihydrorhodamine-123 to the fluorescent rhodamine-123. The complete cell

body and the dendritic tree are thus revealed under viewing in the fluorescence or confocal microscopes. By this method, 30 or so different varieties of amacrine cell can be photographed and drawn in full detail in the rabbit retina. Twenty-two varieties of amacrine cell have been seen in Golgi preparations in cat and primate retinas, so either some have been missed that were seen in rabbit, or else they are not as well deveoped in these less complex mammalian retinas. In any event, the narrow-field and medium-field types revealed by MacNeil and Masland's work (8) are shown in Fig. 4b and Fig. 4c. Another five different, wide-field, monostratified types were also encountered in rabbit retina by this method (not illustrated). They correspond closely to the wide-field types seen in monkey, cat, and human (2, 9, 10).

Amacrine Cell Circuitry as Revealed by Electron Microscopy

Kidd (11) and later Dowling and Boycott (12) were the first to identify the three types of profiles that contribute to the IPL by electron microscopy. The electron micrograph (Fig. 5) shows the cytological criteria on which we now recognize bipolar, amacrine, and ganglion cell profiles in the neuropil. Thus bipolar cell axonal endings are recognized by being filled with synaptic vesicles and having a ribbon-shaped density (red spots) pointing to two postsynaptic profiles (amacrine and ganglion). Amacrine profiles are also filled with synaptic vesicles but make synapses characterized by membrane densities at which the vesicles are particularly clustered (yellow spots). Ganglion cell profiles are recognized as being only postsynaptic to either bipolar axons or amacrine processes, containing no vesicles but instead a content of neurotubules, ribosomes, and glycogen granules.

Amacrine cell synapses are frequently seen to be reciprocal to bipolar ribbon input, i.e., the amacrine returns a synapse in the vicinity of the ribbon input synapse (arrowheads). Most amacrine cells are inhibitory neurons in the vertebrate retina, containing the common inhibitory neurotransmitters GABA or glycine. GABAergic amacrine cells, in particular, typically make reciprocal synapses with bipolar cells. A17 is the most well studied of the GABAergic reciprocal amacrine cells in the retina, and we shall return to this cell later.

We have learned much concerning the synaptic relationships of certain narrow-field amacrine cells as well as bipolar and small ganglion cell types, such as midget ganglion cells of the primate retina, from reconstructions of serial-section electron micrographs. The circuitry of the AII amacrine cell in the cat retina was first appreciated by this means (13, 14). However, with the advent of intracellular dye injection of electron-dense materials (horseradish peroxidase, HRP, or the photo reduction of Lucifer yellow) after physiological recordings or the development of electron-dense immunostains for electron microscopy, neurocircuitry was made easier for us. We could look at amacrine cells and their synaptic inputs by study of fewer sections, and it was not as critical to photograph every single section in a series. The amacrine cell of interest would always be clearly marked black and easily found in the synaptic neuropil. It is from this technique that we have learned most about amacrine cells and their circuitry in the mammalian retina. The remainder of this chapter will describe the morphology, circuitry, and intracellular responses of the amacrine cells that are most completely understood at present.

A2: Narrow-field, Cone Pathway Amacrine Cell

A2 is a narrow-field amacrine with a 20-60-µm-wide dendritic tree composed of multi-branched, beaded, and appendage-bearing dendrites, mostly confined to stratum 2 of the IPL (Fig. 6).

Intracellular recordings from A2 cells (formerly called A4) indicate that these cells give true slow potential, hyperpolarizing response to light (OFF-center) at all positions of the slit in their receptive fields, and they have no sign of an inhibitory surround (15).

A2 cells receive bipolar input from OFF-center types of cone bipolar cell of sublamina **a** and make reciprocal synapses to these bipolar axons. A2 amacrine cells then synapse upon OFF-center ganglion cell dendrites of sublamina **a**. The A2 cell makes an inhibitory synapse upon these ganglion cells, because it is thought to be a GABAergic cell type (16).

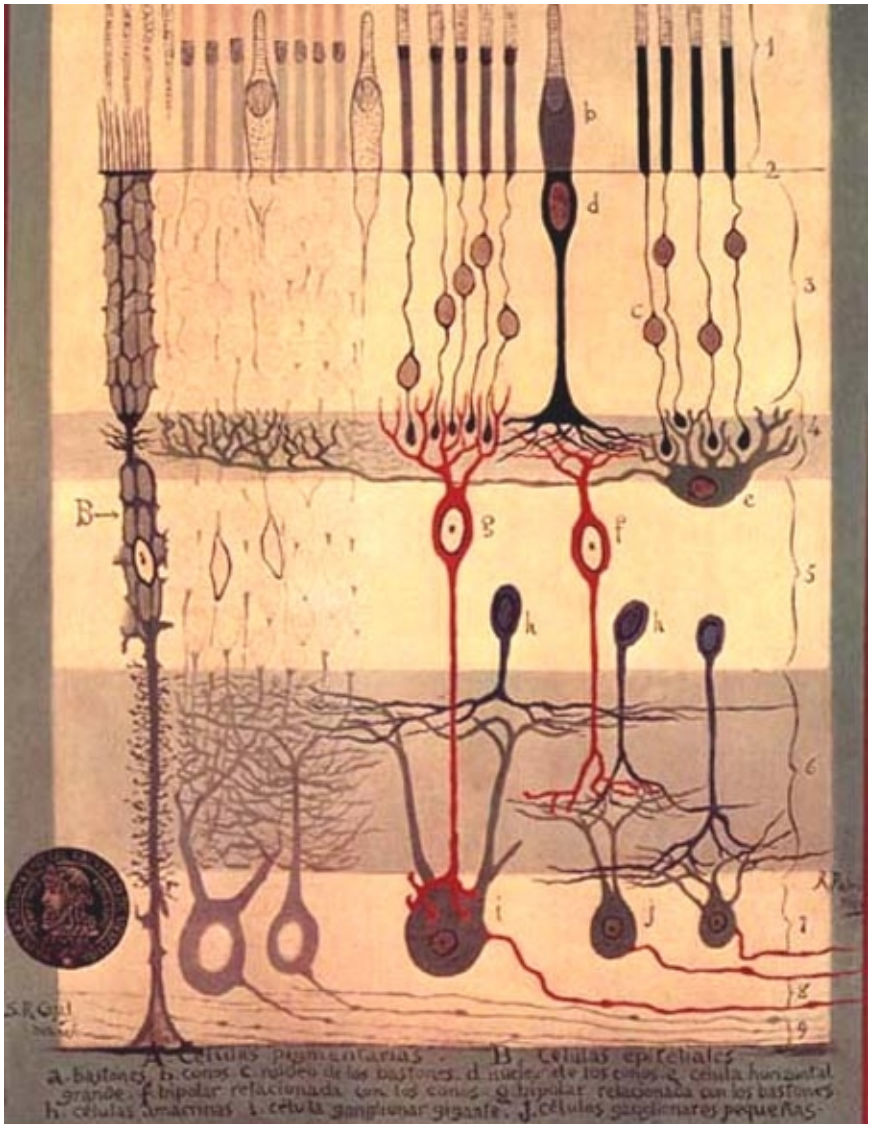

Figure 1. Drawing of the retina made by Cajal.

A possible role is in disinhibition of the ganglion cells' center responses. Alternatively, A2 cells, despite being small-field types, might have a role in the generation of antagonistic surrounds of ganglion cells (17). A2 cells receive a great many amacrine inputs to their dendritic trees, which could be from wider field cells than they are are themselves, so giving them a much larger receptive field size than their actual dendritic tree size would indicate (Fig. 7).

AII: A Bistratified Rod Amacrine Cell

In Fig. 8 are shown four examples of the best-studied amacrine of all in the vertebrate retina: the AII "rod amacrine" of the mammalian retina. These cells have been recorded from by microelectrodes, and dyes have been iontophoresed into the cell after the intracellular recordings (18). The AII cell was first described from Golgi staining and electron microscopic examination (13, 19).

AII is a narrow-field amacrine (dendritic tree diameter typically 30-70 μm) with a bistratified morphology: the mitral-shaped cell body gives off a single, stout apical dendrite, and a cluster of lobular appendages (round blobs just below the cell body) (Fig. 9) arise from the main dendrite in sublamina **a** of the IPL. The finer "arboreal

Figure 2. Picture of Camillo Golgi.

dendrites" (20) penetrate down into sublamina **b** to end close to the ganglion cell layer. In the human retina, such an AII amacrine cell is seen in a surface view of a wholemount.

In cat and rabbit retinas, from which AIIs have been recorded, the AII cell is a rod-dominated depolarizing (ON-center) cell (18, 21, 22). Thus, in the center of its receptive field the cell gives a transient depolarizing response with a pronounced sustained plateau (ON-center) and a long, drawn-out hyperpolarization after light off. By 140 μm to either side of the center, the response to a light flash is now an inverted response, indicating a hyperpolarizing surround (OFF-surround) (18) (Fig. 10).

Electron microscopy has shown that the AII is primarily postsynaptic to rod bipolar axon terminals in lower sublamina **b** of the IPL (30% of its input) (23). Its major output is upon ganglion cells that have dendrites only in sublamina **a**, i.e., AII cell lobular appendages synapse upon OFF-center a and b ganglion cells (17) (Fig. 11).

The AII also passes rod-driven information through the ON-center cb5 cone bipolar to ON-center a and b ganglion cells by means of gap junctions (Fig. 12, black spots on AII primary dendrites to pink cb axon). A little OFF-center cone bipolar input is provided to the AII lobular appendages by cb1 and cb2 OFF-center cone bipolar cells in sublamina **a** (19% of input) (Fig. 12, yellow cb profiles) (23).

Thus, AII cells do carry some cone pathway components to their ON-center responses, which could come from excitatory input from ON-center cb5 at the gap junctions or from the direct cb1 or cb2 synapses, which would have to be inhibitory, in this case. AII amacrine cells are also couple across the retina in a weak electrical syncytium by virtue of their gap junctions between their arboreal dendrites in sublamina **b** (Fig. 12, gj, lower right; see an animation of the wiring pattern) (13, 18, 24).

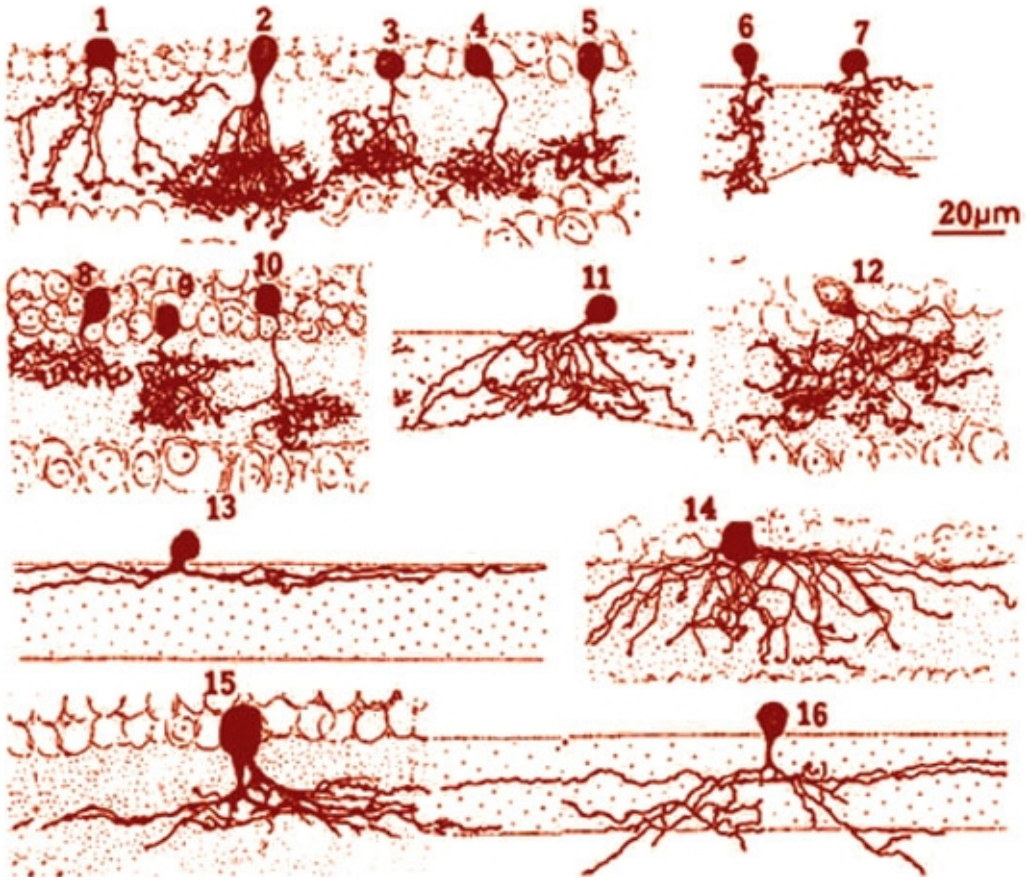

Figure 3. Stratification patterns of small and medium-field amacrine cells in primate retina. From Polyak (81).

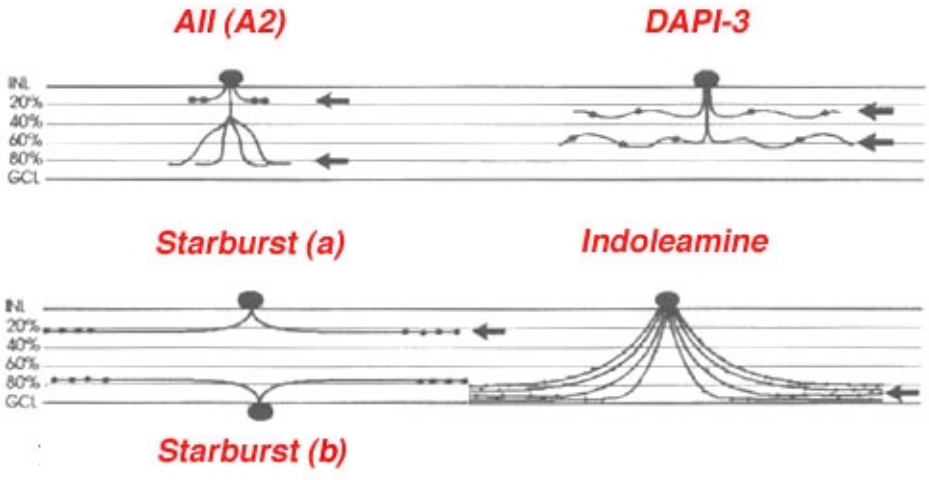

Figure 4a. Golgi-stained, wide-field amacrine cells as seen in whole-mount retina of the cat. Amacrines are classified by number and strata of the IPL in which they branch.

The dopaminergic amacrine cell provides a considerable number of synapses to the AII cell, either directly upon its cell body or upon its lobular appendages (Fig. 11, A, red arrowheads) (25, 26). Dopamine cells are thought to have a function in the inner retina to uncouple AII amacrine cells from both their contacts with the depolarizing cone bipolar and the AII amacrine coupled network (24, 27). As much as 51% of the input to AII amacrine cells is from various other amacrine cells though, and most of these inputs occur in the central part of the cells'

dendritic tree in strata 3-4 (23). AII amacrine cells are glycine immunoreactive (28, 29) and contain the calcium-binding proteins parvalbumin, calbindin, and calretinin (Fig. 13) (30).

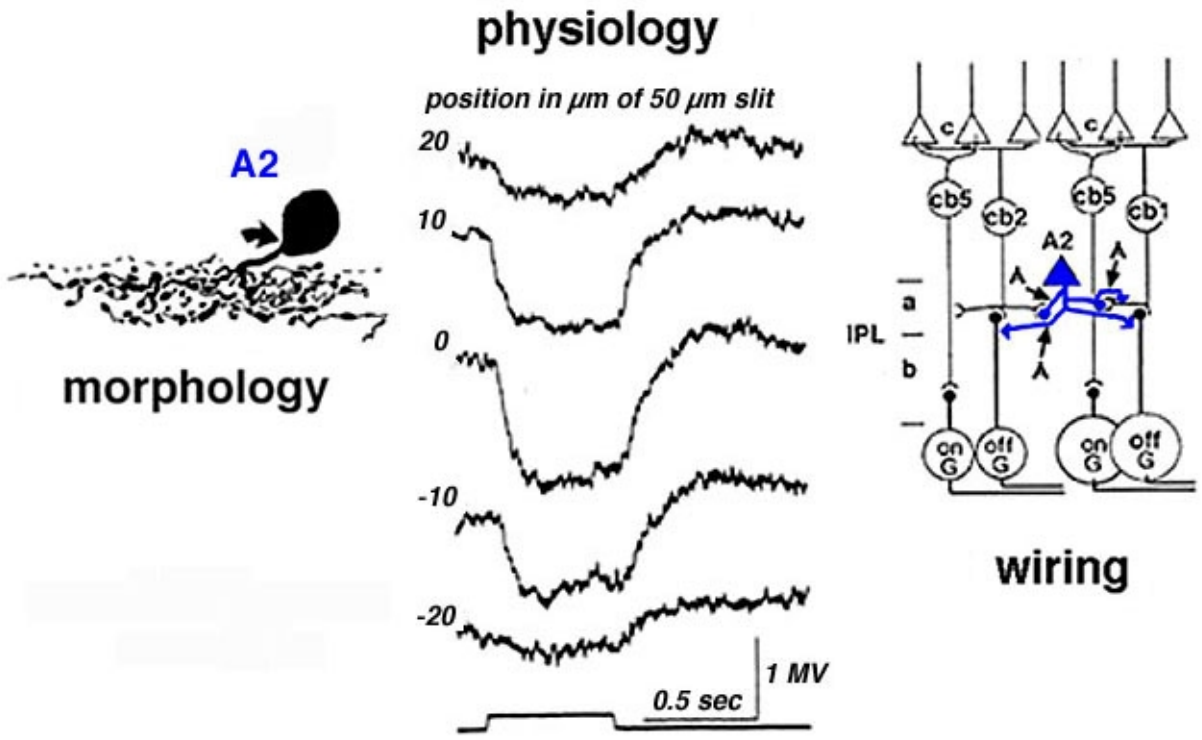

Figure 7. Summary diagram of A2 amacrine cells.

The AII amacrine cells are the major carriers of rod signals to the ganglion cells in the retina. As such, they play a role in speeding up the slow potential rod messages for presentation to ganglion cells (18, 31). Their distribution in the retina suggests that they tile the complete retina (32). AII amacrine cells peak in density at 1.5 mm from the foveal center in monkey and at the area centralis in cat (33). In addition, because of their high density across all parts of the retina and their synaptic involvement with millions of rod bipolar cells, they may contribute in a major way to the pattern ERG (34).

A8: A Bistratified Cone Amacrine Cell

A8 is a bistratified, narrow-field amacrine cell that is easy to confuse with AII in whole-mount, stained retina. It actually looks like an upside-down AII cell. A8 has short, wispy processes coming from the apical dendrite to ramify in sublamina **a** of the IPL, whereas heavy-beaded dendrites penetrate down to sublamina **b** to run in strata 4 and 5. This cell type may correspond to the DAPI-3 of the rabbit retina, described by Vaney (32) and Bloomfield (21) (Fig. 14).

The A8 cell has been intracellularly recorded and studied by electron microscopy after iontophoresis of horseradish peroxidase. In Fig. 15, we shown two of the most important synapses of this cell type.

The A8 amacrine cell is involved in the cone pathways of the cat retina, rather than the rod pathways that the AII is committed to. Thus, in sublamina **a**, excitatory cone-driven signals come from cone bipolar cells such as cb2, which we know are OFF-center in physiology (Fig. 16, yellow cb profile), and in sublamina **b** from cb6, another OFF-center bipolar cell (Fig. 16, cb, pink profile) (35). Altogether cone bipolar synapses account for 42% of the input to A8 cells. Lesser rod bipolar input (20%) also occurs to the lower dendrites in sublamina **b** of the IPL. Like AII amacrine cells, A8 cells also engage in gap junctions with a cone bipolar type of sublamina **b**, but the bipolar is a different type and, in addition to the gap junction, makes the common ribbon synapse to A8

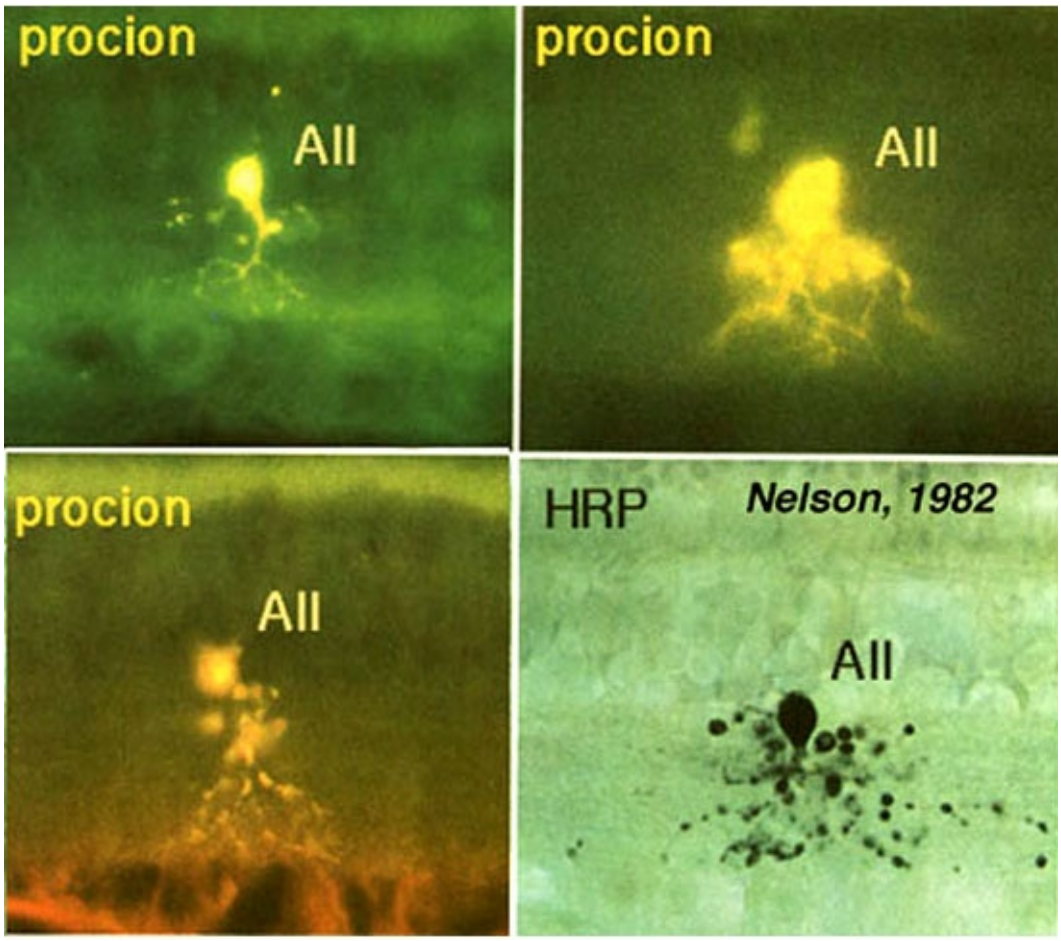

Figure 8. AII amacrine cells stained with different methods.

dendrites (Fig. 16; see an animation of the wiring pattern). A8's major output is to beta ganglion cell dendrites in sublamina **a** of the IPL (above GC). We have not seen A8 synapses to alpha cells in the cat retina (36).

The intracellular response of A8 indicates a hyperpolarization to light at the receptive field center with a rather transient OFF-response to light. The transientness could reflect the amacrine synapses (38% of input) occurring over all parts of its dendritic tree (Fig. 16, red arrowheads) (0, response is at largest magnitude).

Both rod-driven and cone-driven signals contribute to the response. Its receptive field extent can be mapped with a slit of light. As the slit is stepped some distance to either side of the center of the receptive field, the response of the cell inverts and a depolarizing or ON-surround appears by 700 μm from the central position (Fig. 17, top and bottom trace) (36).

Some part of the amacrine input to A8, particularly that upon its cell body and proximal dendrites in stratum 1 of the IPL, may be from dopaminergic amacrine cells (A18) (25). So it is probable that this cell type is also under the control of the dopaminergic amacrine cells, similar to the AII amacrine cell (see above). Thus, the dopamine cell may control A8's spatial characteristics through gating its gap junctions in light and dark. A8 is intensely glycine immunoreactive (28, 29). We have suggested that A8 cells also function in the disinhibition of ganglion cell receptive field centers (36).

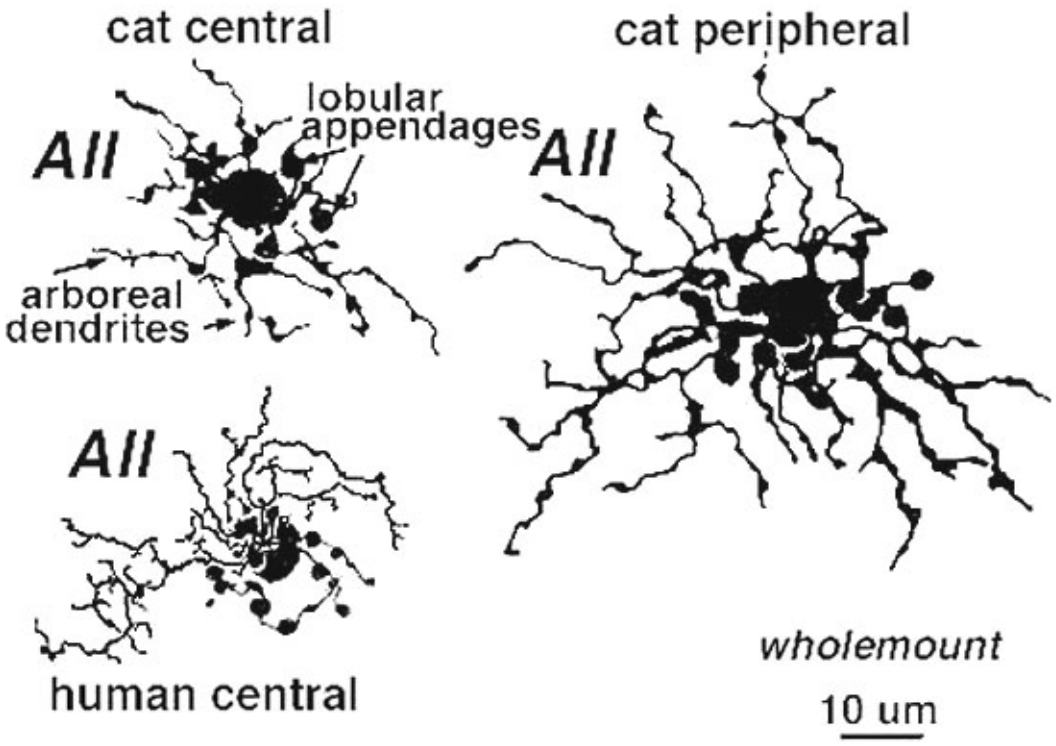

Figure 9. AII amacrine cells.

A13: A Small-field Diffuse Amacrine Cell of the Cone System

Cell A13 is a diffusely branched cell with a large cell body (12 μm diameter) and fine dendrites bearing distinct beads at regular intervals that run through mostly strata 3-5 of sublamina **b** of the IPL to end up along the top of ganglion cell bodies. The complete tree covers a 100-μm area (Fig. 18).

Electron microscopy shows that A13 cells, similar to A8 cells, get only a minor rod bipolar cell (12%) input, whereas three different types of cone bipolar cell have major synaptic input (28%). The cone bipolar inputs are from axons in sublamina **a**, stratum 3-4 of sublamina **b**, and stratum 5 of sublamina **b**. A13 cells appear to make reciprocal synapses upon cone bipolar cells and possibly also upon rod bipolar cells. Amacrine cells provide much more synaptic input than bipolar cells (60%). A13 makes synaptic output to OFF-center ganglion cells, of both alpha and beta types, in sublamina **a**. Gap junctions link A13 cells at their beaded dendrites (36) (Fig. 19; see an animation of the wiring pattern).

The intracellular response of A13 is a slow potential, hyperpolarizing response, looking much like a horizontal cell response in the cat retina. Mixtures of rod and cone signals contributed to the intracellular response of A13 cells. Its receptive field is large and does not appear to exhibit a surround. The spatial extent of the receptive field is very suggestive of a coupled electrical syncytium of cells at least seven cells wide (Fig. 20) (36).

A17: The Wide-field Reciprocal Rod Amacrine Cell

A17 is a wide-field *diffuse* amacrine. Its dendritic tree can span close to a millimeter of retinal surface. Its very fine dendrites bear pronounced beads at regular intervals along their lengths. The majority of the dendritic tree runs in sublamina **b** of the IPL, along the top of the ganglion cell layer in stratum 5 as a dense network of fine

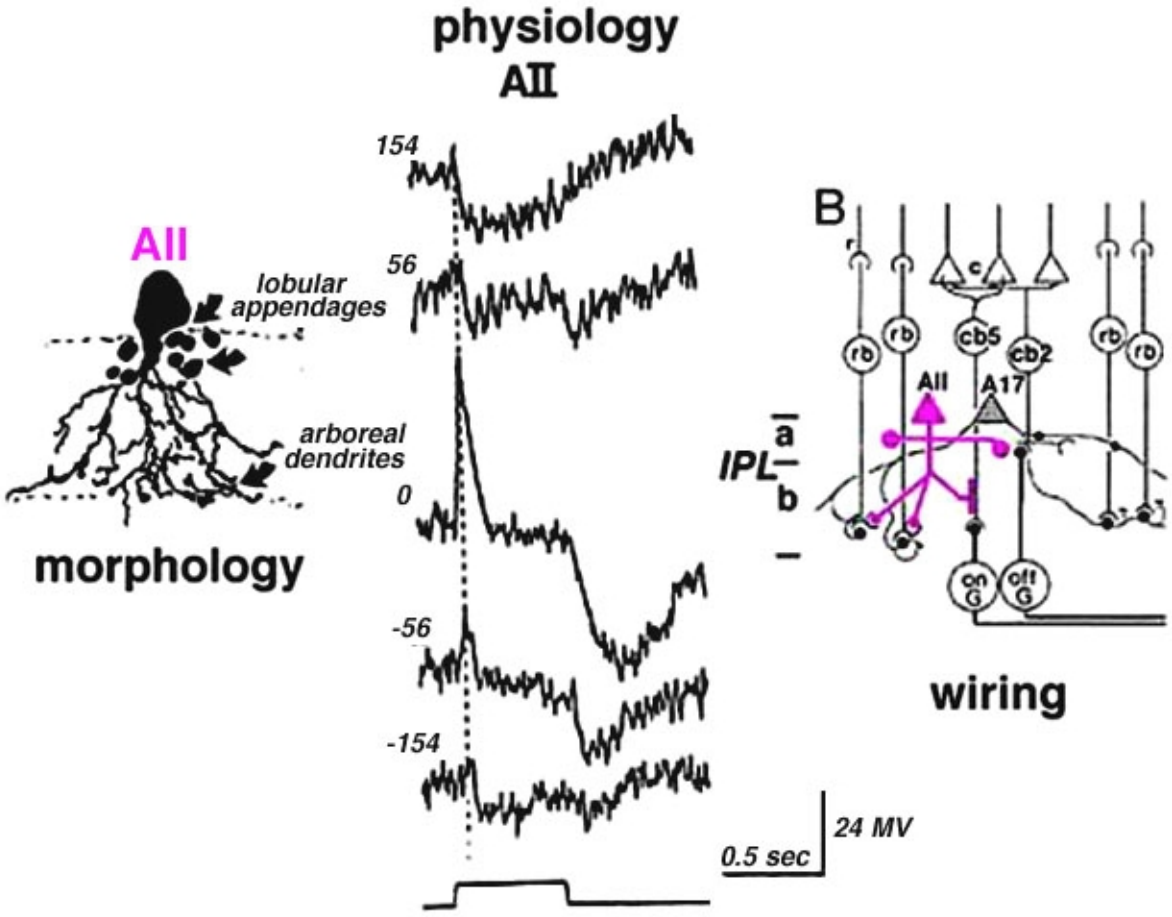

Figure 10. Schematic diagram of the morphology, physiology, and wiring pattern of the AII amacrine cell.

fibers. Over 1000 beads have been counted on such A17 amacrine cells in the cat retina (37), and as we shall see later, the beads are the synaptic points where reciprocal synapses with rod bipolar cells occur (38) (Fig. 21).

Electron microscopy shows that A17 cells are the predominant reciprocal amacrine cell at the rod bipolar cell axon terminals in sublamina **b** of the IPL. In addition, their fine dendrites in sublamina **a** receive some synapses from the dopaminergic amacrine cell A18 (Fig. 22). However, there has not yet been discovered any synaptic output of the A17 except the reciprocal synapses with the rod bipolar axon.

A17 cells are driven almost exclusively by rod-matched stimulating conditions. In the intensity series is shown using wavelengths of light matched for rods at rod- and cone-stimulating wave lengths. The responses at each light intensity superimpose, indicating that only a single receptor mechanism is present, that due to the rods. At all intensities, the response is a depolarization and, up until the highest intensities (Fig. 23, bottom trace), essentially a slow potential response. At the highest light intensity, the response becomes slightly transient, although there is a depolarizing plateau phase. The response now resembles that of its input neuron, the rod bipolar cell (22). A17 cells do not appear to have inhibitory surrounds, although they exhibit spatially dependent characteristics to their response amplitudes with far surround stimulation (37).

The A17 cell wiring diagram is shown in Fig. 23. Its huge coverage of the IPL neuropil by its up-to-a-millimeter dendritic spread allows it to collect scotopic rod signals from several thousand rod bipolar axons. Its high sensitivity to scotopic conditions (rod-driven light intensities) suggests hat this amacrine plays a role in converging rod signals from huge areas of retina and in amplifying them at very low light intensities. A17 is

known to accumulate serotonin in rabbit retina (39) but is thought to be a GABAergic neuron in terms of neurotransmission in all mammalian retinas (16).

A19 and A20: ON-OFF Wide-field Amacrine Cells

A19 and A20 are similar appearing, wide-field radiate amacrine cells with 300-500-µm-diameter fields. However, their fields are further expanded to several mm by the presence of fine axon-like processes coming either from the ends of tapering dendrites (A19, A20) or from primary dendrites or even from the cell body (Fig. 24).

They differ in stratification levels levels in the IPL, although A19 stratifies on the sublamina **a**/**b** border and A20 in stratum 2 of sublamina **a.** A19 has distinctly spiny dendrites, whereas A20 has long, smooth, spineless but beaded dendrites.

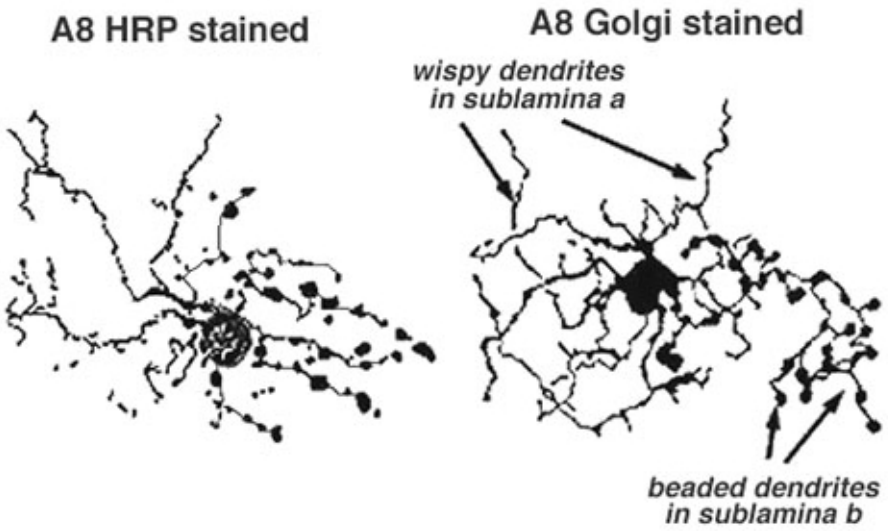

Figure 14. Golgi and HRP appearance of A8 amacrine cells.

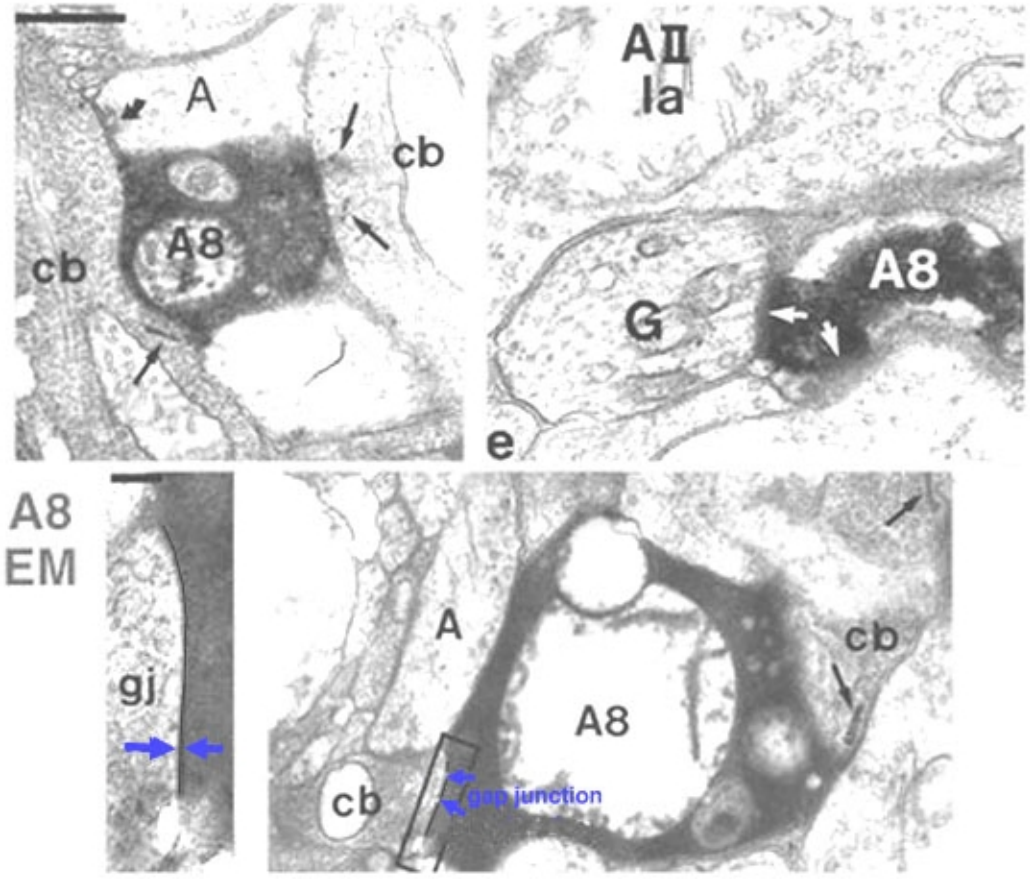

Figure 15. Electron micrograph of A8 synapses in the IPL.

A19 and A20 are both transient depolarizing ON-OFF cells, otherwise known as ON-OFF amacrine cells in response type. Such cells have been difficult to record long-term responses from in a mammalian retina (40), and the example illustrated in Fig. 25 of an A19 is one of the longest held, and thus a receptive field was mapped.

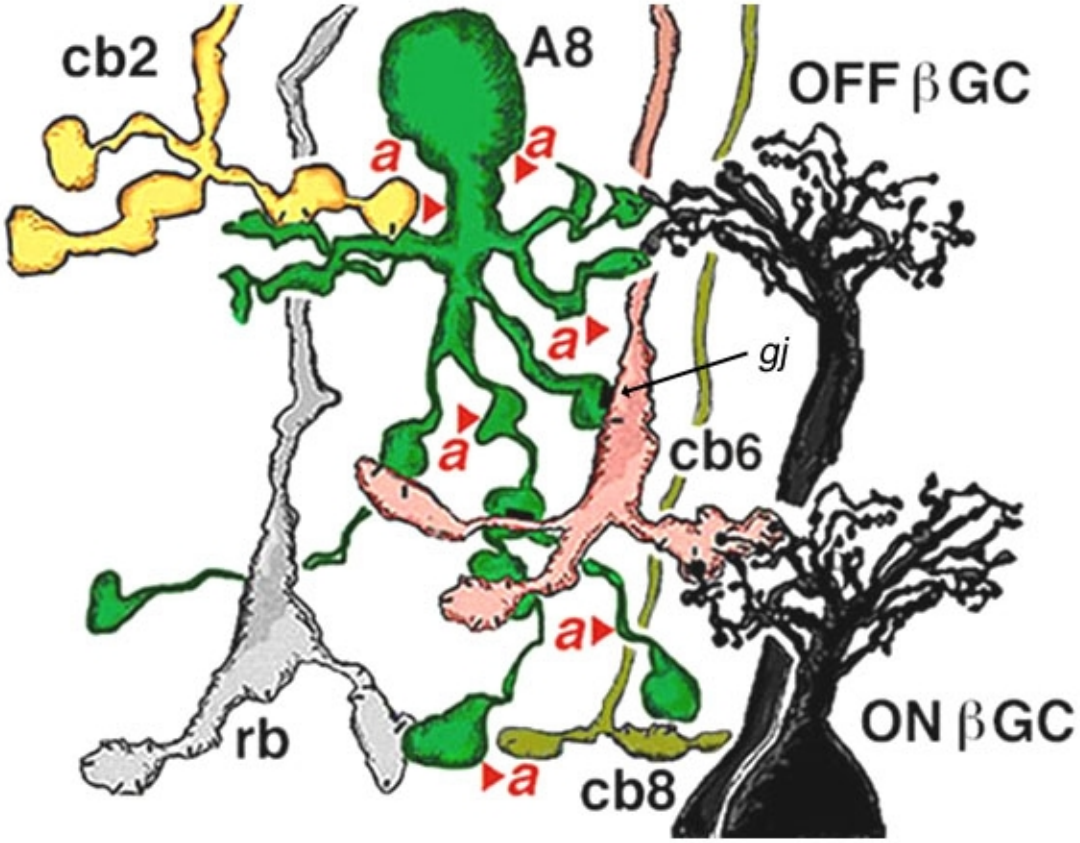

Figure 16. Summary diagram of the wiring pattern of the A8 amacrine cell.

Movie 2. Animation of the wiring pattern of the A8 amacrine cells.
Download video

The receptive fields are large, i.e., >550 μm radius, rather larger than their immediate dendritic tree sizes, and undoubtedly due to their axon-like extensions (40). Neither A19 nor A20 exhibited antagonistic surrounds.

Electron microscopy for circuitry of A19 and 22 has been performed. A19 receives two types of cone bipolar input (24%): the first is from OFF-center cb2 cone bipolar cells of sublamina **a**, while the other is ON-center input from cb5 at the sublamina **a/b** border, where cb5 passes in to sublamina **b**. OFF- and ON-center bipolar input could account for this cell's ON-OFF physiology. The predominant input is from amacrine cells of sublamina **a**, though (76%). Some of the amacrine inputs could be from rod amacrine AII cells, others from A2 cells, while some looked like they could be from other A19 cells. A19's output is reciprocal synapses to both

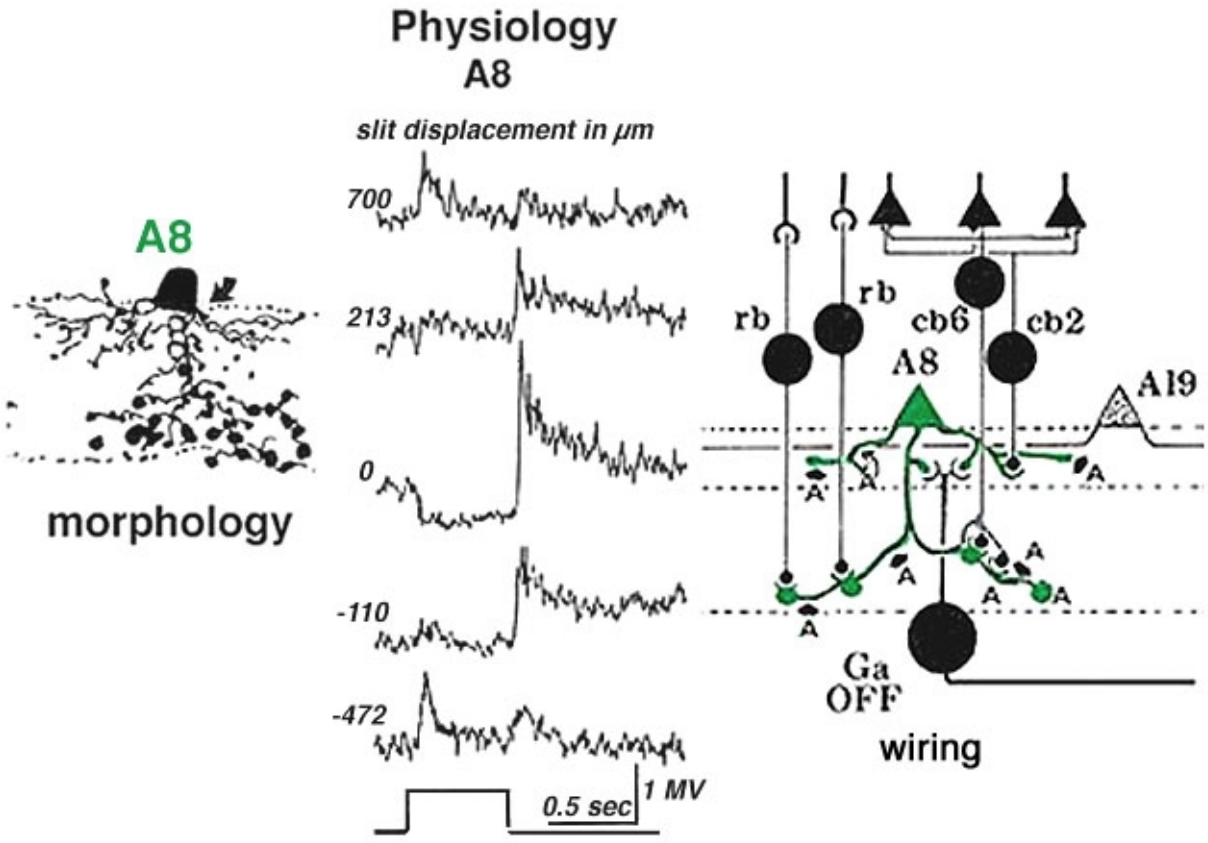

Figure 17. Summary diagram of the A8 amacrine cell.

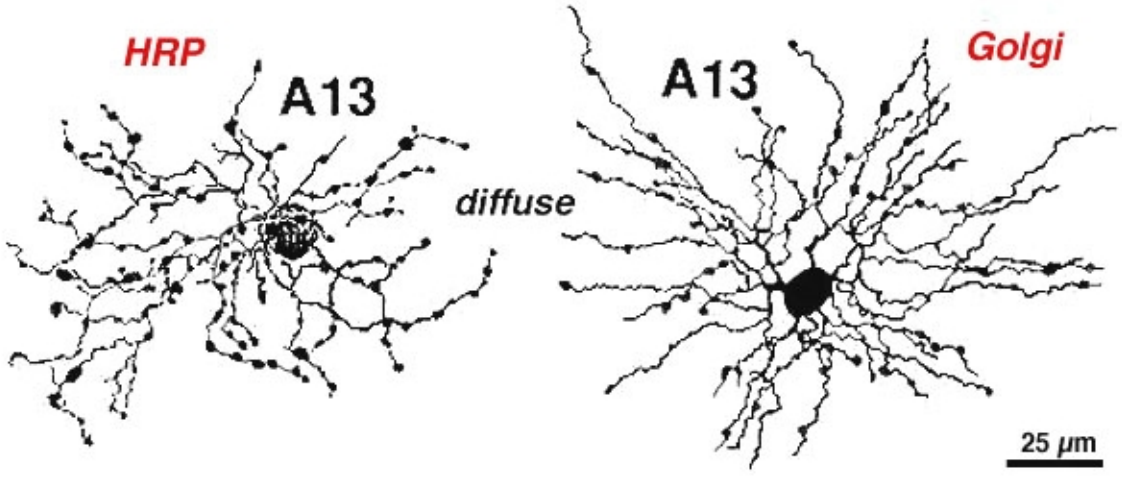

Figure 18. HRP and Golgi appearance of A13 amacrine cells.

types of bipolar (40%), to unknown dark amacrines (40%) and possibly some fine-diameter ganglion cell dendrites (20%) (40) (Fig. 26).

Gap junctions may connect A19 dendrites one to another (Fig. 11, A19, gj). A19 is GABAergic (16).

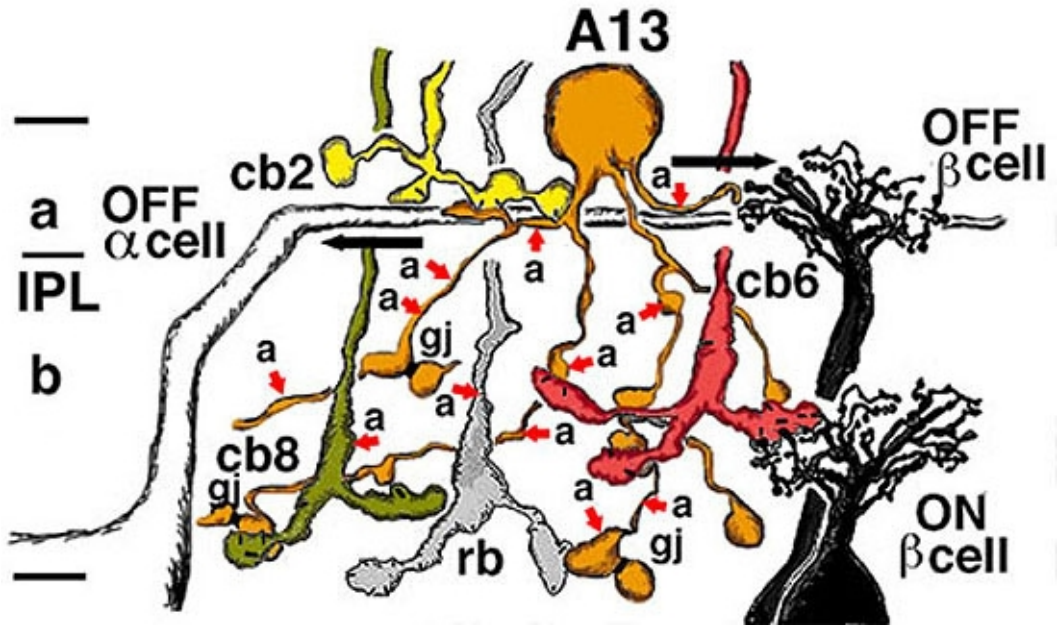

Figure 19. Wiring pattern of the A13 amacrine cell.

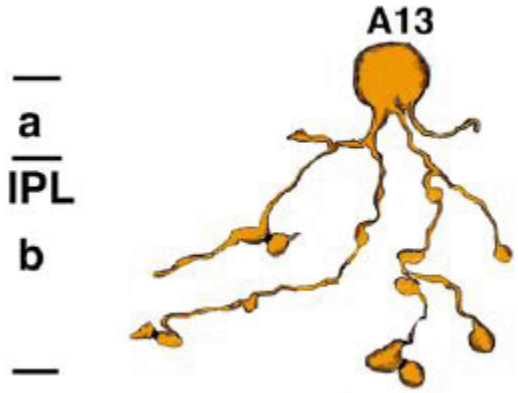

Movie 3. Animation of the wiring pattern of the A13 amacrine cell.
Download video

A20 cells, running in upper stratum 2 of sublamina **a**, have slightly different synaptic relationships with other nerve cells in the neuropil from A19, which will be remembered, sits on the sublamina **a/b** border (Fig. 27). Thus, A20 receives some cone bipolar inputs in stratum 1/2 and 2 (7%), but they are dominated by amacrine cell inputs (93%). Much of this input is recognizable as being from lobular appendages of rod AII cells. A20's output is about equally as reciprocal synapses to bipolar cells (5%) and synapses to amacrine cells (5%), but the cells have major output to alpha ganglion cells of sublamina **a** (90%). The latter ganglion cells would be OFF-center types, of course.

Both A19 and A20 cells are probably involved in the transfer of fast messages from one area of retina to another. They may be the basis of the proximal negative response recordable in the intraretinal ERG and in the shift effect in Y-type ganglion cells.

A22: A Putative Substance P-containing, ON-OFF Neuron of the Cone System

Immunocytochemical staining with antibodies against the neuropeptide substance P (SP) reveals a large-field amacrine cell in human retina (41). The SP-containing amacrine is possibly equivalent to the wide-field A22 cell of cat that has been intracellularly recorded as an ON-OFF cell (Fig. 27) (40).

SP-containing and A22 cells are wide-field amacrine cells (dendritic trees of 500-µm span), often having large cell bodies (14-16 µm) displaced to the ganglion cell layer, with their major dendritic stratification in strata 3 and 4 of sublamina **b** of the IPL. Both cells have long axon-like processes that pass up into sublamina **a** to run for up to 1 mm and also down into stratum to run over ganglion cell bodies. Their major dendrites are covered with spines (Fig. 28).

Electron microscopy shows that the spines are postsynaptic with reciprocal synapses to cone bipolar cells. They also receive synapses from unidentified amacrine cells and other SP-IR cell dendrites. They are presynaptic to ganglion cell dendrites and directly to ganglion cell bodies (possibly some of the latter are of SP-IR ganglion cells). Their axonal processes are presynaptic to amacrine and ganglion cells in stratum 5 and in stratum 1 of the IPL. Probably the latter ganglion cells are OFF-center (see above). They receive cone bipolar input from a cone bipolar type in stratum 1 of the IPL. Almost certainly A22 cells, SP-IR amacrine cells of cat and human, are GABAergic (42). This ON-OFF cell probably plays a similar role as the A19 and A20 cells above in being recordable in the proximal negative response (PNR) (43) and being involved in fast-moving aspects of visual coding (Fig. 29).

A18: The Dopaminergic Amacrine Cell

The dopaminergic amacrine cell types have been revealed by immunostaining with an antibody directed against tyrosine hydroxylase (TOH) (the rate-limiting enzyme for dopamine) and are wide-field cells that stratify almost exclusively in stratum 1 of the IPL (under the amacrine cell bodies). It has been identified with A18 cells or type 1CA (CA = catecholamine) of the Golgi studies (2, 10). Their dendrites form a densely packed network of processes leaving only few "rings" for other amacrine cell bodies and major dendrites to pass through. The rings are are beaded dendrites that appear to be synaptic points on amacrine cells, particularly the AII amacrine cell of the rod system (Fig. 30). Another feature of dopamine cells is only seen after dye injection (44) or immunostaining (45) (Fig. 31), and this that their dendrites emit long, axon-like processes running in different strata of the IPL, in the ganglion cell layer and sometimes into the outer plexiform layer (OPL).

A second type of dopaminergic cell has been described in the monkey and human retinas (28, 46). This type 2 CA cell is described as a "wispy" cell in Golgi studies (10) (Fig. 32).

There is still not a convincing electrophysiological study of the dopamine cell in the mammalian retina. However, in turtle and fish retinas, the equivalent to type 1 CA cells is an ON-center cell. In turtle, the cell gives as light ON transient, which continues as a sustained depolarization during the light ON. At light OFF, it has a very distinct, slow, sustained hyperpolarization that lasts for several seconds. The increasing spot sizes bring out the depolarizing ON-plateau, whereas with an annulus, a sustained OFF-surround is evident (see Fig. 33a) (47).

Synaptic relations of Type 1 CA cells have been studied by electron microscopy. This amacrine makes most of its synaptic arrangements in stratum 1 of the IPL as would be predicted from its branching pattern. Sparse cone bipolar input occurs to the cell's primary dendrites in stratum 1. The cone bipolar input is either from a diffuse cone bipolar that has axons in startum 1 or else from giant bistratified cone bipolar cells known to be present in cat and monkey retinas. Both bipolar types are probably hyperpolarizing (OFF-center) in response. Thus, the fact that the dopamine amacrine cell is a depolarizing ON-center cell makes the OFF-center bipolar input difficult to understand. Both the cell body and primary dendrites in stratum 1 of the IPL also receive GABAergic

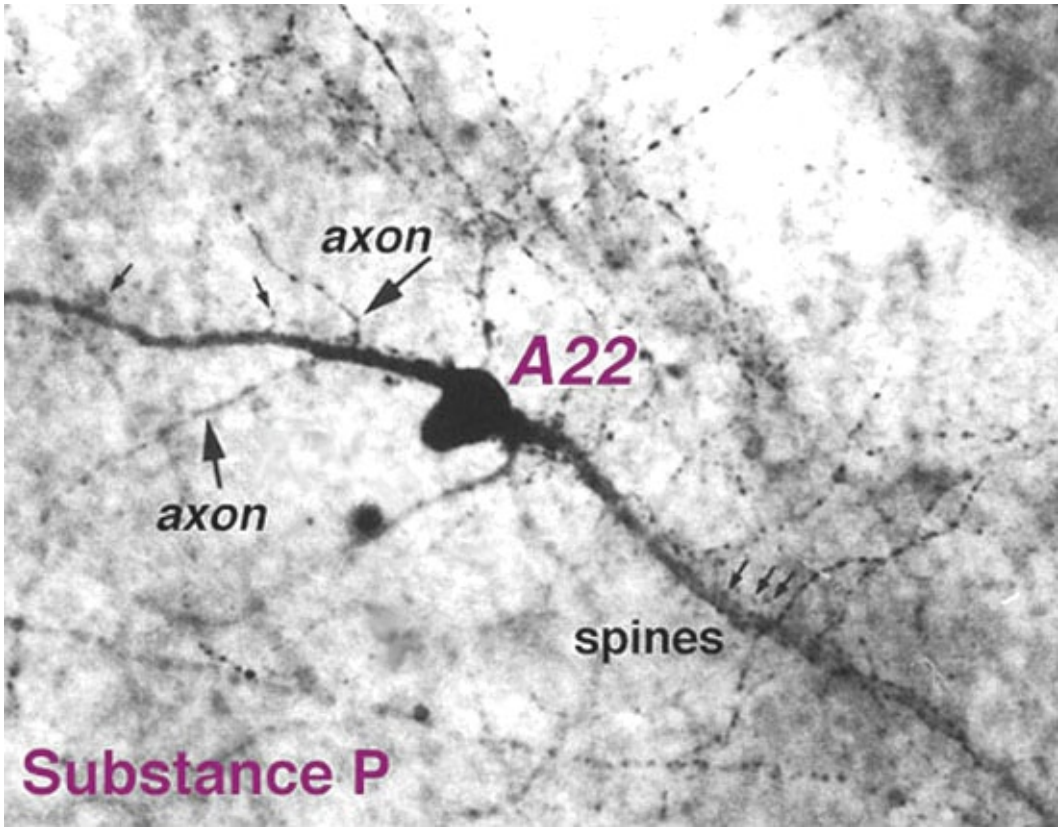

Figure 28. Substance P-containing amacrine cell in human retina.

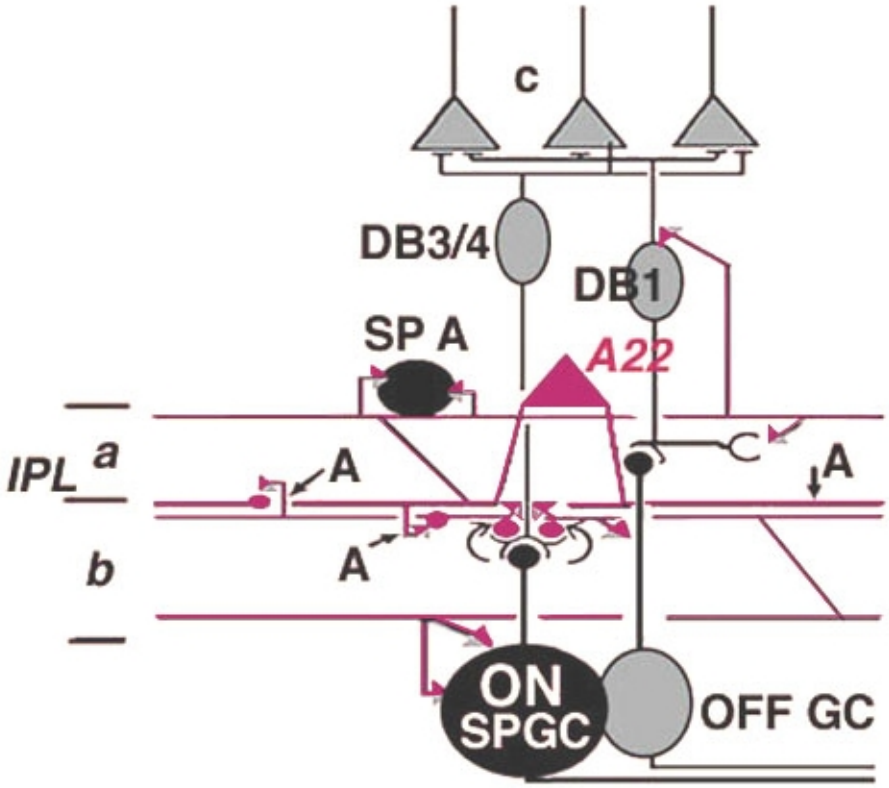

Figure 29. Diagram of the organization of the A22 amacrine cell.

and glycinergic amacrine cell inputs. Therefore, it has been suggested (48) that the GABAergic amacrine input comes from a GABAergic amacrine intermediary between the OFF-center bipolar and the dopamine cell, thereby giving the dopamine cell its ON-center response (Fig. 33b). The major output of the A18 cell is in the fine network of dendrites and axon terminals surrounding the cell bodies and apical dendrites of AII and A8 cells (25). The rings of dopamine processes surround many unfilled, stained cell bodies (Fig. 31). So we also think it probable that the dopamine cell in the mammal makes ring contacts upon both A17 and A13 cell bodies and main dendrites in stratum 1 of the IPL (Fig. 33b). Dopamine cell axons also contact AII dendrites in sublamina **b** of the IPL, and the few processes that run into the OPL make synapses upon the GABAergic interplexiform cell (25).

Dopamine cells in the fish retina are true interplexiform cells (IPC) and have profuse arborations in the inner nuclear layer and very extensive synapses upon the three types of horizontal cells. In the inner plexiform layer, the dopamine IPC makes some synaptic connections with the Mb (rod-dominated) bipolar axon terminals (49) (Fig. 34a).

Dopamine IPCs are thought to be influential upon the horizontal cells by decreasing their light responsiveness (50) and modulating their spatial extent by uncoupling their gap junctions (51). Horizontal cells in all retinas are joined by gap junctions in a strong syncytium (52) (reviewed by Negishi et al. (53)). Dopamine uncouples horizontal cells from the syncytium by interacting with D1 receptors, on the horizontal cell bodies and dendrites, linked to the second messenger cyclic AMP (see Dowling (54) and Witkovsky and Dearry (55) for reviews on dopamine effects in the retina). In the mammalian retina, a similar but lesser amount of uncoupling of horizontal cells due to dopamine has been reported (56, 57) (Fig. 34b).

The dopamine cell is, however, primarily an amacrine cell and not an interplexiform cell in the mammalian retina; thus, their effect on inner retina circuitry would be expected to be more pronounced than on the outer retina. We know that ganglion cells have their spiking properties variously altered by dopamine and by agonists and antagonists of dopamine and D1 receptors (58-61). These neuromodulatory effects are thought to occur via amacrine intermediaries, particularly the AII cell, or by diffusion of dopamine transmitter from a distance to ganglion cell bodies and dendrites, because there are no direct contacts of dopamine amacrine cells and ganglion cell dendrites. Both D1 and D2 receptors have been seen upon some ganglion cell bodies (62-64). The second effect of dopamine in the inner retina is thought to be upon amacrine cell coupling via gap junctions, somewhat analogous to the effect upon gap junction between horizontal cells in the outer plexiform layer. Dopamine uncouples AII amacrine cells in the mammalian retina, mediated through a D1 receptor (see above) (65, 66).

ACh Amacrines: Mirror Symmetric Starburst Cells

Golgi studies and intracellular Lucifer yellow staining has revealed amacrine cells that are known to use acetylcholine as a neurotransmitter (67). These cells have also been called "starburst" amacrine cells and are particularly striking in appearance in turtle, rabbit, and ground squirrel retinas (32, 68-71) (Fig. 35 and Fig. 36).

ACh amacrines occur as two mirror symmetric pairs of cells. One type, ACh-a type, has its cell body in the amacrine cell layer, and its dendrites stratify in stratum 2 of sublamina **a.** The other type, ACh-b type, has a cell body displaced to the ganglion cell layer, and its dendrites stratify in stratum 4 of sublamina **b.** ACh-b cells are medium-field in size but have a tremendous overlap of their dendritic trees such that as many as 70 cells overlap a single central cell in peripheral retina (33, 71). ACh-a type cells have slightly larger dendritic tree sizes (13% larger), and their overlap values can reach 90 or more (24). The ACh cells in the human retina are similar to those in rabbit but less dramatic in shape and branching pattern (see below). ACh starburst cells are particularly striking in the turtle retina, where the mirror symmetric amacrines are arranged in an essentially one-to-one relationship (Fig. 37a and Fig. 37b) (see a rotation of the mirror symmetric starburst cells).

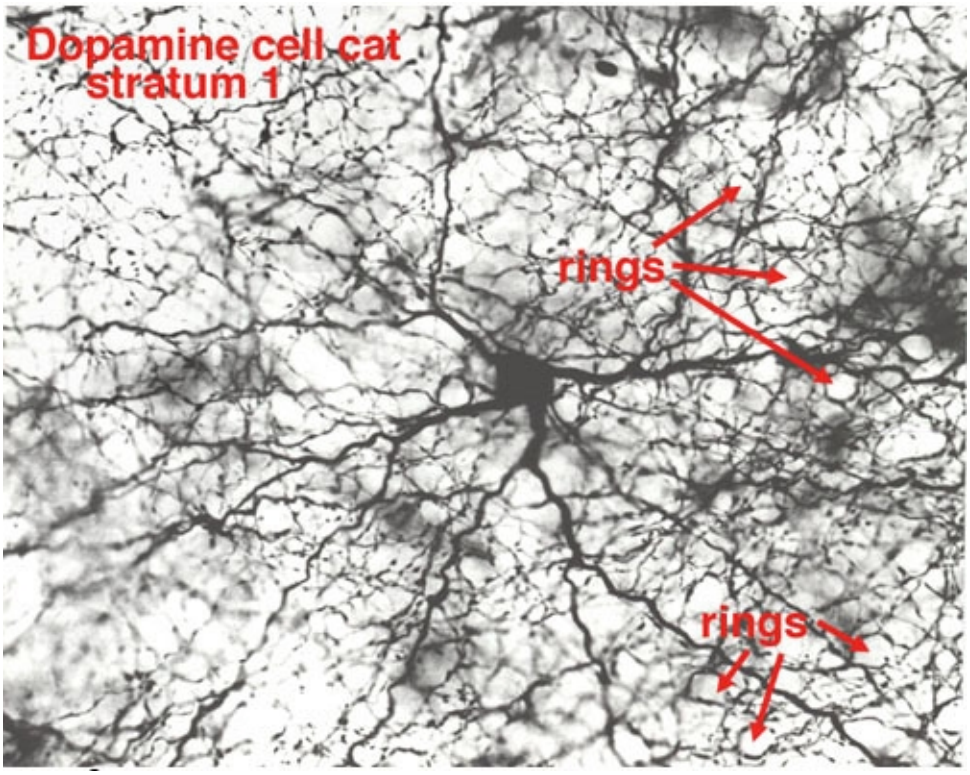

Figure 30. Immunostaining with antibodies to TOH. A18 amacrine cells stain and have overlapping dendrites that form into rings.

Golgi ACh-containing starburst amacrine cells of the rabbit retina have been extensively studied by electron microscopy (72). Cone bipolar and amacrine cell inputs are distributed irregularly over the entire dendritic tree, but the proximal dendrites to the cell body, containing small spines, are particularly choice for bipolar input. A small amount of AII amacrine input may occur to the proximal dendrites of the ACh-a type cell. The varicosities on the distal dendrites (see above) are the only sites of synaptic output to ganglion cells. The postsynaptic ganglion cells for both ACh-a and ACh-b type cells, are thought to be ON-OFF directional selective bistratified ganglion cells (32, 66, 71-75). Additionally, the monostratified ON-directionally selective ganglion cell may be postsynaptic to the ACh-b type cell (72) (Fig. 38).

Both mirror symmetric pairs of starburst cells of the rabbit retina have been intracellularly recorded from and dye marked by Bloomfield (21). The a-type of the pair is an OFF-center cell, giving a transient burst of small spikes at light off, whereas the ACh-b type is an ON-center cell (Fig. 38, top traces, above). Both types have antagonistic surrounds (Fig. 38, bottom trace).

ACh amacrine cells are thus thought to be involved in the generation of directional selectivity (DS) in certain retinal ganglion cells, particularly in rabbits and turtles with visual streak topography. They may not be as well developed in form and function in foveal-based retinas, such as cat and human (Fig. 39).

DAPI-3 Cells in the Rabbit Retina

In 1997, another bistratified, medium-field amacrine cell that is nucleus stained with DAPI was revealed by intracellular dye injection of Lucifer yellow. It was given the name DAPI-3 (76). Since then, the DAPI-3 cell has also been revealed by the fluoresecent rhodamine probe used by MacNeil and Masland (8) (see Fig. 4a, Roles of amacrine cells) and glycine immunoreactivity in the rabbit and ground squirrel retinas (77, 78). DAPI-3 cells are medium-field in size, i.e.. have a 100-μm field diameter and a profusion of overlapping dendrites, as seen in whole-mount views (Fig. 40b) that prove to be the two tiers of branches of a bistratified cell (Fig. 40d). One of

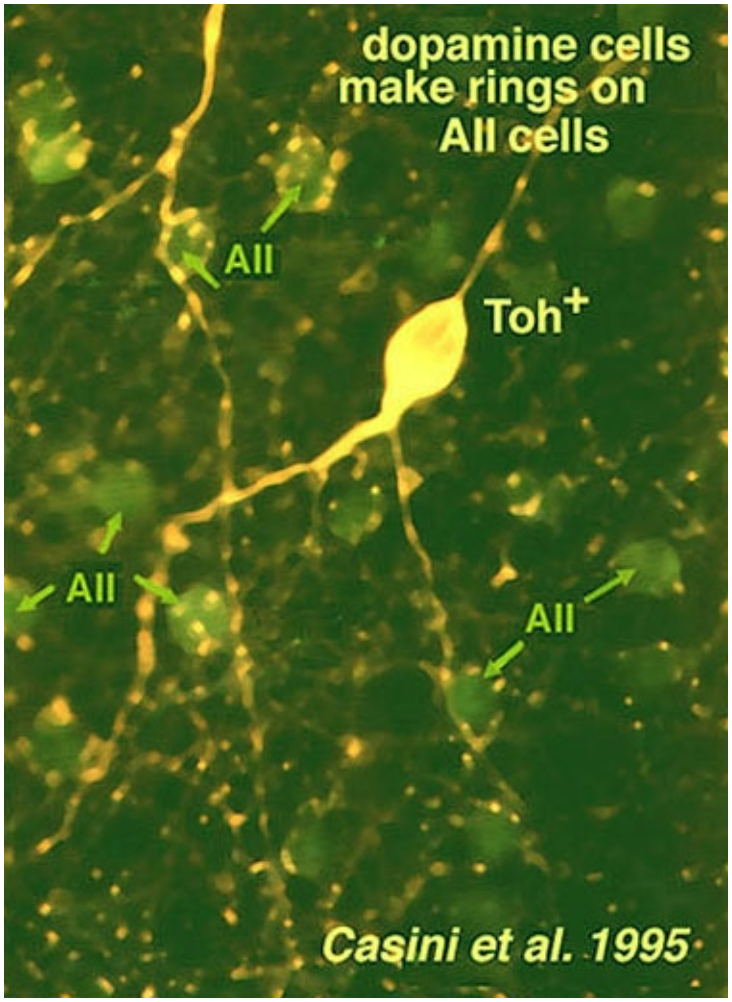

Figure 31. Dopaminergic and AII cells. From Casini et al. (82).

the tiers of dendrites in sublamina **a** run just below the ACh-a type (starburst a type), and the other tier run in sublamina **b**, just above the ACh b type (starburst b type) cells (Fig. 40d).

The DAPI-3 cell proves to be glycinergic and can be stained with the glycine transporter (Fig. 40c, green). It is also immunopositive for $GABA_A$ receptors (Fig. 40c, red). Thus, the cell appears to be orange in the figure (Fig. 40c, red and green combine to make orange-stained cells with a blue DAPI nucleus, arrows). The starburst ACh cells stains with CHAT in Fig. 40d, and the overlapping dendrites of the DAPI-3 cell stained for $GABA_A$ receptors are juxtaposed to the cholinergic cell's dendrites.

Zucker and Ehinger's (79) nice study on the DAPI-3 cells and immunostaining with the glycine and $GABA_A$ transporter/receptors allowed them to draw a summary diagram of the probable manner on which the DAPI-3 amacrine cells interact with the starburst ACh cells (Fig. 41). The DAPI-3 cell is acetylcholine receptive at nicotinic and muscarinic synapses and feeds back upon the starburst cell via a glycinergic synapse (glycine receptors have been identified on starburst cells). The DAPI-3 cell also contacts the cone bipolar cell that has input to the starburst cell. We know the starburst cell contains GABA in addition to acetylcholine, and the starburst cell can presumably feed forward to the DAPI-3 cell at a GABAergic synapse with $GABA_A$ receptors on the DAPI-3 cells. The starburst cell is known to synapse upon a directionally selective ganglion cell type in rabbit retina (Fig. 41). It is not clear yet whether the DAPI-3 cell exists in other mammals that do not have a pronounced visual streak as does the rabbit.

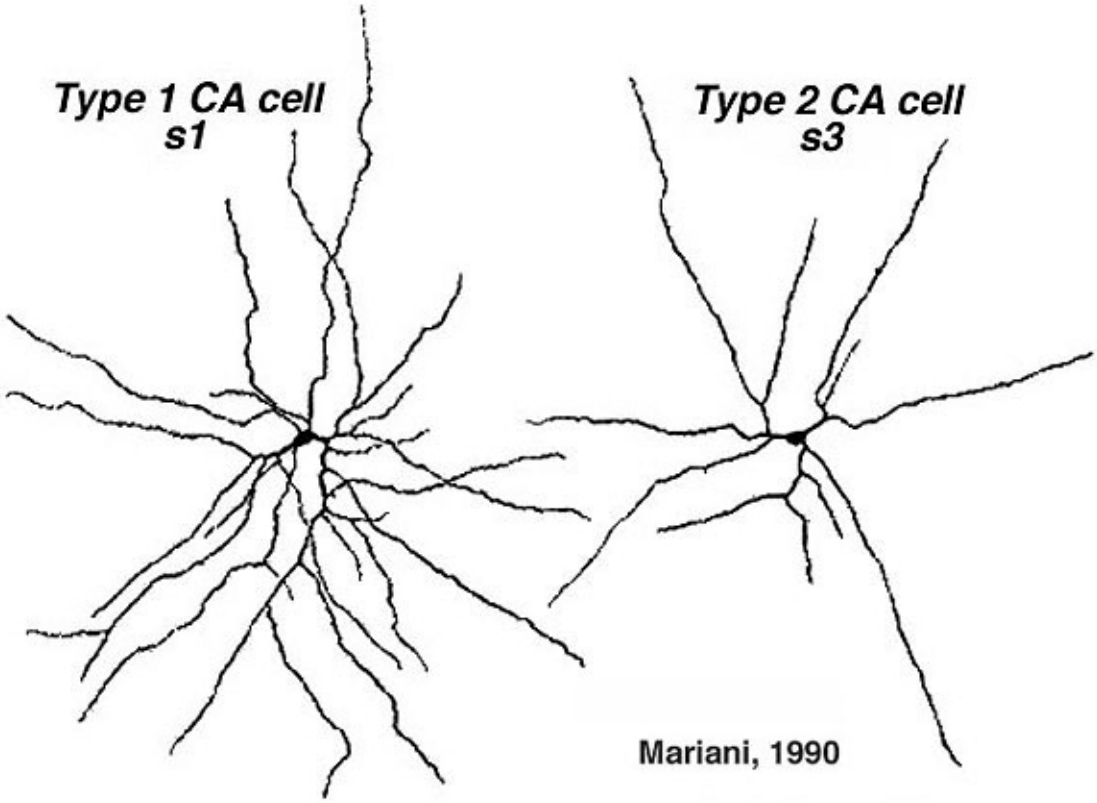

Figure 32. Types of dopaminergic cells.

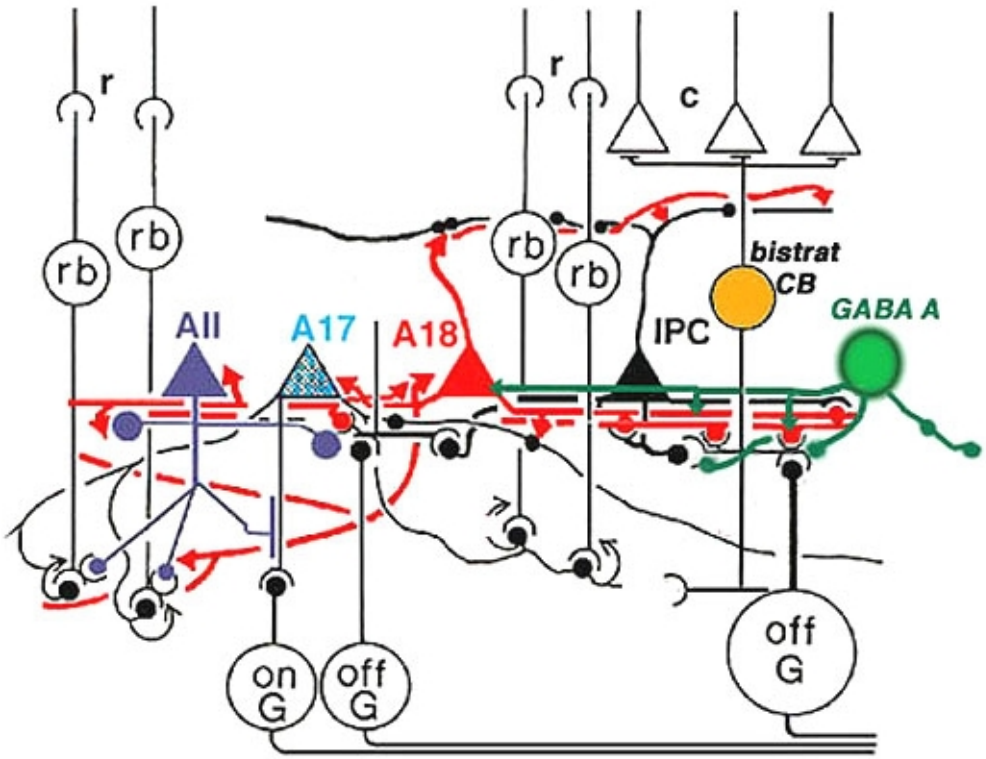

Figure 33b. Wiring diagram of the A18 amacrine cell.

Midget System Amacrine Cell

The calcium binding protein calretinin is found in three types of amacrine cell in the monkey and human retinas (80). The most numerous population are the AII amacrine cells, but a small- to medium-field diffuse amacrine cell and a large-field, stratified A19 type are also calretinin immunoreactive (IR). Of these non-AII cell types, the small diffuse (or tristratified cell type, difficult to know which) is of particular interest.

Its appearance is shown in Fig. 42 (A, arrow) in immunostained slice preparations. The cell has a large cell body, but unlike the AII cells (Fig. 42, AII), many fine dendrites are given off the cell body instead of the typical AII thick primary dendrite. The dendrites pass down to all levels of the IPL as thin, beaded, and branched processes (Fig. 42, fine arrows). This small-field diffuse calretinin-IR cell is found in high numbers in the foveal, rod-free area of the retina and in lesser numbers in the peripheral retina. Electron microscopic examination of foveal diffuse calretinin-IR cells has shown that they get synaptic input from ON- and OFF-midget bipolar terminals, reciprocate synapses to these bipolars, and have synaptic output to ON-center midget ganglion cells (Fig. 43, wiring diagram). In more central to peripheral retina where rods are present, the diffuse calretinin-IR amacrines are probably also in synaptic interplay with both diffuse bipolar cells and larger parasol ganglion cells (Fig. 43). Because these calretinin-IR amacrines are found in the fovea and have particular relationships with the midget bipolar and ganglion cell systems, we have suggested that they may have a role in the antagonistic surround generation for midget ganglion cells. Moreover, they could also contribute to color opponency in these ganglion cells (80).

Figure 42. Cryostat sections of calretinin-IR monkey retina to show the different amacrine cell types that are immunoreactive. Three calretinin-IR cells are shown, of which only one has all the features of an AII amacrine cell (AII). The middle cell (A, curved arrow) has very fine, beaded dendrites running in S1, S3, and S5 (fine arrows). The third cell is difficult to identify (A).

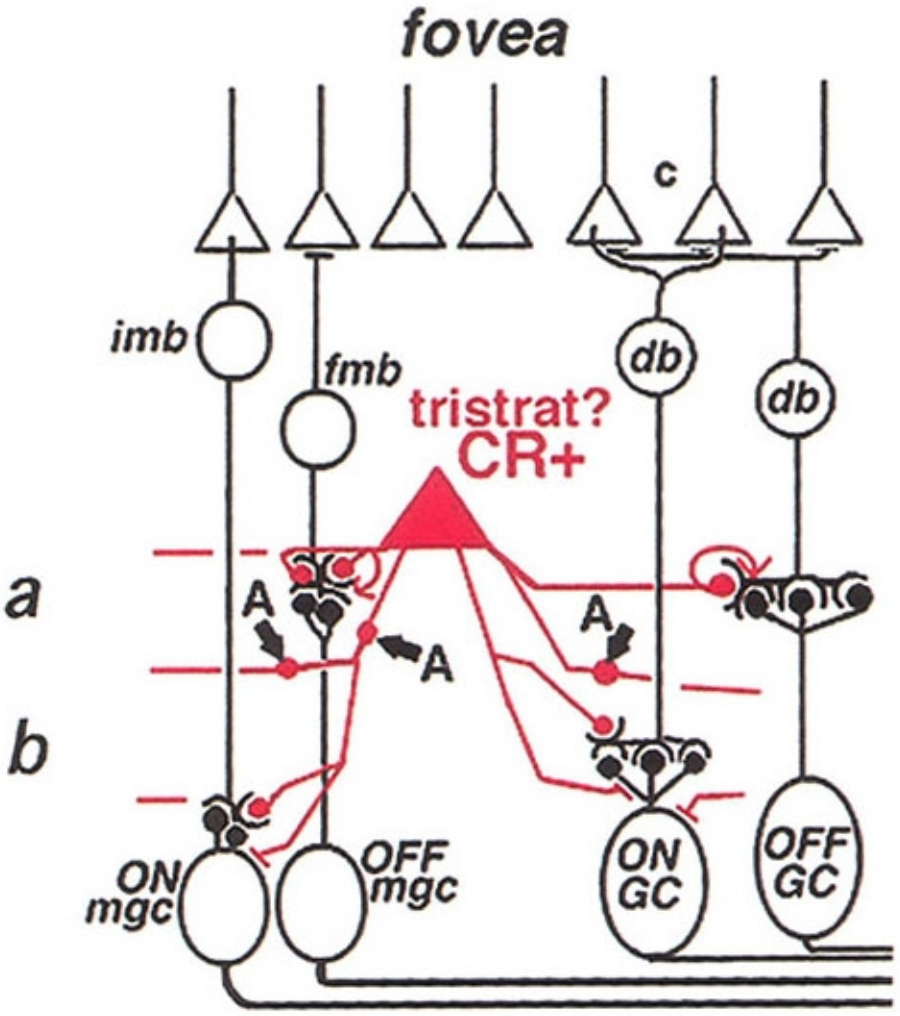

Figure 43. The calretinin-IR amacrine of the rod-free fovea (red cell) receives inputs from diffuse cone bipolar cells (db) and both invaginating and flat midget bipolar cells (imb and fmb) and many amacrine cells types (A arrows). It makes synapses upon ON-center midget (ON mgc) and other ON-center ganglion cells (ON GCs) in sublamina b of the IPL. OFF-center ganglion cells (OFF GC) in sublamina a could be indirectly affected by the tristratified calretinin-IR amacrines through their reciprocal synapses to dbs or fmb bipolar cells (return arrows).

AII Amacrine Cells

Mahnoosh Farsaii and Victoria P. Connaughton

Created: June 1, 2005; Updated: April 26, 2007.

Introduction

The AII amacrine cell is characterized by a multifaceted connectivity and physiology. It is unique among amacrine cells in that it participates predominantly in the vertical flow of information though the inner retina, contributing to center mechanisms, rather than in lateral inhibitory pathways. As its multilayer stratification, and synaptic partners, suggest, the AII transmits both rod and cone-driven signals within the ON- and OFF-retinal pathways to the inner retina. This chapter summarizes the morphological and physiological characteristics of AII cells focusing on data obtained from four mammalian species: rat, cat, rabbit, and monkey.

Morphology and Distribution

The AII amacrine cell, originally described by Kolb and Famiglietti (1, 2) is the most studied amacrine cell of the vertebrate retina. It has been identified in a variety of mammalian retinas. The AII is a narrow-field, bistratified amacrine cell that is involved in synaptic contacts throughout the IPL. Its morphology has been identified using a variety of staining methods, such as Golgi techniques (Fig. 1a) (1-3), Lucifer and HRP labeling of recorded neurons (4), and fluorescent dyes such as 4,6-diamidino-2-phenylindole (DAPI) followed by Lucifer Yellow injection (5-7), or by small-spot photo-oxidation of dihydrorhodamine 123 (8, 9).

More recently, immunocytochemical methods targeting various calcium-binding proteins (parvalbumin and calretinin) have been used to selectively label AII cells in rabbit (10, 11) and rodent (Fig. 1b) (12). Primate AII cells are also labeled with calretinin (11, 13), although not selectively (14). Regardless of technique used, the AII cell has a consistent morphology (Fig. 1a) with a round or oval-shaped cell body 8-10 µm in diameter located in the proximal inner nuclear layer. In peripheral retina, the cell body often extends into the IPL. The distribution of AII cell bodies is non-random, forming a regular mosaic (5, 6, 15). Calculated regularity indices range from 4.0 (inferior retina) to 5.4 (temporal midperipheral retina) in rabbit (16), cat (6), and rat (12); a lower value was calculated in monkey (13). AII dendritic trees are reported to be more regularly distributed than their cell bodies, with their processes filling in gaps between adjacent cell bodies to get full coverage of the IPL (13, 16).

The bistratified nature of AII cells arises from two distinct dendritic trees (Fig. 1a and Fig. 1b). The dendritic tree in sublamina **a** (s1 and s2) is composed of short, thin processes ending in lobular appendages that radiate in all directions from typically a single primary dendrite (1, 17-19). Quantitative analysis of serial sections of one particular rabbit AII cell (18) identified 21 lobular appendages ranging in diameter from 1.6 to 5.5 µm. In contrast, the processes that form the dendritic tree in sublamina **b** are called the distal (or arboreal) dendrites and terminate predominantly in stratum 5. The distal dendrites are thin processes that possess spines along their length and branch more widely than the lobular appendages (Fig. 1a). The above characteristics are conserved in rabbit, rat, cat, and macaque monkey retinas (6, 12, 13, 20-22).

AII distribution and morphology is different in central *versus* peripheral retina. AII density is greatest in extrafoveal central retina and decreases with increasing eccentricity. Simultaneously, both dendritic fields enlarge with eccentricity (Fig. 2a) (5, 12, 16, 19, 23), with a more pronounced change reported for the distal dendrites. For example, AII cell density in central cat retina is maximal at 5,300 cells/mm^2 and decreases to 500-800 cells/mm^2 in the peripheral retina. The diameter of the lobular appendage field increases from 16 µm (central retina) to 30 µm (8mm eccentricity), whereas the diameter of the distal arbor expands from 18 µm to 58 µm (6) (Fig. 2b). This morphological trend has also been identified in other mammalian retinas.

The distal dendrites in sublamina **b** of adjacent AII cells overlap. The amount of overlap has been quantified by calculating the coverage (dendritic field area × cell density) of each cell (10). In rabbit, a coverage value of 1.8

was calculated for distal dendrites in the central retina (visual streak) and 2.4 in the inferior retina. The greatest overlap is seen in the superior peripheral retina, where a coverage value of ~10 was calculated (16). In contrast, there is little or no overlap between the lobular dendrites in sublamina **a** of adjacent rabbit AII cells, as coverage varied from ~1.0 in the inferior retina and ~0.8 in the superior retina (16) were calculated. These values show that the lobular appendages maintain a constant coverage over the entirety of the retinal area, whereas the distal processes vary in overlap along both central-to-peripheral and superior-to-inferior axes. Similar differences in AII dendritic processes have been reported in cat, monkey, and rat, suggesting differences in function between AII processes in the distal and proximal IPL (6, 12, 13).

Synaptic Connectivity

Chemical Inputs to Distal Dendrites in Sublamina b

The AII receives direct glutamatergic inputs in sublamina **b** (s5) from rod bipolar cells (RBC) (Fig. 3). At this synapse, the AII forms one member of the postsynaptic dyad (1, 2, 18, 24-27); the other member (discussed below) is a GABA-containing amacrine cell known as A17 in cat and S1/S2 in rabbit (28). The latter cell types make reciprocal synapses back onto the RBC terminal at $GABA_C$ receptors on the RBC (24, 26, 27, 29-33). Each AII receives input from several RBCs.

In all mammals, physiological studies show that glutamate-elicited currents in AII amacrine cells are mediated by AMPA-preferring receptors (34-36) sensitive to the nonselective antagonist CNQX and the AMPA receptor-specific compounds GYKI-52466 and cyclothiazide (36-38). The receptors are formed from GluR3 (39-42) and/or GluR4 (43, 44) subunits (Fig. 4), which confer high calcium permeability to the channel.

NMDA responses have also been identified on rat (45) and rabbit (46) AII cells. These findings contradict immunocytochemical studies that note the absence of NMDA receptor subunits on AII dendritic processes (47-50). Recent findings indicate that NMDA responses do not mediate transmission at the RBC-to-AII synapse (37), suggesting that these receptors, when present, may be located extrasynaptically. The NMDA response in AII cells may also depend on an intracellular signaling pathway, because the response runs down quickly in patch-clamp studies (45).

Although one AII amacrine cell is associated with almost all RBC dyads, rod bipolar connections make up only ~30% of the inputs to AII cells (18). These cells also receive chemical inputs from other amacrine cells within s1 and s5 in rabbit and s1, s3-s5 in rat and cat and in monkey. The amacrine cell(s) presynaptic to AII distal dendrites have not generally been identified, except for dopaminergic amacrine cells in cat (51). Amacrine contacts make up ~40% of the synaptic inputs in sublamina **b** according to Strettoi et al. (18).

Electrical Connections of Distal Dendrites in Sublamina b

AIIs are electrically coupled to ON cone bipolar cells (CBC) throughout sublamina **b** (Fig. 3) (1, 2, 18, 52, 53) and to other AII cells in s5 (18, 27, 54). AII/AII junctions are structurally formed from connexin 36 (55, 56). Signal propagation is bidirectional, promoting synchronized responses (i.e., action potentials) among connected cells (57).

Dopamine application reduces AII/AII coupling (58) through the activation of D1-type dopamine receptors (59) and the formation of cAMP (Fig. 5a) (59, 60). In contrast, gap junctions formed between AII and ON-CBC are heterologous, formed by connexin 36 on AII processes and either connexin 36 or another (possibly 45) connexin on CBC (55, 56, 61). These junctions are also bidirectional (35, 46, 62), although signals are more effectively propagated in the direction of AII to ON-CBC (53). The permeability of AII/ON-CBC channels appears to be regulated by nitric oxide and cGMP (58). Nitric oxide activates guanylate cyclase (increasing intracellular cGMP) and decreases coupling between these cell types.

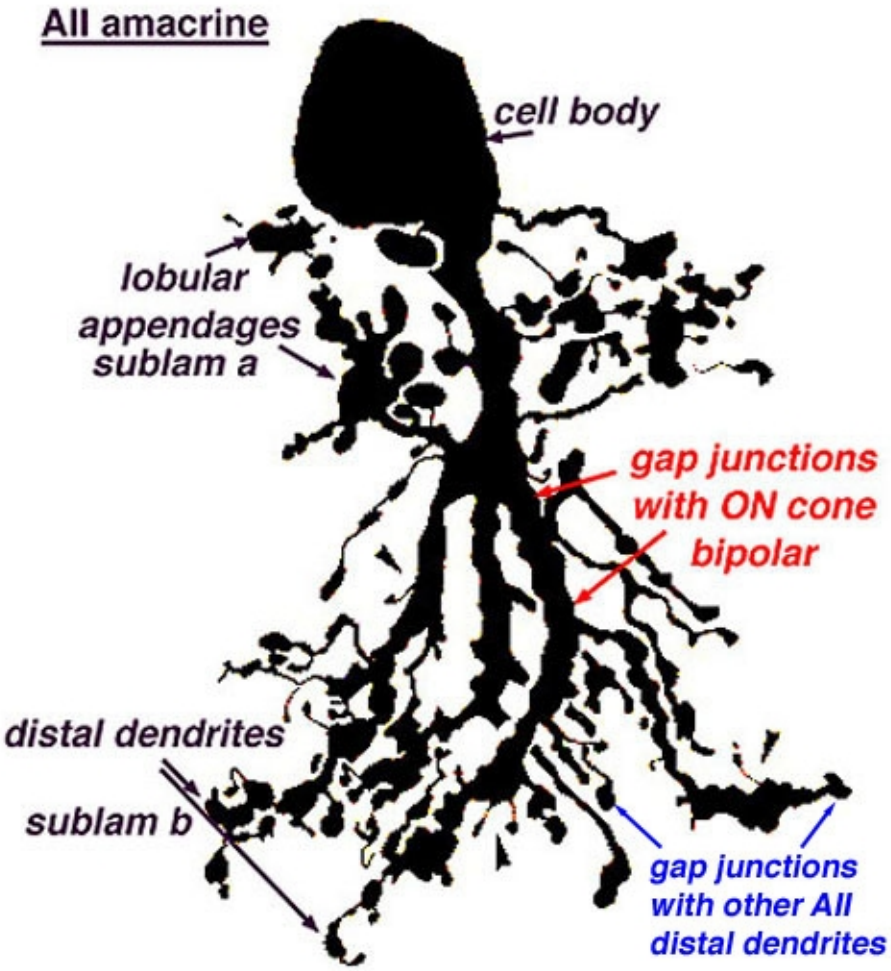

Figure 1a. A Golgi-stained example of an AII amacrine cell in cat retina.

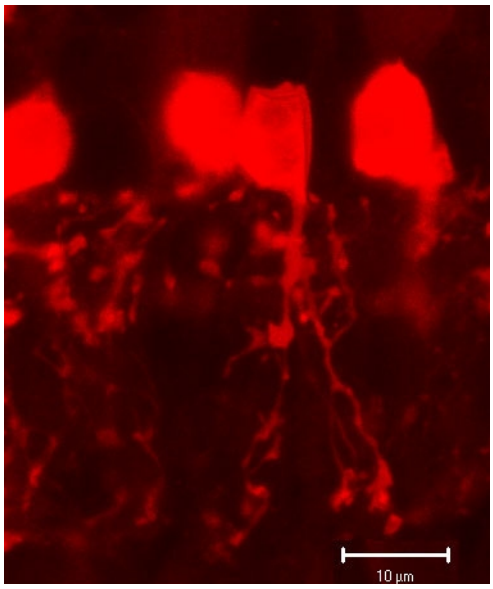

Figure 1b. AII amacrine cells immunocytochemically stained with anti-parvalbumen in rodent retina. Courtesy of Nicolas Cuenca.

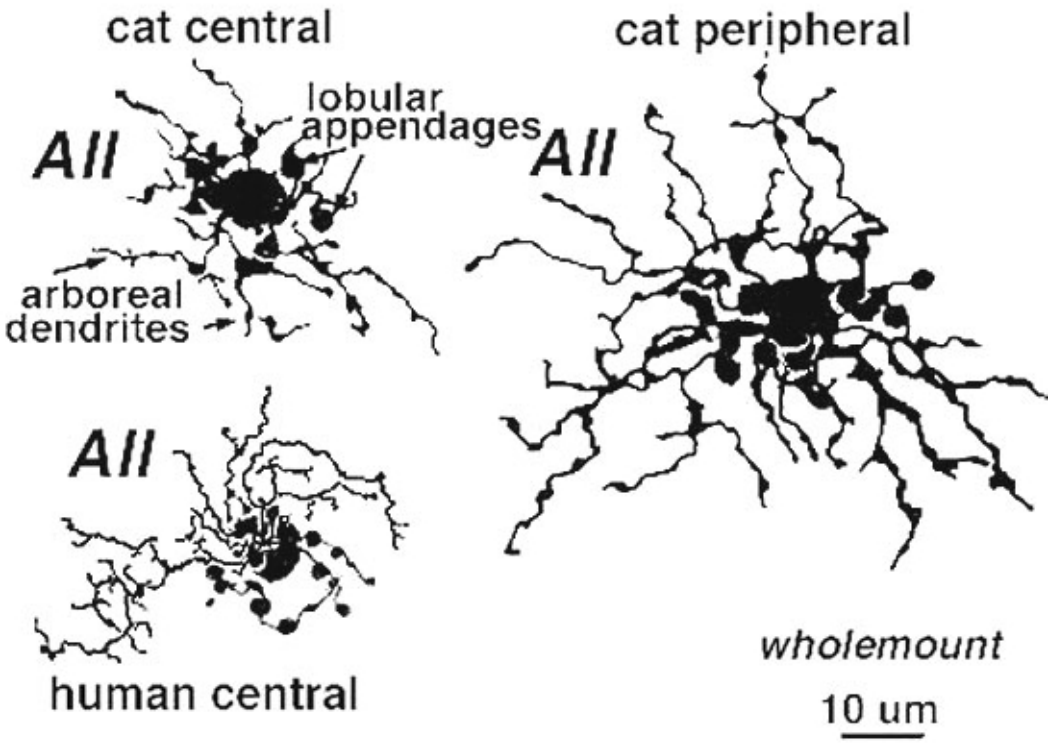

Figure 2a. Golgi-stained whole-mount views of AII amacrine cells.

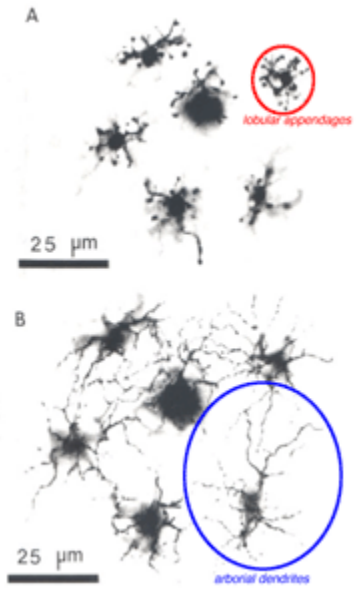

Figure 2b. AII amacrine cells stained with Lucifer Yellow and viewed in whole-mounts reveal two distinct types of processes. In sublamina a, the shorter lobular dendrites (A) encircle the cell body, whereas in sublamina b, thin distal dendrites (B), end in stratum 5. From Mills & Massey (5).

The reported extent of coupling among AII cells varies greatly, from modeling estimates that each AII is coupled to three other AII cells (63) to dye-coupling studies showing that the network can range from ~20 to >300 coupled cells (7, 64). This difference in coupling extent is dependent upon adaptational state (Fig. 5b). Changes

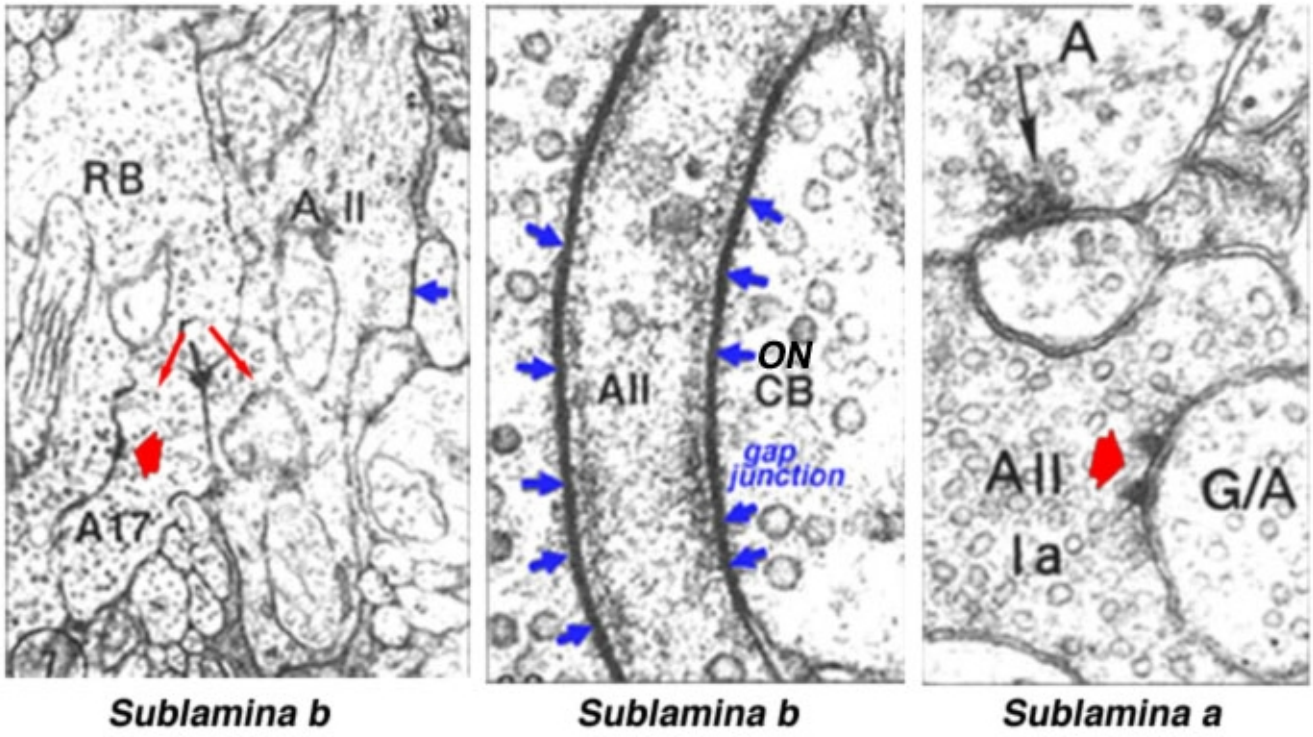

Figure 3. Electron micrographs of AII amacrine synapses. In sublamina a, AII cells synapse on cone bipolar, ganglion cells, and amacrine cells. In sublamina b, AII cells receive ribbon synapses from rod bipolar cells and make gap junctions with ON-center cone bipolar cells.

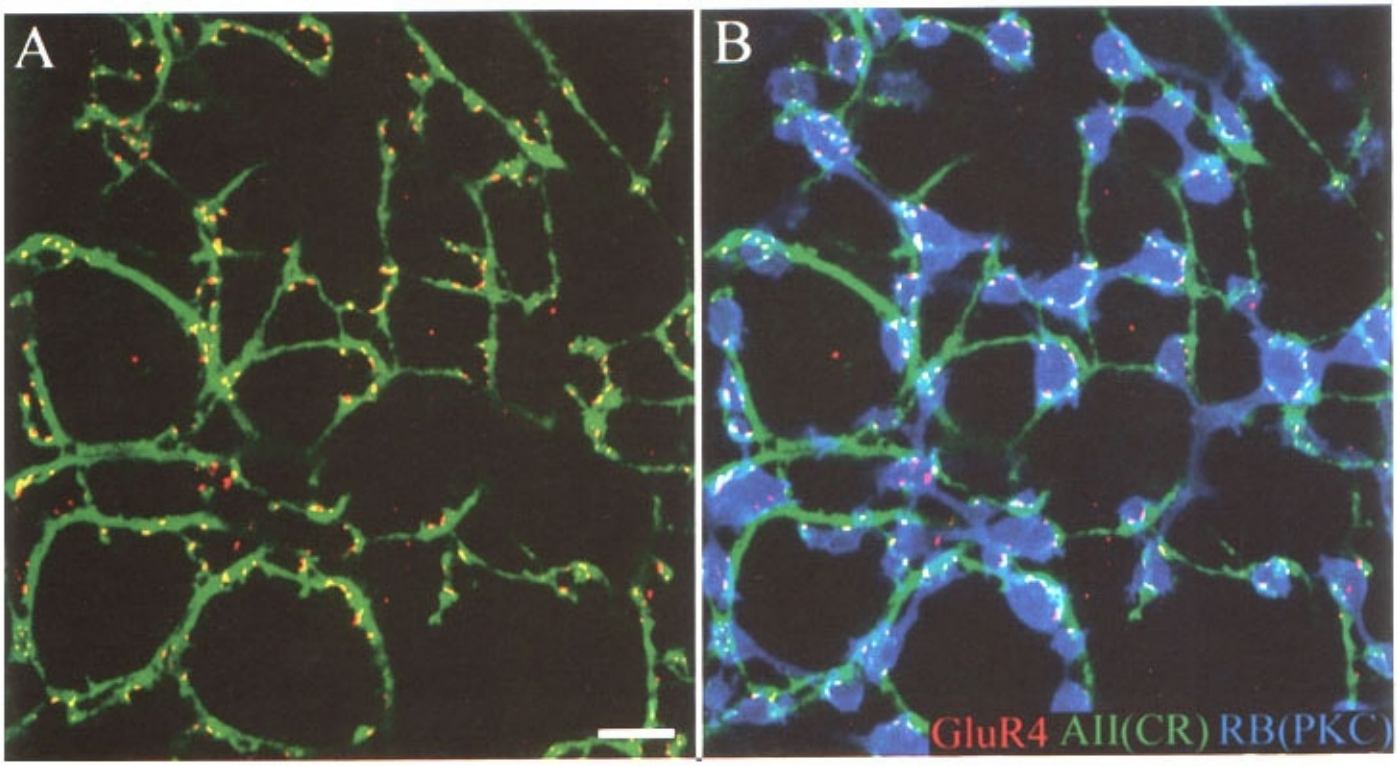

Figure 4. Immunostaining of AII distal dendrites (calretinin, green) and rod bipolar cell terminal (protein kinase C, blue). The yellow/white dots indicate immunostaining for GluR4 receptors at the rod bipolar-AII amacrine synapses. From Li et al. (44).

in AII/AII coupling have been shown to reflect changes in the diameter of the receptive field center (Fig. 5b). For example, in dark-adapted tissue, one AII cell is coupled to a network of ~20 other cells, and the corresponding diameter of the receptive field center averages ~74 μm (64). When the intensity of light is increased but still within the operating range of the cell (~2.25 log intensity unit), both the extent of coupling and the diameter of the receptive field center increase (Fig. 5b). Further increases in light intensity actually results in a decrease in coupling to levels comparable with those seen in dark-adapted conditions (Fig. 5b). Thus, the cells are extensively coupled over their operating range but uncouple at the edges of this range.

What is the benefit of varying the extent of coupling? AII/AII coupling is integral in optimizing the signal-to-noise ratio of the AII network (64, 65) because it allows the smaller correlated rod signals to be increased while uncorrelated noise is decreased (63, 66). This would be important when the retina is operating at dim light intensities (mesopic conditions) because increased coupling maximizes the area from which each AII can merge spatially correlated signals, thereby increasing signal-to-noise ratio. In dark-adapted conditions, however, a miniscule number of photons are intermittently absorbed by the rods, and the correlated signals are few (65). Because coupled AII cells all receive common inputs, AII coupling would strengthen the response by summing correlated signals and reducing noise (63, 66). However, given that the number of correlated signals reaching the AII network is few, extensive coupling at these low light levels is of no advantage because it would increase background noise, causing the faint signals to spread laterally and decrease the overall amplitude of the response. Coupling is also reduced in light-adapted conditions, reducing the transmission, and loss, of cone signals through the AII network, facilitating the high spatial acuity in photopic conditions (65). Furthermore, the high signal-to-noise levels in the cone system reduce the need for spatial averaging.

Gap junctions between AII/ON-CBC provide the mechanism through which rod signals reach ON-ganglion cells (52) via the circuit: rod-to-rod bipolar to AII to ON-cone bipolar cell to ON-ganglion cell (Fig. 6, red circle, blue square). Because these gap junctions are also bidirectional, they provide an alternate pathway through which AIIs receive cone-driven inputs (35, 67, 68). The alternative route would be through rod/cone gap junctions, thus getting rod signals into cone photoreceptors themselves (69). Rod signals would be transmitted to cone bipolar cells and then pass to AIIs in the circuit rod-cone-ON-cone bipolar-AII (67). Signals originating in cone photoreceptors would be relayed via this path as well, and cone-driven responses have been recorded in AII cells (4, 68). Photopic inputs from ON-CBC depolarize AII cells which, in turn, hyperpolarize OFF-CBC (Fig. 6), suppressing light-adapted OFF-center responses (68). As noted above, AII/ON-CBC junctions appear to be modulated by NO, but not by light as physiological studies report changes in background light levels do not alter the observed overall extent of AII/ON-CBC coupling (64), and cone-driven responses can be recorded from AII cells in photopic conditions (4, 68).

Given the morphological diversity of CBC types, it is useful to identify which specific cell(s) is coupled to AIIs to better understand the underlying circuitry. Mills and Massey (70) identified electrical coupling between AIIs and the calbindin-positive bipolar cell in rabbit. However, because only one-quarter of the bipolar cells (23%) tracer-coupled to AIIs are calbindin positive, more than one type of ON-CBC probably makes gap junctions with AIIs (70, 71). In agreement with this, a recent study by Veruki & Harveit (53) examining the electrical properties of AII/ON-CBC gap junctions in rat identified four types of bipolar cells, namely CB5 through CB8, electrically coupled to AIIs in rat (72). Furthermore, the latest evidence from Masland's group suggest that some of the ON cone bipolars coupled to AII cells express connexin 45 but not connexin 36 (61). In cat, the cb5 bipolar cell was found to be coupled to AII processes (73). The cb5 bipolar cell probably corresponds to the calbindin bipolar cell in rabbit, because the latter makes the greatest number of gap junctions with AII cells (54).

Thus, electrical coupling within the AII network functions to maximize signal transmission to postsynaptic ganglion cells. As AIIs receive both rod- and cone-driven inputs, the caliber of the signal varies, depending on stimulus intensity. Consequently, the dynamics of the AII network must also vary continuously. In contrast, synaptic transmission through AII/ON-CBC gap junctions is not affected by adaptational state (64), suggesting

this pathway may function on a sustained level, continually relaying signals independent of light level to ganglion cells.

Synapses of the Lobular Appendages in Sublamina a

The lobular appendages are the major chemical synaptic output sites of AII amacrine cells (Fig. 3) (1, 18). These appendages form reciprocal, inhibitory synapses in s1-s2 (18) with OFF-CBC terminals (18, 24, 74, 75). These synapses account for 90% of the output from AII cells in rabbit (18). AII amacrine cells in rabbit rarely synapse directly onto OFF-ganglion cells, whereas in cat and monkey synapses to OFF ganglion cells are common (52, 76). Inhibitory signals from AIIs are passed to OFF-CBC, decreasing glutamate release onto OFF-type ganglion cells during light stimulation (Fig. 6, blue circle).

Merighi et al. (75) have shown in rabbit that at least two different OFF-CBC types (DAPI-Ba1 and DAPI-Ba2) are postsynaptic to AII cell lobular appendages in different regions of the inner plexiform layer (IPL). The axon terminal of DAPI-Ba1 cells ramifies in s2, whereas DAPI-Ba2 cells are multistratified with boutons located within s1-s3. In cat, cb1 and cb2 bipolar cells (23), which correspond to DAPI-Ba2 and DAPI-Ba1 cells, respectively, contact AII cells in sublamina **a**. In primates, AII lobular appendages participate in reciprocal synapses with calbindin-positive DB3 axon terminals in s2 (77). Another bipolar cell in macaque, DB2, is similar in stratification pattern to the rabbit DAPI-Ba2.

Both AII dendrites and the cell body are postsynaptic to other amacrine cells in S1. Double labeling studies have shown that the dendrites of dopaminergic amacrine cells encircle AII somata, forming characteristic rings as shown in Fig. 7 (78-80). These dopaminergic inputs are believed to mediate changes in AII/AII coupling that occur with adaptational state. However, recent findings show that direct contacts between the dopaminergic processes and AII somata are GABAergic rather than dopaminergic (because dopaminergic amacrines are said to be also GABA positive (81)). Thus, AII cells may receive direct GABAergic inputs at the cell body, which could also regulate AII cell light responses. These GABA-elicited responses, from $GABA_A$ receptor activation, would result in a faster modification of AII responses compared with dopamine actions, which are mediated through slower second messenger cascades and may be considered paracrine in nature. It has to be mentioned here that the dopaminergic amacrine cell is now considered to contain glutamate (82), and if this is the case, a faster transmitter action would also be expected.

Physiological Responses

AII cells themselves are inhibitory glycinergic neurons (83, 84). Their strongest response, and unique role, is during scotopic levels of illumination. In this case, the AII assists in increasing both the speed of transmission and the amplitude of the rod signals seen by the ganglion cells (4).

AII amacrine cells are also called the "rod amacrine cell" because they have response characteristics, such as threshold, saturation level, and spectral sensitivities, similar to rods (4, 65). These cells display complex physiological responses that serve both rod and cone retinal pathways and are sensitive to adaptational state (Fig. 8a). In general, AIIs generate TTX-sensitive action potentials and respond to the exogenous application of GABA, glycine, and glutamate (34). AIIs are classified as ON-center amacrine cells that display center-surround antagonism (4, 39, 68, 85) when dark-adapted; surround antagonism is abolished in light-adapted cells (68).

Generation of the ON-Center Response

On the basis of the synaptic connections of AII cells, ON-center responses could be generated via two pathways: 1) direct rod-driven inputs from (ON-type) RBC at chemical synapses or 2) direct cone-driven inputs from (ON-type) CBC via electrical synapses. Physiological recordings showing rod- and cone-driven responses in AII

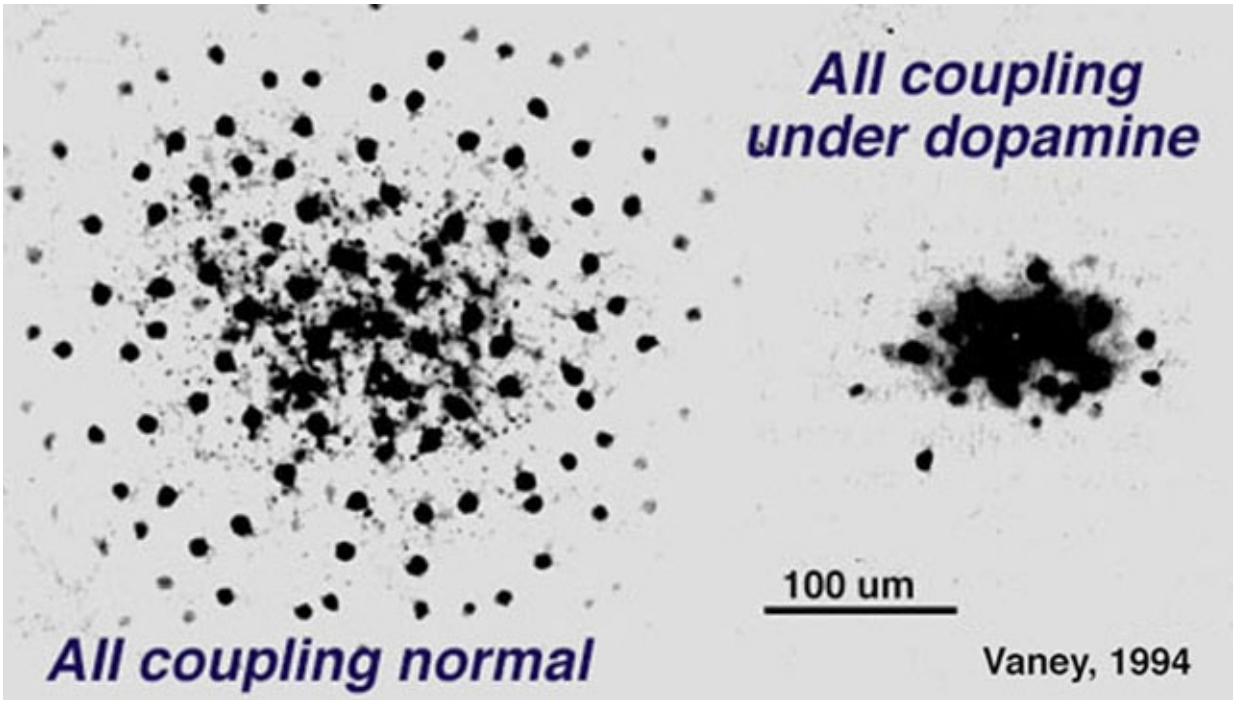

Figure 5a. Dopamine application to retina when the AII cells are injected with biocytin cause a reduction in the numbers of cells that are coupled via gap junctions as compared with normal conditions. Rabbit retina. From Hampson et al. (59).

cells (68, 85) and pharmacological studies (68) indicate that ON-center responses are blocked by the application of 2-amino-4-phosphonobutyric acid (APB), indicating they are generated by ON-type bipolar cells (86, 87).

How is the ON-center response generated? Interestingly, signals transmitted within both of the above pathways can generate the center response, with the contributions of each pathway varying, depending on the intensity of the stimulus (Fig. 8b). In dark-adapted conditions, center responses are derived from rod-driven or cone-driven inputs transmitted directly to AIIs from rod BCs or from cone BCs through gap junctions. Exogenous application of either 8-bromo-cGMP or SNAP, which uncouple AII/ON-CBC gap junctions, does not block scotopic ON-center responses but does block the cone signal component. Bright stimuli saturate the rods, reducing rod-driven inputs to AIIs. In these conditions, ON-center responses are blocked when AII/ON-CBC junctions are pharmacologically uncoupled (68). Thus, the ON-center responses in AII cells comes from either rods or cones. Rod signals depolarize AIIs in dark-adapted (scotopic) conditions; cone-driven signals are relayed in light (photopic) conditions (Fig. 8a and Fig. 8b). Interestingly, a temporary OFF-center response has also been identified in light-adapted AII cells. This response is blocked by CNQX and is believed to be generated via direct glutamatergic inputs from OFF-cone bipolar cells onto AII lobular appendages in sublamina **a** (68).

The AII light response is biphasic, with an initial transient depolarization followed by a more sustained component (Fig. 9). This allows the AII to respond faster to a light stimulus than the presynaptic rod bipolar cell and to reach its maximum amplitude more rapidly. In fact, at the peak of the AII response, the rod bipolar response is one-third of its maximum amplitude (see Fig. 9). The AII cell also repolarizes at a faster rate (4). The transient nature of the AII light response is unexpected because both presynaptic RBC (39) and rod photoreceptors generate slow sustained responses. This leads to the conclusion that the change from a sustained to a transient signal originates in the AII and serves to quicken rod signals relayed to the inner retina (4). What underlying mechanism accounts for the change in response kinetics? This question was answered in a recent paper by Singer and Diamond (37). They examined the RBC/AII synapse using dual patch clamp techniques in rat retinal slices. The transient component of the AII response was not attributable to feedback inhibition onto RBC or to postsynaptic AMPA receptor desensitization, because it was present when either picrotoxin or

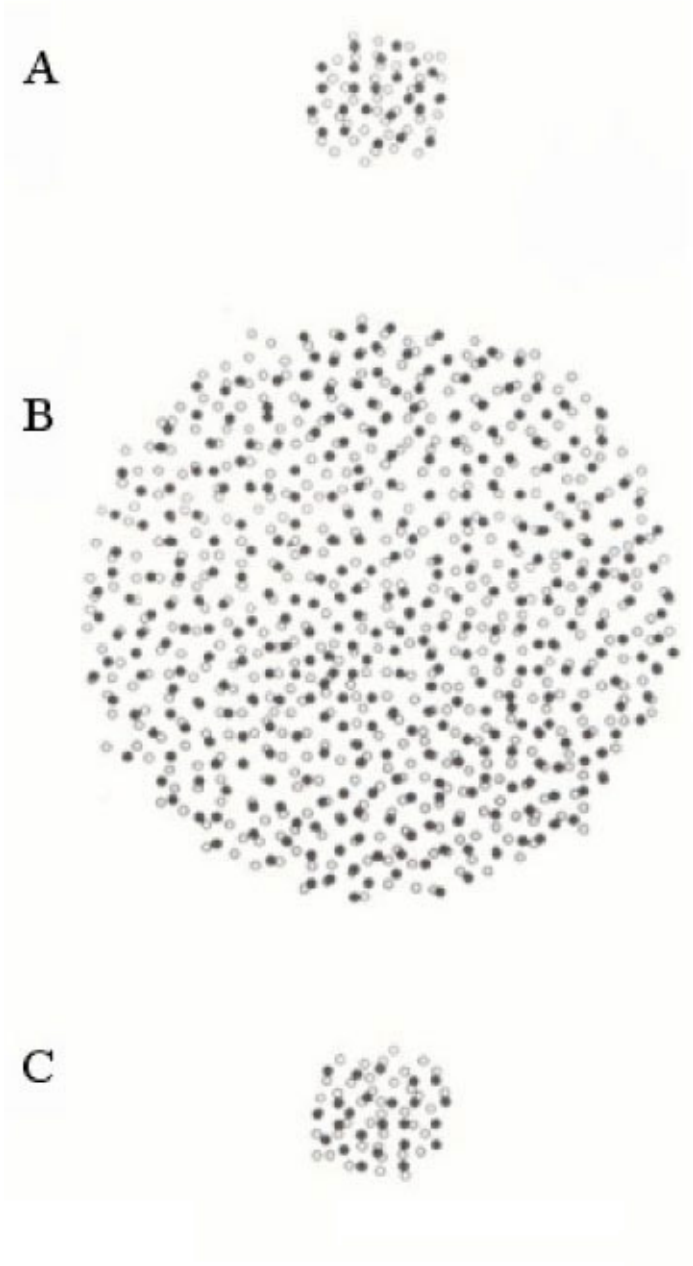

Figure 5b. Coupling between AII cells changes with the level of illumination. In dark-adapted (starlight/scotopic) rabbit retinas (A), only a small number of AII amacrine cells are coupled. Retinas that are light adapted at low/mesopic/twilight intensities (B) display the greatest degree of AII coupling. When light-adapted at the cone threshold/daylight (C), the extent of AII/AII coupling decreases to a value similar to (A). These observed changes in AII/AII coupling reflect changes in the diameter of the receptive field center. Overall coupling between AII/ON-cone bipolar cells did not vary with light level (65).

cyclothiazide was applied. However, the EPSC waveform did vary with calcium influx into the presynaptic terminal, suggesting that activation of calcium channels limits the rate of exocytosis. The authors conclude that the initial transient component of the AII light response is due to the rapid rate of neurotransmitter release from RBC terminals coupled to the fast kinetics of postsynaptic AMPA receptors (37).

Generation of the OFF-Surround Response

In the initial physiological characterization of AIIs, surround responses were only identified in some cells (4). Subsequently, it was shown that the antagonistic surround is present only when cells are dark adapted (46, 68). A

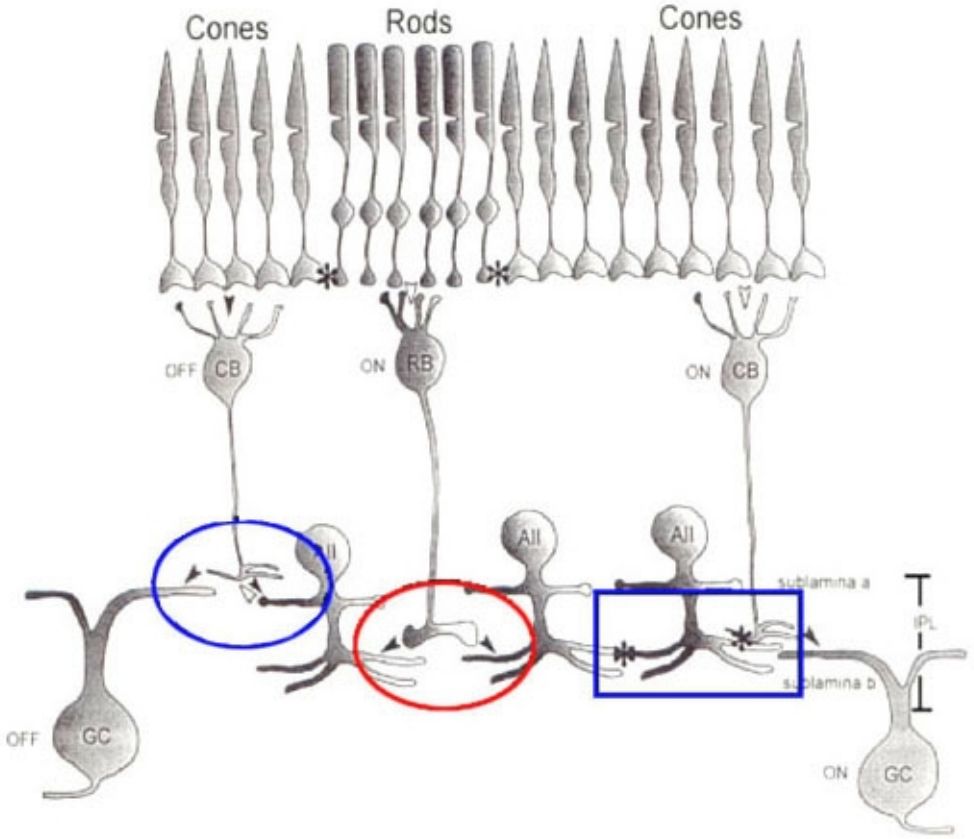

Figure 6. The AII has synaptic contacts throughout the inner plexiform layer (IPL), including synapses with both rod (RB) and cone bipolar (CB) cell types. AII cell processes are postsynaptic to rod bipolar terminals in sublamina b (red circle). In this region, the terminal dendrites also participate in gap junctions (*, blue rectangle) with other AII cells and with ON-CB. In sublamina a, AII cells form synapses (often reciprocal) with OFF-CBC processes (blue circle). GC, ganglion cell; ON, ON-center; OFF, OFF-center. Open arrowheads indicate sign-inverting synapses; filled arrowheads indicate sign-conserving synapses. From Xin and Bloomfield (68).

reasonable hypothesis, given AII morphology, would be that the surround is generated through connections between AII cells and OFF-CBC, because this synapse would be functioning in dark-adapted conditions. However, the surround response is blocked by CNQX (consistent with a role for OFF-CBC) and is also blocked by APB, suggesting that the surround originates at rod bipolar synapse(s) in the IPL (sublamina **b**), although RBC themselves do not display center/surround organization (46, 68).

Two pathways have been proposed to account for the circuitry underlying the OFF-surround response (Fig. 10). First, another amacrine cell may synapse directly with and provide inhibitory inputs to AII distal dendrites, as suggested by anatomical studies. Second, inhibitory feedback synapses onto RBC terminals from A17 amacrine cells may generate surround responses (46, 88). Recent evidence favors this latter pathway, which is summarized below (Fig. 10).

The A17 amacrine cell in cat, rat, and monkey is equivalent to the S1/S2 indolamine-accumulating amacrine cell in rabbit (32). This cell, like the AII, is rod driven (89) and transmission from RBC to A17 cells in rat is blocked by CNQX (90). In other species, however, immunocytochemical studies have identified metabotropic glutamate receptors (91) and GluR1/2 receptor subunits (43, 44) on A17 dendrites. These findings suggest that information flow across the RBC dyad may be mediated by several different glutamatergic mechanisms (43, 44). Cat A17 cells display a sustained light response and lack an antagonistic surround (89), whereas center-surround antagonism has been reported for rat A17 cells (92).

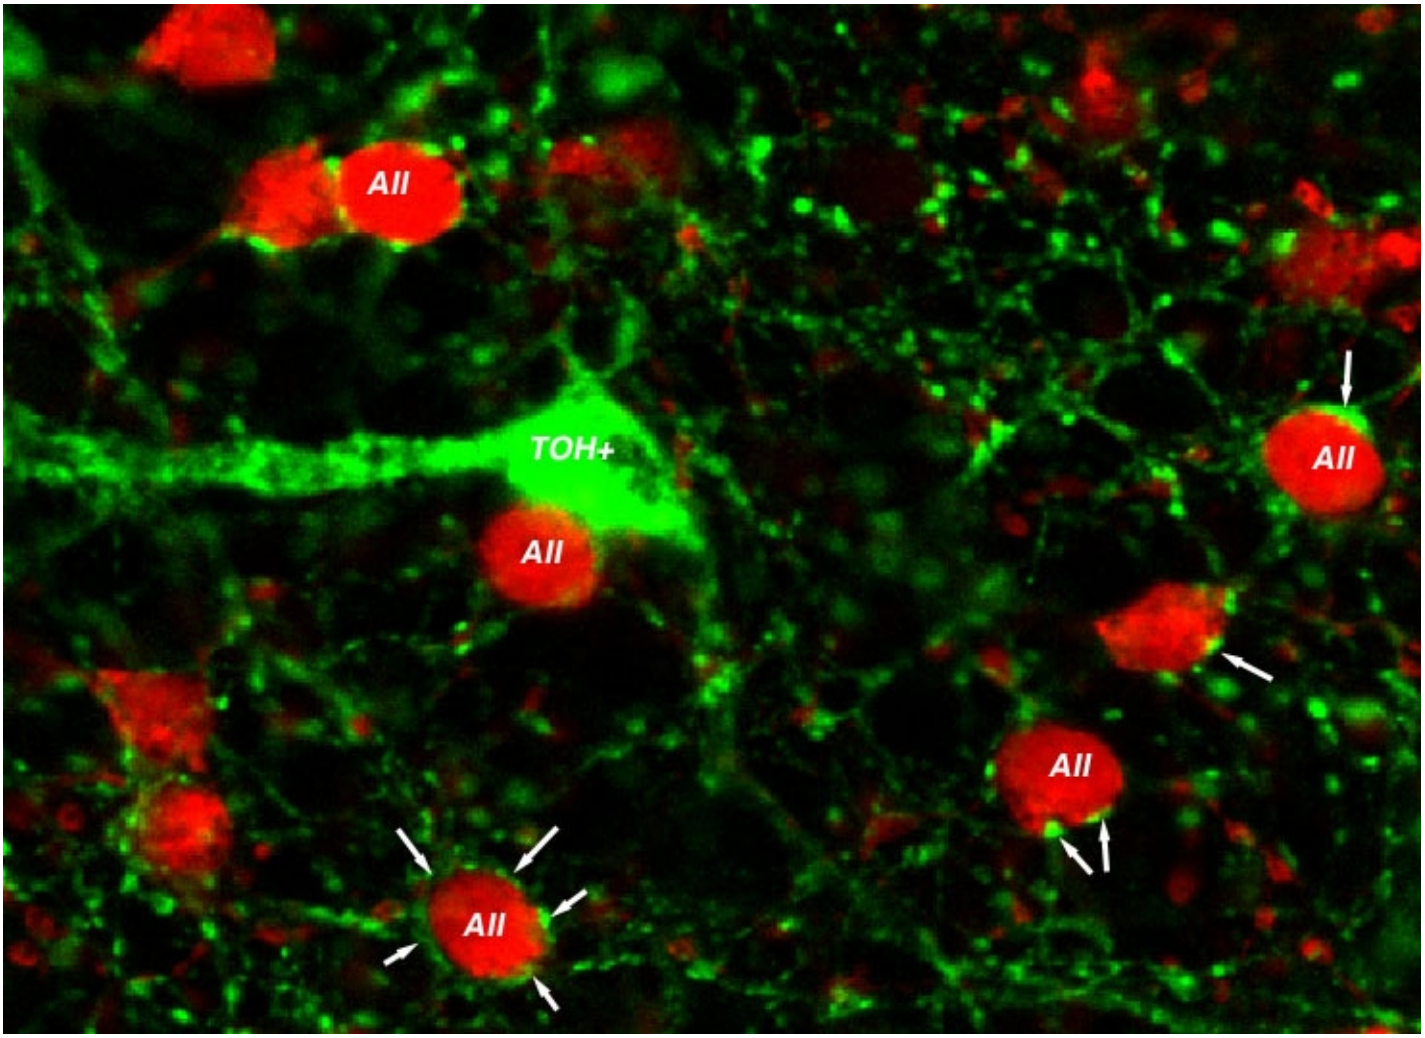

Figure 7. A dopaminergic amacrine cell immunolabeled for tyrosine hydroxylase TOH+ (TOH+green) has fine terminal dendrite "rings" that surround AII amacrine cell bodies (red, AII) in S1 of the IPL. Courtesy of Nicolas Cuenca.

A17 and S1/S2 amacrine cells make reciprocal contacts onto RBC terminals. A17 cells contain GABA (26, 28, 31, 93) and inhibit RBC through the activation of $GABA_C$ receptors (33, 94). This GABAergic feedback is modulated by light intensity; the activation of $GABA_A$ receptors (94) also present on rod bipolar terminals (29, 30, 88, 95, 96), and the activation of presynaptic mGluR1/5 receptors (95). Physiologically, this feedback changes rod bipolar responses, making the scotopic b-wave more transient (94), and may be involved in altering calcium currents in RBC terminals (97), ultimately modifying glutamate release contributing to the surround mechanism in both ganglion cells (98) and AII amacrine cells (88).

In cat, the A17 cell is always the other member of the postsynaptic dyad with AII amacrine distal processes, although other amacrine cell types also receive inputs from rod bipolar cells (74). In contrast, in rabbit, either the S1 or the S2 indolamine-accumulating amacrine cell could partner with the AII at the dyad. Why is this synapse more complex in rabbit? The answer can be found in the differences in morphology and coupling extent between these two cell types. S1 cells are wide-field amacrine cells that display extensive coupling with other S1 cells (i.e., up to ~130 cells coupled), whereas S2 cells are smaller and not as extensively coupled (maximum of 35 cells coupled) (44). These differences suggest that S1 cells provide a wide-field component to the AII surround response, whereas S2 cells provide inputs from a more local circuit (33, 44).

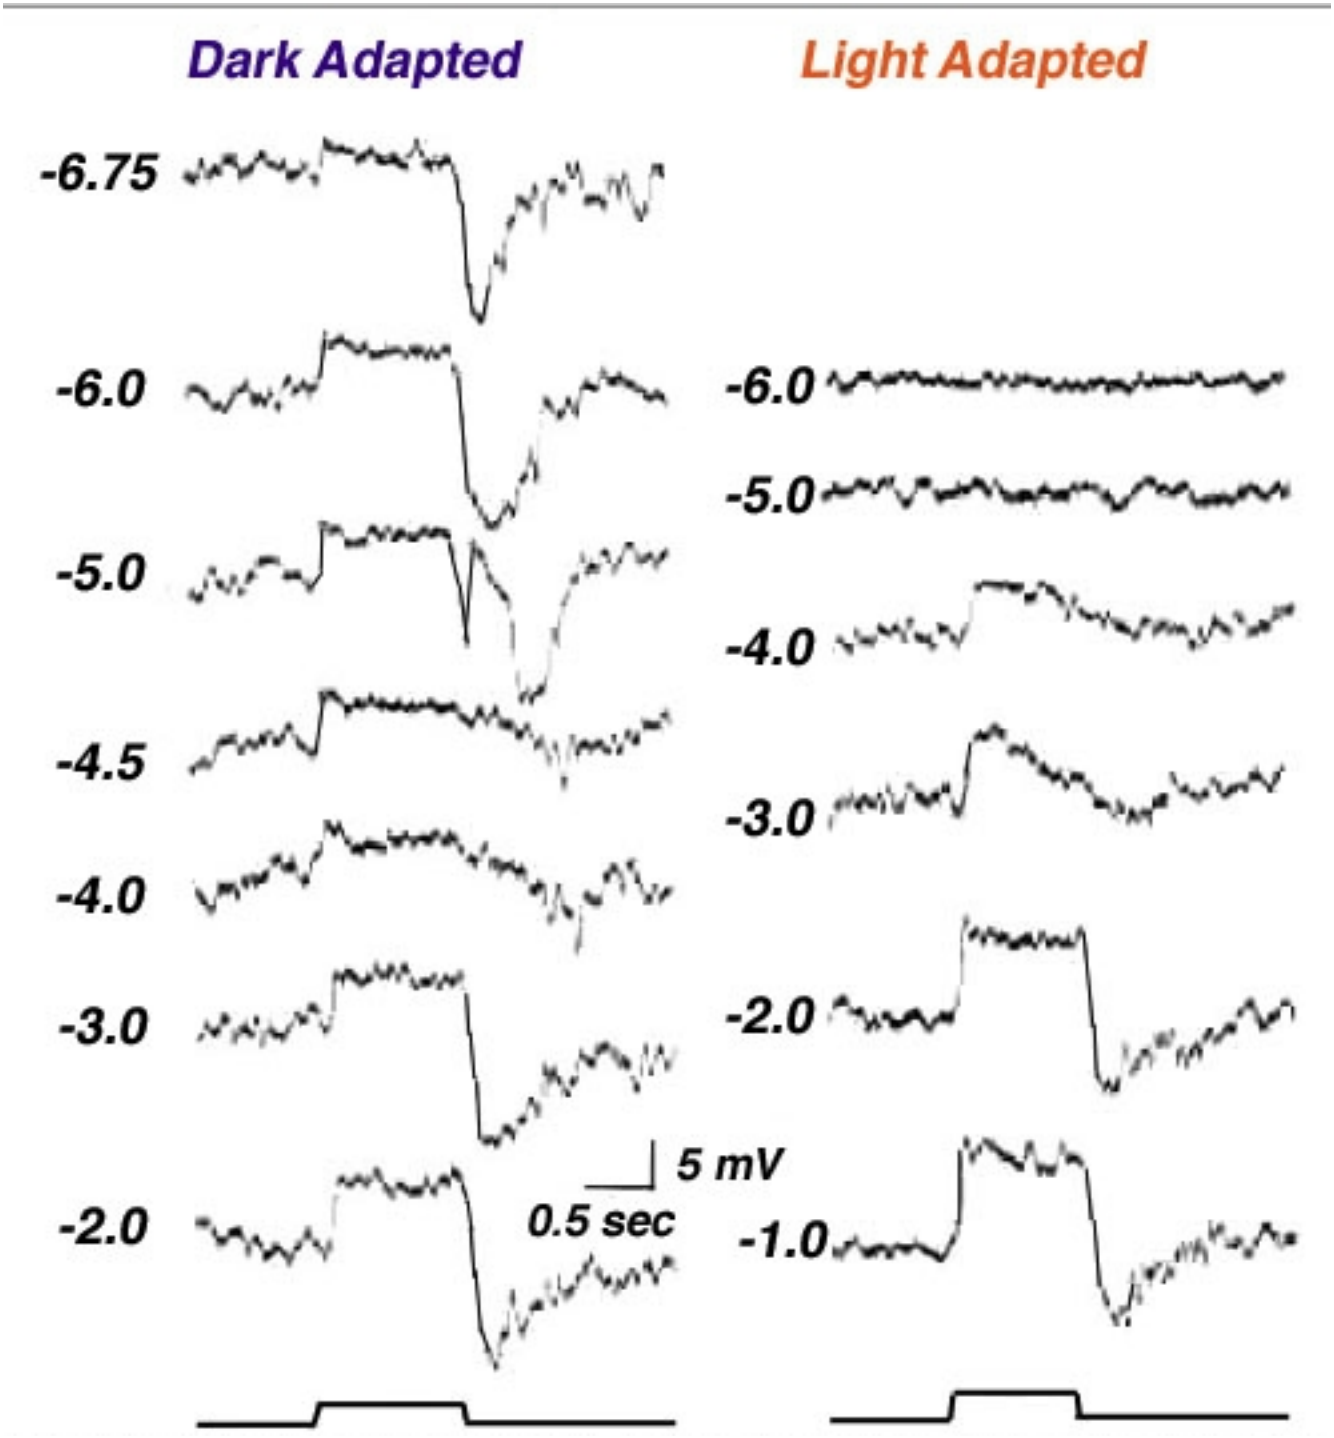

Figure 8a. In dark-adapted conditions (A, left), an ON-center response was recorded at all light intensities tested (threshold = log -6.75). The amplitude of the ON-center response increased with increasing light intensity until saturation at ~ log -4.5 to log -4.0. An ON-center response was also recorded from light-adapted cells (A, right), although the threshold under these conditions was higher (~ log -4.0). The light-adapted ON-center response also increased with increasing light intensity but reached saturation (log -1.0 to 0.0) at a higher light intensity than dark-adapted AIIs. From Xin and Bloomfield (68).

Role in Duplex Vision

The AII amacrine is the place where rod and cone pathways, as well as ON- and OFF-pathways, cross. It is central to scotopic (night) vision. The complex physiology of AII cells is paralleled by their diffuse morphology:

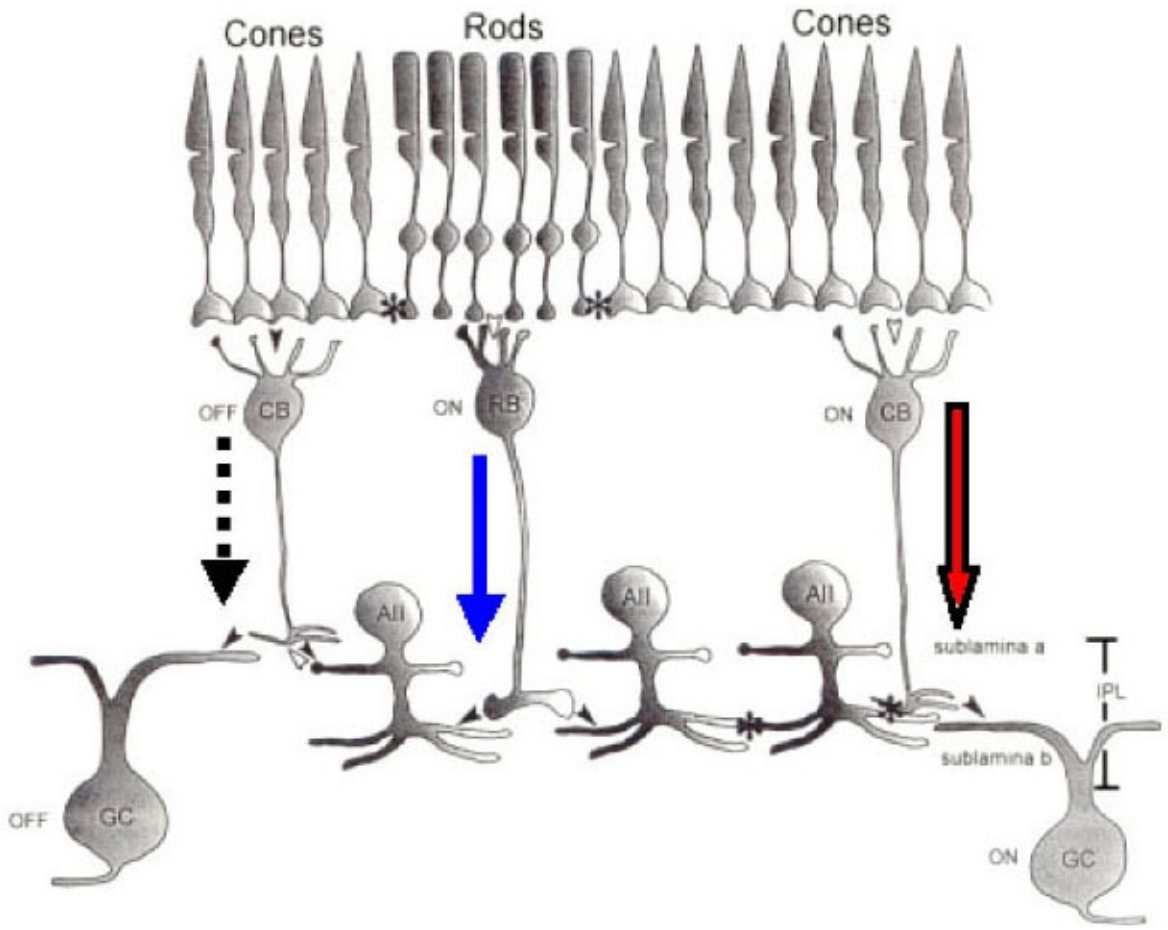

Figure 8b. Schematic diagram showing the circuitry underlying AII ON-center responses. In dark-adapted conditions, the scotopic ON-center response results from direct glutamatergic inputs from rod bipolar cells (RB) (blue arrow). In contrast, cone-driven ON-center responses occur as AIIs are depolarized by signals relayed through AII/ON-CB gap junctions (red arrow). Both of these inputs occur onto the distal dendrites in sublamina b. Light-adapted AIIs also display a small, transient OFF-center responses due to direct inputs from OFF-CB onto lobular appendages in sublamina a (dashed arrow). The ON- and OFF-center responses of light-adapted AII cells are generated simultaneously. From Xin and Bloomfield (68).

their processes are located throughout the IPL, and synapses have been observed within all strata (i.e., chemical synapses in s1, s2, and s5; electrical synapses in s3, s4, and s5). Because of these connections and the parallel retinal pathways, AII amacrine cells always receive inputs, providing the inner retina with a sustained inhibitory pathway (35).

Within the rod pathway (or scotopic levels of light), the light-stimulated decrease in rod photoreceptor glutamate release depolarizes rod bipolar cells, in turn causing the release of glutamate from rod bipolar terminals onto the postsynaptic dyad elements—the indolamine-accumulating or the A17 amacrine cell and the AII amacrine cell. Glutamate excites the AII, resulting in three simultaneous synaptic events: 1) the release of glycine onto OFF-CBC, ultimately inhibiting OFF-ganglion cells; 2) the depolarization of ON-CBC (via AII/ON-CBC gap junctions) and the subsequent depolarization of ON-ganglion cells; and 3) and increase in signal-to-noise ratio due to the spread of the signal among the coupled AII network. In addition, cat, monkey, and rat AII cells synapse directly onto OFF-ganglion cells, resulting in direct glycinergic inhibition of these cells (76, 99). AII responses are modified by inhibitory inputs from depolarized A17 (S1/S2) cells, which feed back onto rod bipolar terminals. The overall effect is inhibition of the OFF-pathway and excitation in the ON-pathway, both by rod-driven signals.

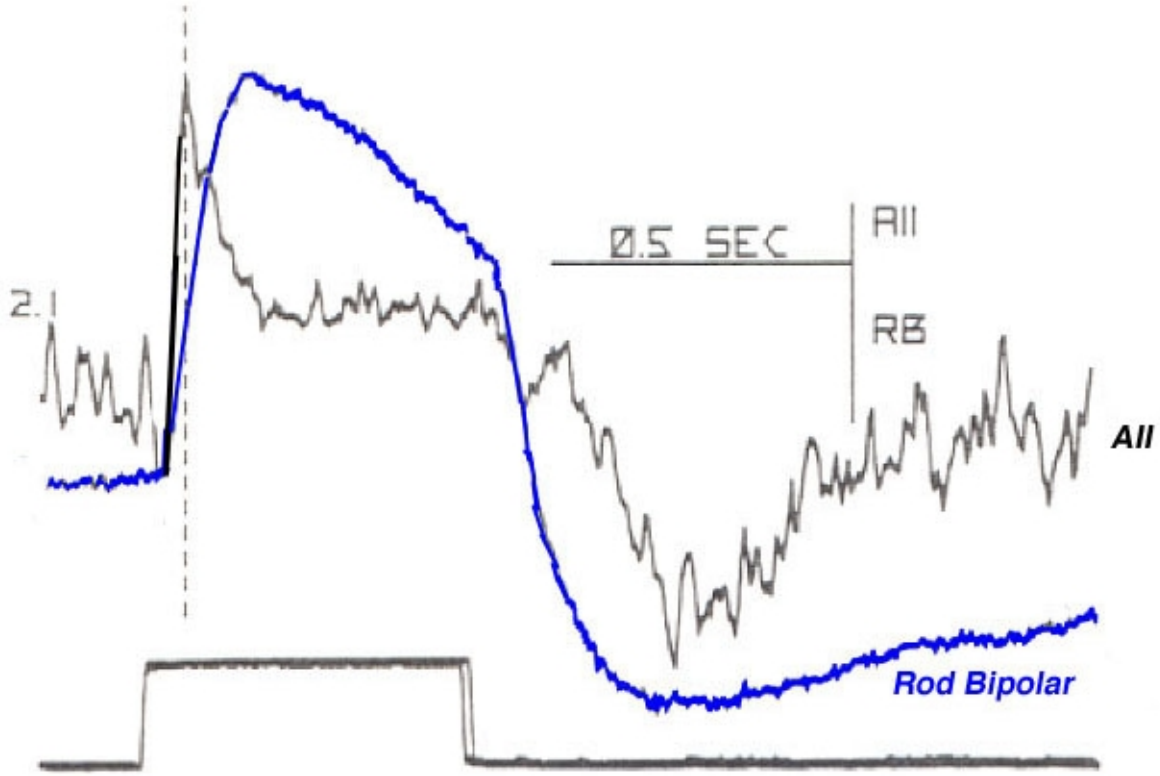

Figure 9. The waveform of the AII amacrine cell reaches its maximum amplitude more rapidly than the presynaptic rod bipolar cell. At the peak of the AII cell's response, the response of the rod bipolar is only one-third of its maximum amplitude. Trace at bottom indicates the duration of the light stimulus. From Nelson (4).

In bright light (photopic) conditions, ON- and OFF-center responses have been recorded from AII cells (68). Both responses are generated via inputs from CBC, with the transient OFF-center response arising from glutamatergic inputs from OFF-CBC and the ON-response arising from transmission through ON-CBC/AII gap junctions. Although both ON- and OFF-responses may be found in the same AII cell, the ON-center response predominates. These inputs from ON-CBC depolarize the AII cells, causing glycinergic inhibition of OFF-CBC and OFF-ganglion cells (99). In addition, under bright light conditions, coupling within the AII network is reduced, preventing the dissipation of cone signals before reaching the ganglion cells. The overall result, again, is that the OFF-pathway is inhibited by the ON-pathway, while high-acuity cone signals are maintained. In this way, the AII mixes not only rod and cone signals but ON- and OFF-pathways as well.

Thus, the inclusion of the AII in the rod circuit (scotopic conditions) is required for the vertical flow of information within the IPL, because it functions to amplify the signal, increase transience, and reduce noise before reaching the ganglion cells. In cone-driven circuits, inputs from ON-CBCs directly stimulate AIIs and ON-ganglion cells. The AII response is a depolarization, with robust ON-center response, resulting in glycine release and the inhibition of OFF-type responses. These glycinergic inputs to postsynaptic CBC and/or ganglion cells allow ON-signals to predominate in the inner retina under these conditions. Thus, AII is always receiving inputs, although the type of input varies (depending on stimulus intensity), causing the AII cell to "shift its focus" from one input pathway to another and from one function to another.

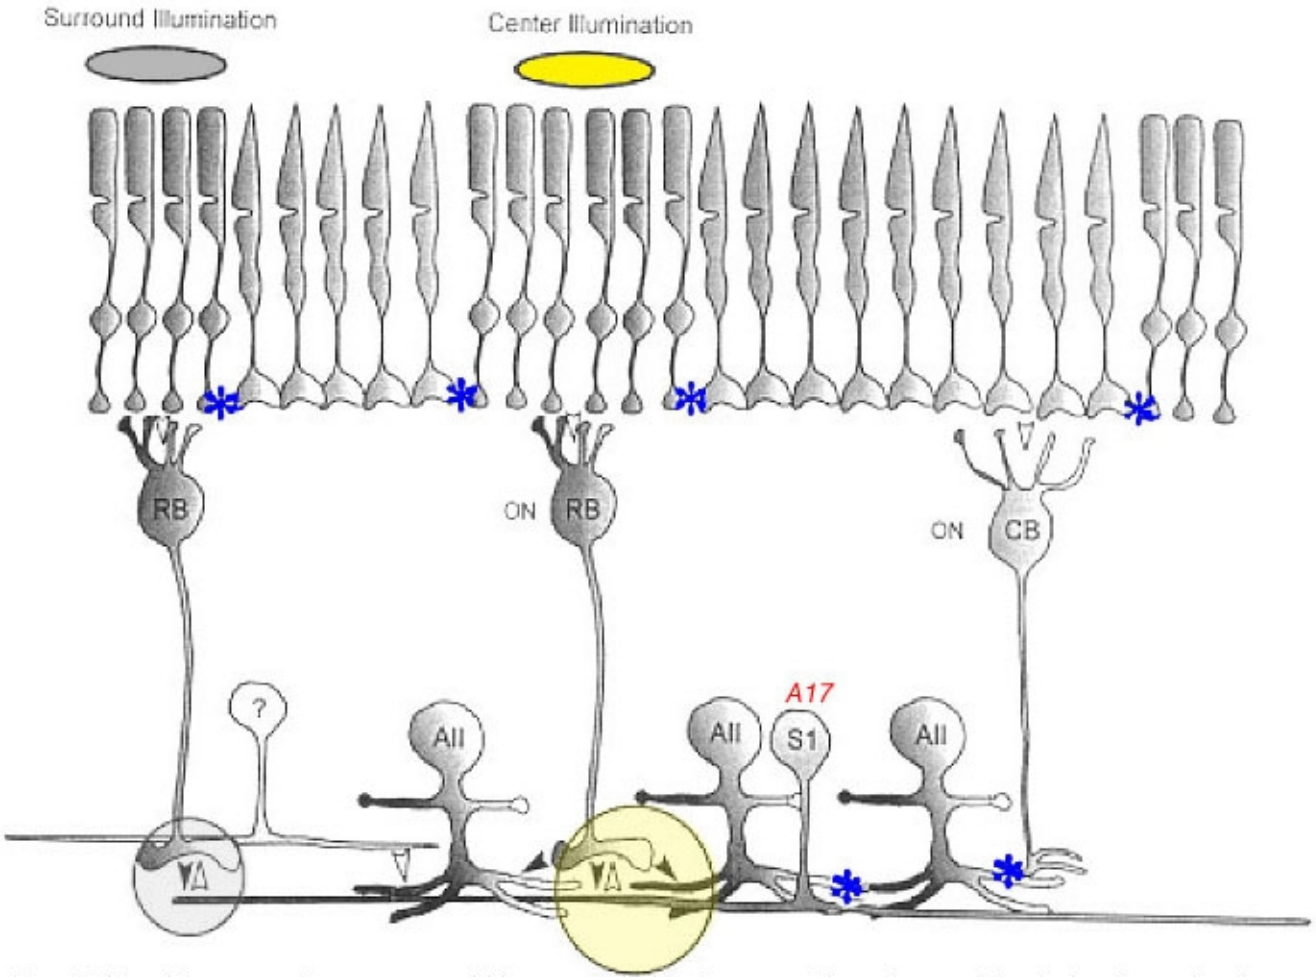

Figure 10. The AII surround response could be generated by two possible pathways. The first pathway involves direct inputs from a GABAergic amacrine cell (labeled with a "?") presynaptic to the distal dendrites in sublamina b. These synapses have been described in many species, although the specific presynaptic cell has not been identified. The second pathway involves an indolamine-accumulating amacrine cell (S1, A17 in cat), which releases GABA at reciprocal synapses onto rod bipolar (RB) terminals. In this diagram, presentation of a light stimulus in the surround region of the AII cell's receptive field (gray circle, left) depolarizes the rod bipolar cell, leading to a release of glutamate onto the process of an S1 amacrine cell (gray circle to the left). The depolarizing signal is transmitted centrally, where the S1 process (yellow circle) releases GABA onto the rod bipolar terminal. GABA inhibition of the rod bipolar cell reduces subsequent release of glutamate onto the AII cell. Experiments suggest that it is the pathway involving the S1 cell that generates the AII surround response. From Bloomfield and Xin (46).

Midget pathways of the primate retina underlie resolution and red green color opponency

Helga Kolb, PhD[1]

Created: May 24, 2007; Updated: April 4, 2012.

1 General characteristics

The specialized cone pathways of the central fovea of human and monkey retinas have the least convergence and the greatest resolution capabilities of the visual system. This is accomplished by making the connections as "private" as possible and narrowing them to a one to one relationship in the so-called midget pathways. Figure 1 shows an older drawing from Polyak's book (1) that shows the very narrowest field bipolars and ganglion cells of the fovea.

The midget pathways consist of midget bipolar cells and midget ganglion cells, the latter of which project to individual parvocellular layer cells of the lateral geniculate nucleus in the brain. Because of the need for the high acuity midget pathways also to be organized into ON- and OFF-center channels like the diffuse cone pathways for maximization of contrast, it means that every cone of the fovea will have dual midget pathways. The two midget bipolars will be an ON-center type and an OFF-center type and will connect with ON-center and OFF-center midget ganglion cells respectively. Because midget bipolar/ganglion cell circuits are devoted to a single cone, and the individual cones are of different spectral type maximally excited by short (S-cone/blue), medium (M-cone/green) or long (L-cone/red) wavelengths, they must carry sensitivity information about one wavelength. Thus the midget system concerned with the M- and L-cones in particular are considered also to carry L- or M-signals to the brain where further processing takes place to allow us the red and green discriminations of color vision.

The S-cone system is rather different from the M- and L-cone systems from the initial level of the cone itself to its circuitry though the retina and into the brain. We do not consider the S-cone pathway as a midget pathway (see later chapter on S-cone pathways). So this chapter is devoted to the M- and L-midget pathways and as we shall see, they carry both a resolution and a chromatic message through the retina to the brain.

2 Visual acuity starts with cone spacing and midget circuitry

Visual acuity is a measure of our ability to discriminate the finest detail: either by discriminating two parallel lines apart (Vernier acuity) or two tiny spots or stars apart (point discrimination). The primate and human visual system is capable of acuity of 1 min of arc or 60 cycles/degree of visual angle. One degree of visual angle is thought to cover approximately 280-300 um of retinal distance (2). The area of the retina where the cone photoreceptors are most closely packed in a more or less hexagonal array, is, of course, the center of the fovea and is about one degree across (Fig. 2). So visual discrimination of 1 min of arc is about the center to center spacing (3 μm) of the cones of the central mosaic in the foveola (Fig. 3).

If the minimum center to center spacing (a) is 3 μm for the cones of the fovea, then the grating resolution limit, known as the Nyquist limit, is $a\sqrt{3}$, about 1 min of arc. One may ask why the grating resolution is not better than 1 min of arc and the size of, or even less than the diameter of each cone, i.e. a or $< a$. For these narrower gratings, the spatial interference of the packed cones would apparently cause Moire effects, or aliasing, if line separations of less than $a\sqrt{3}$ are used, as shown below (3) (Fig. 4). These interference patterns, with a repeat length that

Corresponding author.

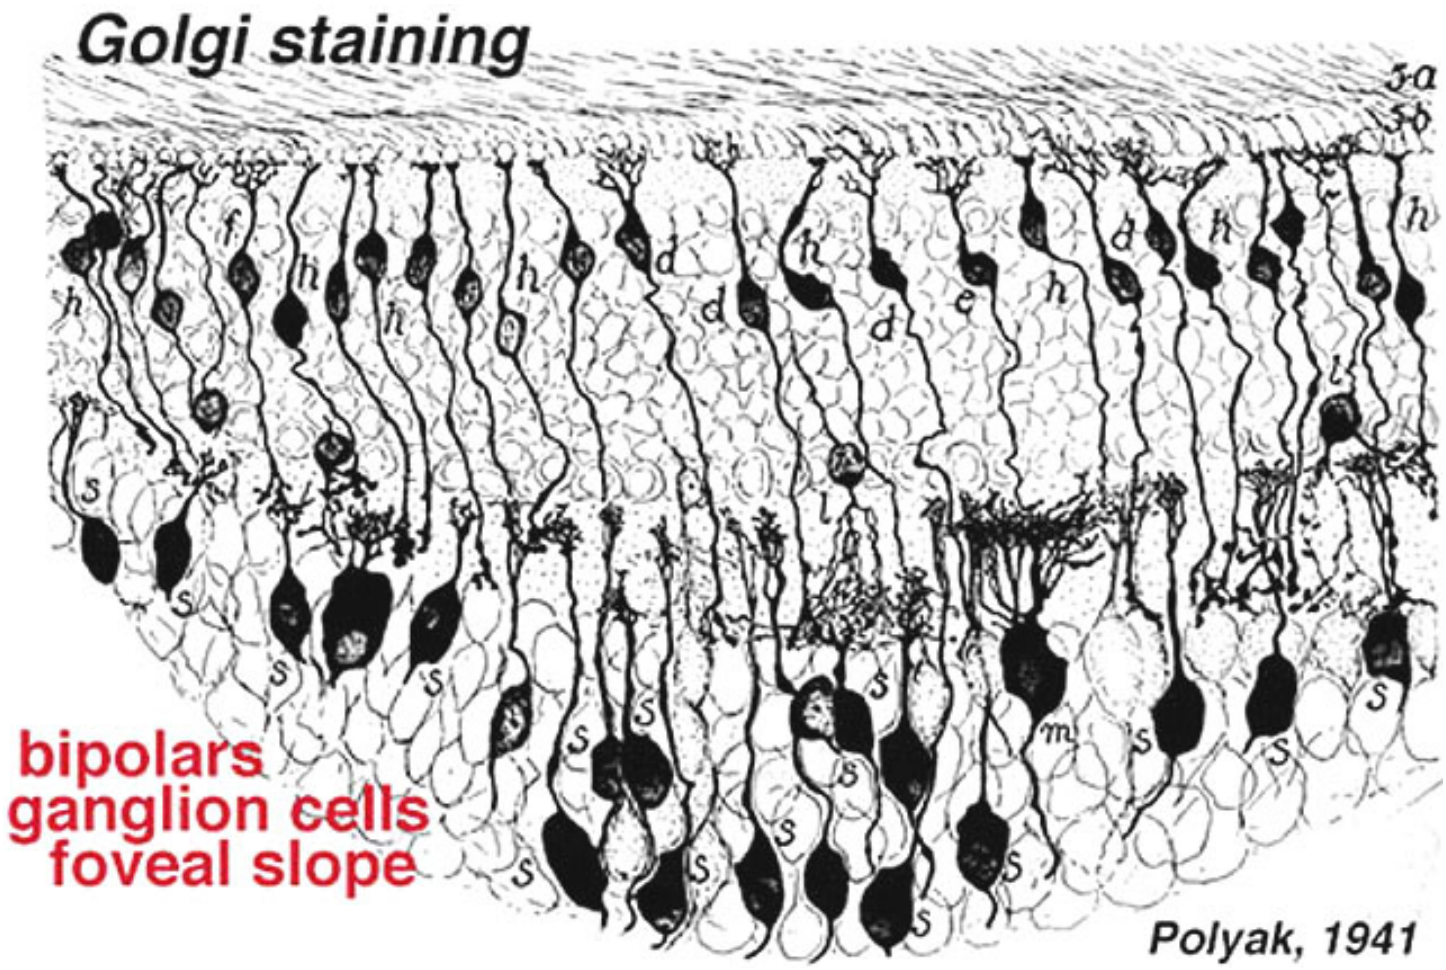

Figure 1. Polyak's drawing of bipolar and ganglion cells in the foveal slope of the monkey retina. The illustration is taken from Polyak, 1941 (1).

depends on the angle that the grating makes with the cone mosaic, make it impossible to determine the wavelength of the grating. It turns out that under normal conditions, the optics of the eye do not sharply image gratings of greater than 60 cycles/degree (4). The optical blur of the eye minimizes Moire effects in spatial sampling (Fig. 4).

The image is also blurred by the optics of the eye to project onto about 10 cones (Fig. 4). Lateral shifts of this image can then be compared over these 10 cones and their midget chains of neurons for later computation in the brain. This allows better discrimination (resolution) because of the possibility of imposing antagonism from neighboring cone systems, i.e. surrounds on the pathways and increasing contrast and discrimination between the several midget-single-cone originating pathways (5).

We know that three classes of cone comprise the cone foveal mosaic, but we have long been curious as to how the three different spectral types of cone are arranged in the hexagonal mosaic. The S-cones (blue cones) are fairly easily picked out from the L-cones (red cones) and M-cone (green cones) on some distinguishing morphological features (see chapter on S-cone pathways). In fact the S-cones are seen as the larger profiles disrupting the hexagonal mosaic in the wholemount view of the foveal mosaic of Figure 2 (arrows point to S-cones). In the foveal region of the cone mosaic S-cones form from 8-12% of the cones (6). The very center of the foveal pit is almost devoid of S-cones. So the remainder of the cones are somehow divided into the L- and M-cone populations. In the human fovea, psychophysical measurements have suggested that red cones outnumber green by 2:1 (7). However, direct measurements by microspectrophotometry of all cones in small patches of

cones in the fovea of monkeys, has revealed that red and green cones occur in about equal proportion (Fig. 5) (8). Roorda and Williams (9) made direct measurements of spectral sensitivity of foveal cones in the living human eye by a sophisticated technique of adaptive optics to increase spatial resolution. They found that humans varied greatly in their proportions of red cones to green cones: some individuals have almost equal proportions while others have a higher proportion of red cones, to the extreme of 2 red cones to every green cone. The red and green cones lie randomly in the mosaic meaning that clusters of cones of the same spectral type will occur together as illustrated in figure 5 from Mollon and Bowmaker's paper. An interesting point can be deduced from these findings. It does appear possible then, that a multiheaded midget or diffuse cone bipolar with a small dendritic tree, could contact all the same spectral type of cones in the primate fovea.

3. Cone to midget bipolar cell connections

Polyak (Fig. 6) had already described two types of midget ganglion cell in the primate retina in 1941 (1). He had studied and drawn ganglion cells from vertical sections of Golgi-stained monkey retina and noticed that the midget ganglion cells in particular (although it is also true of the small and large parasol ganglion cells) had dendrites branching at one of two levels in the IPL: close to the ganglion cell bodies (the area we now know as sublamina b) or in neuropil close to the amacrine cell bodies (the area we now know as sublamina a). He had also drawn and remarked on the fact that midget bipolar cells came in long and short axon varieties to fit the two midget ganglion cell varieties (Fig. 7) (1)).

The important distinction between two types of midget bipolar cell was not made until an electron microscope study was able to show differences in their synaptic contacts with the cone pedicle (10). Thus, invaginating midget bipolar cells (imb) were found to connect with cone pedicles at central elements, invaginating synapses at the cone pedicle ribbons (Fig. 8 and Fig. 9). Flat midget bipolar cells connect to cone pedicles at wide-cleft, basal junctions (fmb), most often on either side of the invaginating dendrite of the imb (Fig. 8 and Fig. 10).

4. Midget ganglion cells

Viewing Golgi stained whole-mount primate retinas has been particularly helpful in revealing the differences between the three ganglion cell types that are involved with spatial and color vision: namely the midget ganglion cells, the blue/yellow ganglion cells and the parasol ganglion cells (1, 11, 12). The midget ganglion cells are thought to be high acuity cells that also carry a red or green color specific signal. They project to the parvocellular layers of the lateral geniculate nucleus and are thus called P cells (Fig. 11) (13). Midget ganglion cells come in high branching varieties that are probably OFF-center physiologically and low branching types that are ON-center physiologically. Movie 1 is a through focus series of an ON and OFF midget pair in human retina.

Figure 11 shows two midget ganglion cells in comparison with a parasol ganglion cell (M cell) of peripheral human retina. The one midget ganglion cell has an 18 μm diameter dendritic tree and the other has a larger dendritic field at 35 μm in diameter. The movie above shows that the midget ganglion cell with the smaller dendritic field comes into focus at a different level from the larger field cell. The former midget ganglion cell branches high in the IPL and so is probably an OFF center type physiologically. The lower branching midget ganglion cell with the larger dendritic tree is probably an ON center type. Why the OFF center type has a smaller dendritic tree compared with ON center type remains a mystery at present but one implication may be that the midget OFF system acuity is higher in acuity than the ON system (14).

The connections between the midget bipolar and the midget ganglion cells have always been thought to be "private", i.e. one to one. Because of the similar size and branching level of the axon terminal of the bipolar cell and the dendritic arbor of the midget ganglion cell in the foveal area particularly, it has been assumed that axon terminal and dendritic field overlap and synapse, with no room for convergence from more than one bipolar axon per ganglion cell. However, the story may be different in the peripheral retina where the midget ganglion

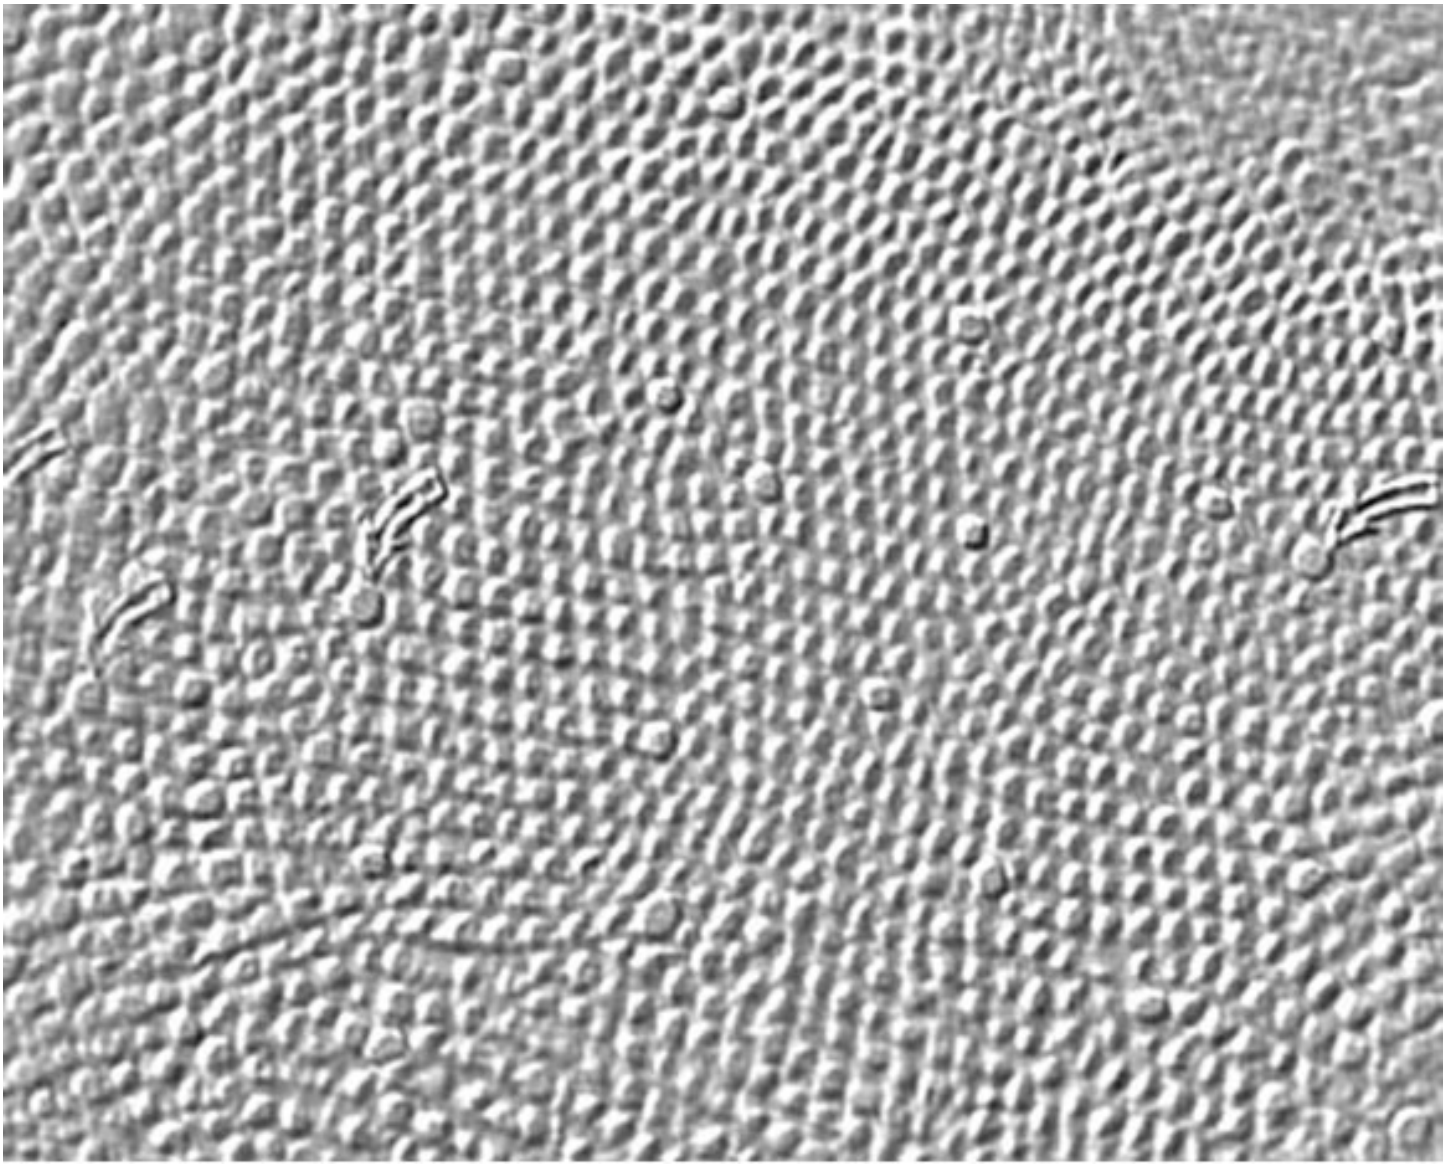

Figure 2. Tangential section through the human fovea. The larger cones (arrows) are blue cones. The illustration is taken from Ahnelt et al., 1987 (6).

cells have larger dendritic fields. Obviously more than one midget bipolar axon could fit the dendritic tree of the receiving peripheral midget ganglion cell as seen in Figure 12.

The one to one relationship was positively proven to be the case in the parafoveal area by an electron microscope study and reconstruction of serially sectioned midget ganglion cells and their input midget bipolar cell axons in parafovea, about 2 mm from the foveal pit (Fig 14) (15). More recently we have also performed a serial section electron microscope study of foveal midget bipolar axons and their connections with the dendrites of foveal midget ganglion cells (Fig. 13) (14).

The respective midget bipolar cells are almost solely synaptic upon single midget ganglion cells (Fig. 14), except in the very central fovea where a few midget bipolar synapses are shared with neighboring midget ganglion cells because of the crowding of neurons and neuropil (Fig. 13). Since we know (16) that ganglion cells branching in sublamina **a** will be OFF center and those branching in sublamina **b** will be ON center we can be sure that midget ganglion cells branching close to the amacrine cell layer will be OFF center and those branching close to the ganglion cell layer will be ON center. This ON and OFF midget ganglion cell organization in primate has

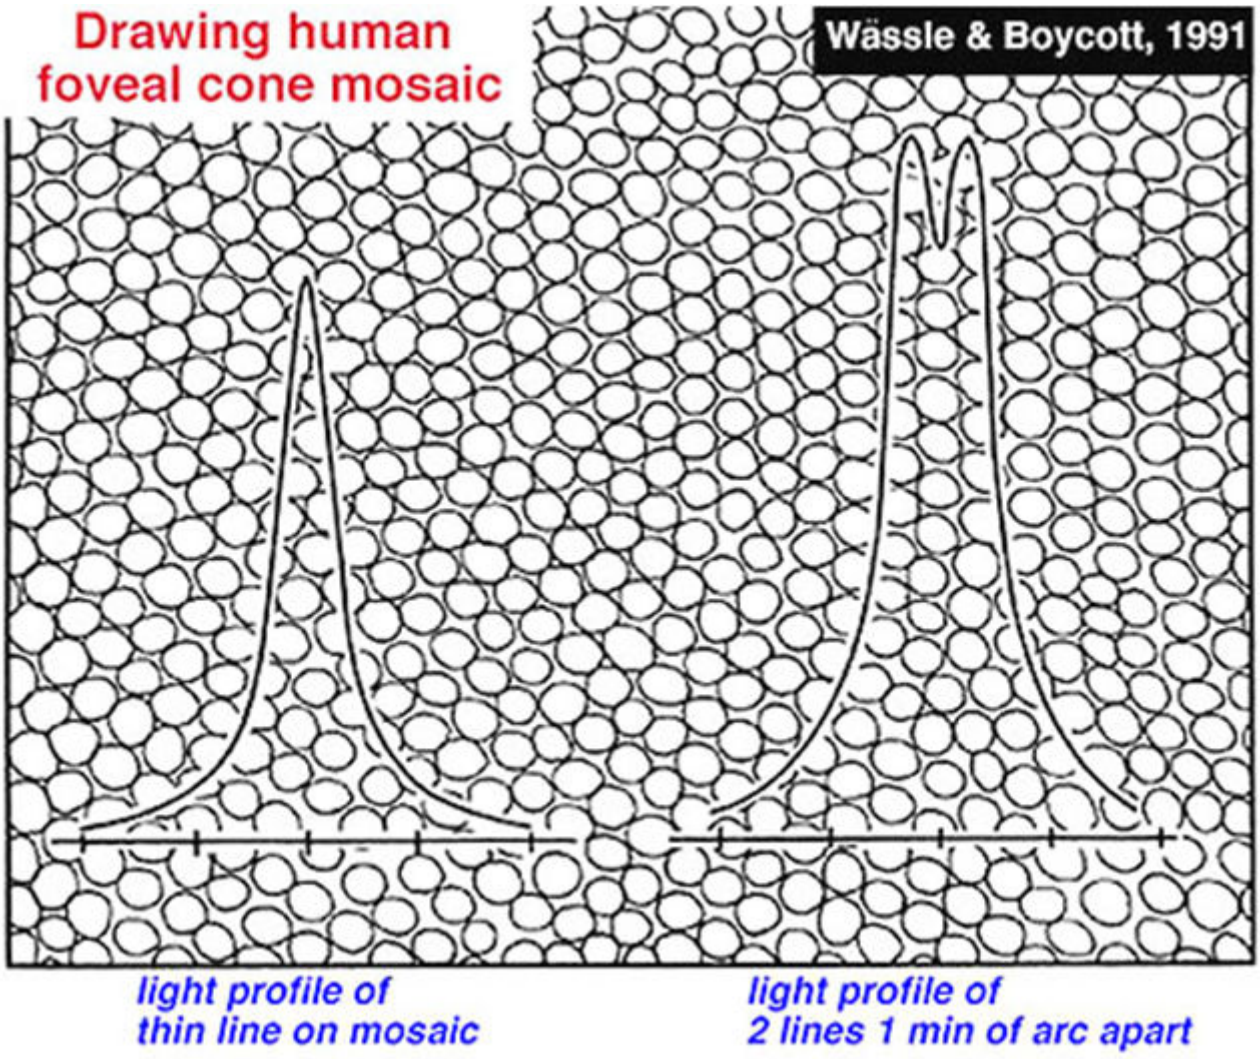

Figure 3. Human foveal cone mosaic. Visual discrimination of 1 min of arc is about the center to center spacing (3 μm) of the cones of the central mosaic in the foveola. The illustration is from Wässle and Boycott, 1991 (3).

now been shown conclusively by Chichilnisky's group (17). So it appears that in the foveal region and out to the borders of the central retina (about 4 mm from the fovea center) the midget pathways of the human fovea are organized in the following manner: 1 cone to 2 midget bipolar cells (ON- and OFF-center bipolar types) to 2 midget ganglion cells (ON- and OFF-center ganglion cell types).

What we find more difficult to say is what spectral type of cone is connected in the midget bipolar to midget ganglion cell chain. M- and L-cones are indistinguishable anatomically. Where we can recognize S-cone (blue) pedicles on unusual morphological features (6, 18, 19) (see chapter on S-cone pathways), the M- and L-cones look the same. There is some evidence that M- and L-connected midget bipolar cells have different numbers of synaptic ribbons associated with their axons and therefore different quantities of output sites to their midget ganglion cell in the fovea (20): but which axon terminal/ganglion cell pair is associated with M- or L-cone pathways is still a moot question.

Four to five millimetres beyond the fovea, in near periphery, the midget bipolar cells become 2- and 3-headed, connecting to 2 and 3 cones respectively (1, 12, 21). Midget ganglion cells are found throughout the near and mid peripheral retina (1, 12, 22, 23) and their dendritic trees increase in size but are often composed of several domains of dendrites. The further peripheral it gets, the more domains of dendrites compose the dendritic tree

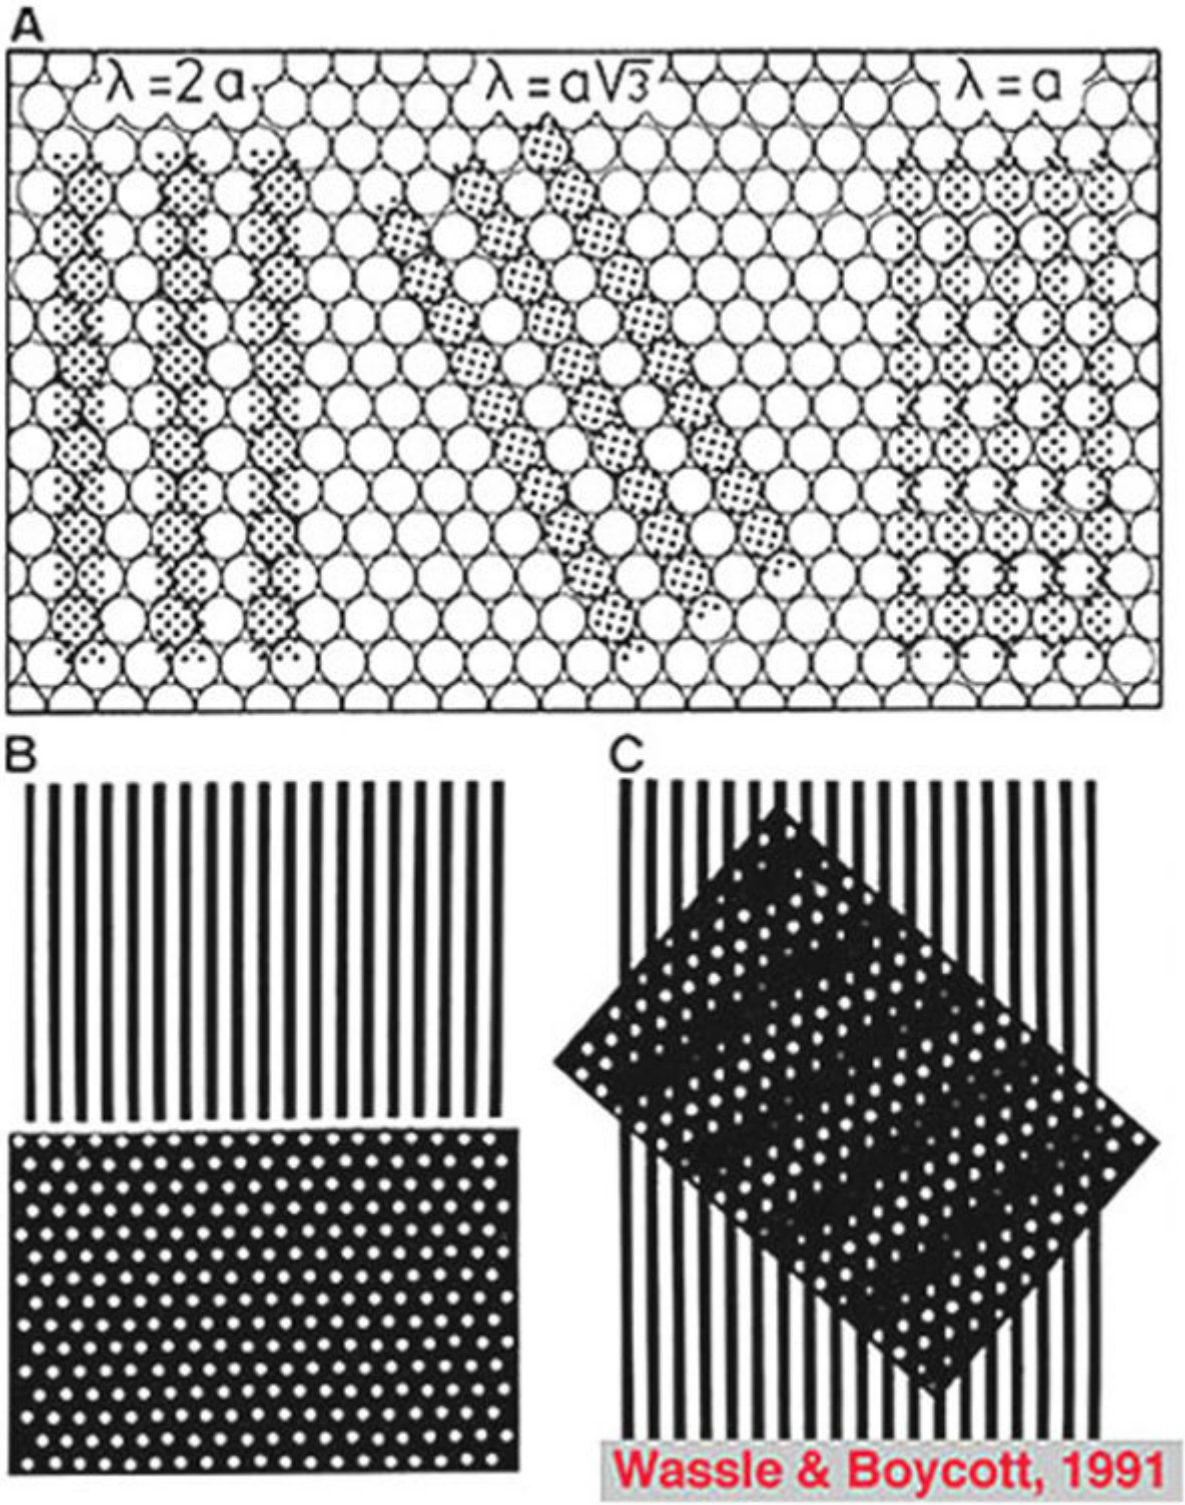

Figure 4. The minimum center to center spacing (*a*) is 3 μm for the cones of the fovea. This determines the Nyquist spatial resolution limit, a√3, approximately 1 min of arc. If the grating wavelength (λ) is less than this, Moire patterns (*B* and *C*) result which vary depending of the angle of the mosaic to the grating. Thus the grating can't be uniquely resolved. The illustration is from Wässle and Boycott, 1991 (3).

of midget ganglion cells. So it seems likely, that more than one midget bipolar cell will synapse upon each midget ganglion cell, probably each bipolar occupying one of the domains of the dendritic tree.

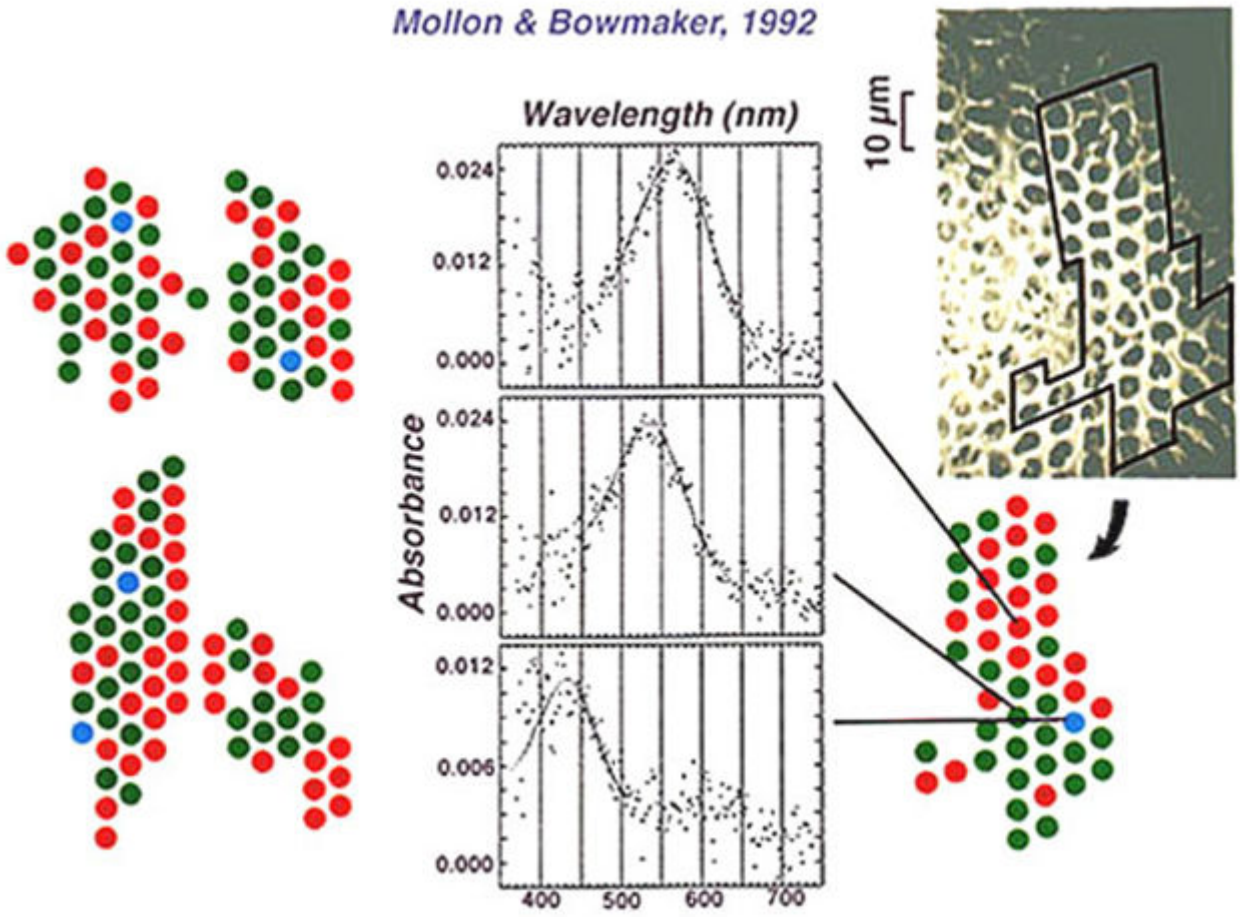

Figure 5. Absorbance spectra of three cone types as measured in foveal patches of cones in rhesus monkey. The spectral composition of these cone patches are shown. The illustration is from Mollon and Bowmaker, 1992 (8).

Serial section electron microscopy and reconstruction of axons and dendrites of midget ganglion cells at the edge of the central area (i.e. 4 mm from the foveal center) and from peripheral retina (12 mm from the foveal center) indicate that the prediction of multiple input from cones to midget bipolar cells, and multiple inputs from midget bipolar cells to midget ganglion cells is correct in peripheral retina (Fig. 15 and Fig. 16). Our estimation (14) is that 3 midget bipolar cells synapse on a single ganglion cell 4 mm from the fovea (Fig. 15) (14). Even more convergence of midget bipolar cells to midget ganglion cells occurs in far peripheral retina where we estimated at least 3 multi-headed midget bipolar cells synapse on a single midget ganglion (Fig. 16).

In the fovea where a single cone connects with its midget bipolar and midget ganglion cell system, the pathway will of necessity be carrying a single color receptive field center. Beyond the fovea where the midget pathway is 2 and 3 channeled and/or many midget bipolars have input, the midget ganglion cell's center may be a mixture of cone color types. Despite the patchy and random nature of the red and green cone mosaic and multiple midget bipolar inputs, does the midget ganglion cell retain a dominant commitment to one spectral class of cone and a color opponent center surround organization? This is in fact is what is concluded in both physiological (24-26) and the most recent functional connectivity report from Chichilnisky's group (Fig. 17) (17). Figure 17 shows the results of midget ganglion cell measurements with multielectrode recordings and high resolution stimulation of single cone types included in these ganglion cells' receptive fields. Although both red and green cones input the cell, single spectral type of cone i.e. either red types or green types, dominate the receptive field centers (Fig. 17, white outlined, and white lines).

Figure 6. Stephen L. Polyak (1889-1955) is a major authority on the anatomy and neural organization of the primate eye.

5. Circuits underlying red and green color opponency in the human retina

Midget ganglion cells of the monkey retina (presumably also of human retina) are known to respond to light with an opponent chromatic organization in their surround (5, 27, 28) (Fig. 18). That is, midget ganglion cells of central retina, when recorded from electrophysiologically, have the smallest receptive fields, and are organized as

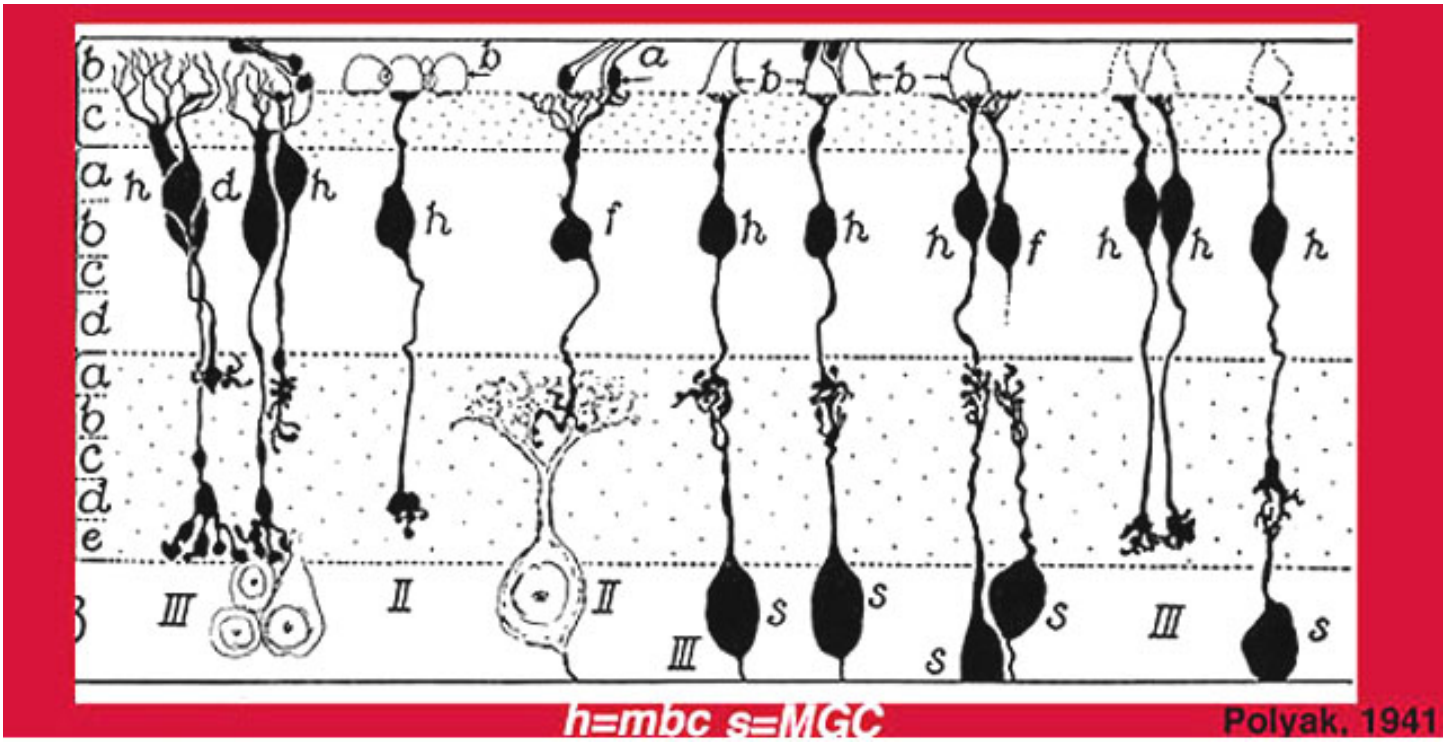

Figure 7. Drawing of Golgi-stained midget bipolar cells (h) in the monkey retina by Polyak, 1941 (1).

L-cone ON or OFF center, and M-cone ON or OFF center. Each midget ganglion cell type has a larger surround of the opposite polarity and the opponent color. The surrounds of the midget ganglion cells, as Chichilnisky's group have elegantly shown (17), That the surround is comprised of many red and green cone inputs, suggesting non-specific, but mixed spectral input to surrounds (Fig. 17e-g, black lines and circles).

The parasol varieties of ganglion cells are the non-color opponent, phasic varieties of ganglion cell recorded in the retina (28) and are also called M cells projecting to the lateral geniculate nucleus (13, 28, 29). A smaller field, tonic and not clearly color opponent ganglion cell type is also recorded in the retina and parvocellular layers of the geniculate nucleus (Fig. 18) (5). Whether these are the minority extrafoveal midget ganglion cells that are no longer color specific like some of the cells in the Field et al., study (17) remains to be seen.

The opponent color surrounds recorded in midget ganglion cells (28) provide color and spatial opponency. It appears clear now that all primate cone bipolar types have a center/surround organization (Fig. 19) (17, 30). This includes the midget bipolar cells (Fig. 19) (30). Where does this antagonistic surround organization come from?

The horizontal cells are thought to contribute to the surround response of bipolar cells in submammalian species and particularly in creatures with good color vision. Horizontal cells have been shown to be color opponent in response in fish and turtles for example (31-34). The situation is different in primate retina where color opponency has been difficult to detect in intracellular recordings of monkey horizontal cells (35) despite the anatomical findings on spectrally selective connectivity (35, 36).

However, it has recently been shown by elegant experiments in macaque monkey that red and green cones receive an antagonistic surround response from horizontal cells, presumably HI cells (37). Similarly, primate (blue) S-cones clearly have an opponent yellow surround that appears to come from horizontal cells driven by L- and M-cones according to Packer and co-authors (38). Very recent evidence from the same group (39) indicates quite definitively that horizontal cell feedback can account for surround opponency to red and green midget ganglion cells in primate retina, showing that the midget bipolar cells are already color opponent in nature. There does not appear to be any inner retina (amacrine cell) input to organize surrounds in midget bipolar cells

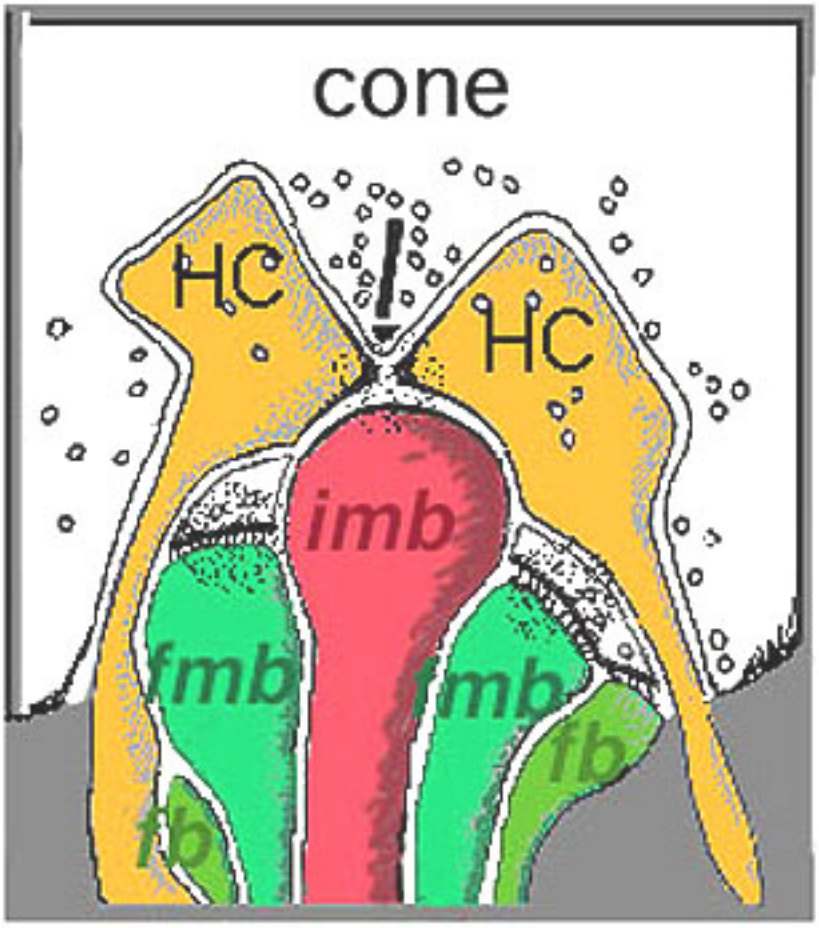

Figure 8. Schematic drawing of a cone pedicle ribbon triad to show the differences in synaptic contacts of invaginating midget and flat midget bipolar cell dendrites.

and midget ganglion cells. The possibility exists that some large field diffuse cone bipolar types that are not spectrally opponent, and have surrounds consistently larger than midget bipolar cells, could involve an amacrine cell content (30, 40).

We believe that L- and M-midget ganglion cell responses are organized in the manner shown in Figure 20. An L-cone would contact two L-cone midget bipolars and through them, two L-cone midget ganglion cells. For example, an L-cone ON-center midget bipolar would contact a single L-cone at invaginating synapses in the OPL, and a single L-cone ON-center midget ganglion cell in sublamina **b** of the IPL. The same L-cone would also be contacted by a single OFF-center midget bipolar at basal junctions, and the bipolar would, in turn, contact a single OFF-center midget ganglion cell in sublamina **a** of the the IPL (Fig. 20, left). Thus L-cone ON- and L-cone OFF-center receptive field ganglion cell types are generated (red + center and orange - center, Fig. 20, left). M-cones would be connected in a similar manner to two midget bipolars (ON and OFF types) and two midget ganglion cells which would also be ON and OFF-center receptive field types (dark green + center and light green - center, Fig. 20, right).

All of the three types of horizontal cell, HI, HII and HIII could make M-cone surrounds to L-cone center bipolars, and L-cone surrounds to M-cone center bipolar cells. However the HII cell may be more involved with spectrally antagonistic fields in the blue/yellow bipolar cell pathways (see Webvision: S-Potentials and Horizontal Cells).

6. Magnocellular and blue/yellow ganglion cells

The large field parasol cells of the primate retina are thought to convey achromatic information concerning low spatial acuity, movement and luminance messages (41, 42). Parasol cells come in ON- and OFF-center varieties like the midget ganglion cells and project to the magnocellular layers of the lateral geniculate nucleus (Fig. 21):

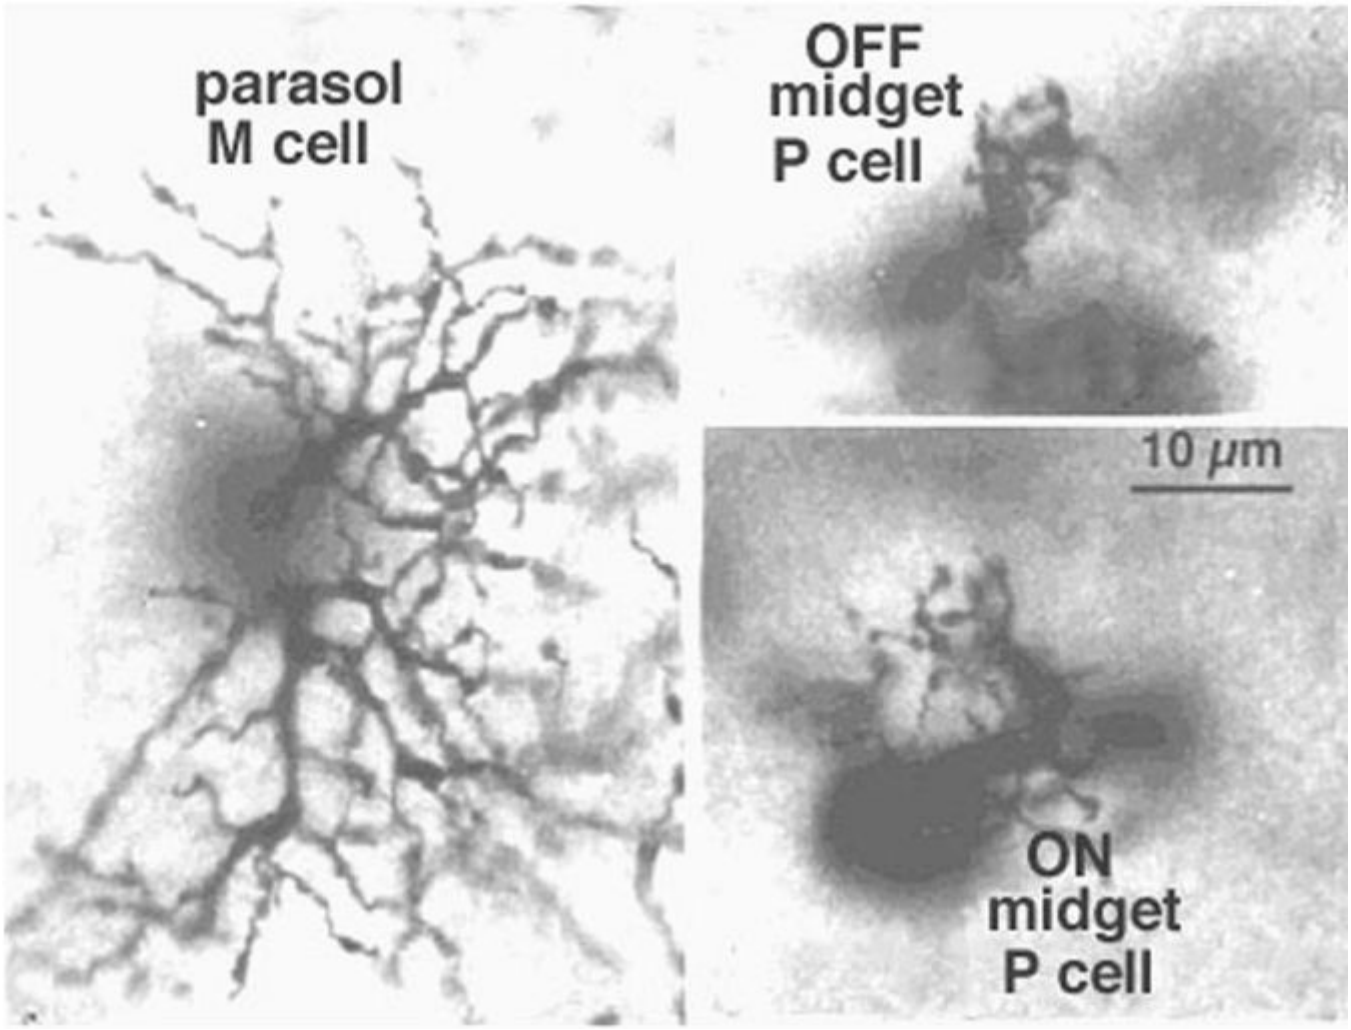

Figure 11.Golgi staining of parasol (M) and midget (P) ganglion cells in the human retina. Scale bar 10 μm for all images. The illustration is from Kolb, Lindberg and Fisher, 1992 (12)

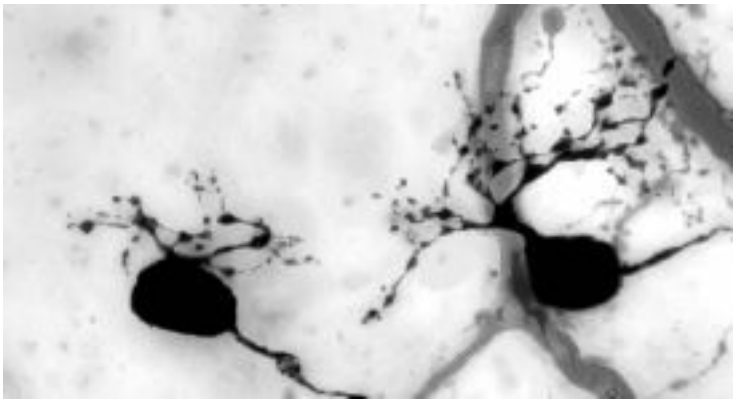

Movie 1. A focus series of two Golgi-stained P or midget ganglion cells in the human retina.

Download video

hence they are also called M cells (13, 43). Parasol ganglion cells also have a surround mechanism to their receptive field physiology, that, like the midget ganglion cells, is thought to originate mainly in the outer

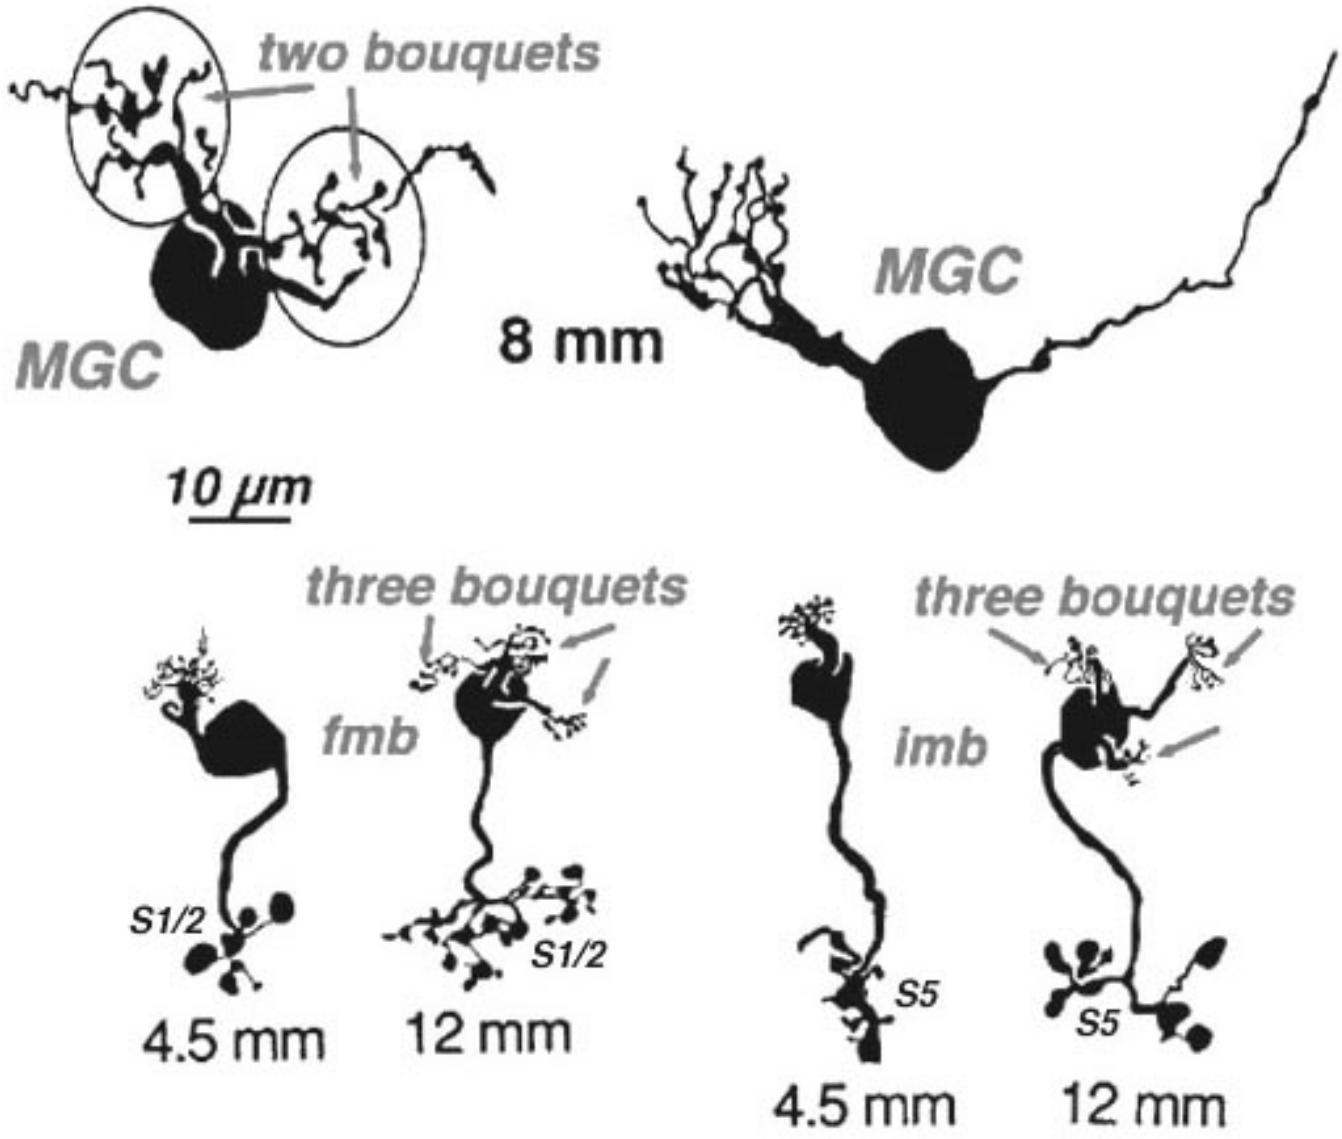

Figure 12. Midget bipolar cells (imb, fmb) have larger axon terminals at greater distances from the fovea (retinal eccentricity of 4.5mm as compared to 12 mm). Midget ganglion cells (MGC) have larger dendritic fields (here seen at 8 mm) as they increase in eccentricity..

plexiform layer from a horizontal cell feedback mechanism (44). The blue yellow ganglion cells (Fig. 21) are a bistratified type and thought to be driven by blue-specific bipolar cells, and other midget or diffuse types to give them their yellow response (11). They project to a special layer of the geniculate nucleus called the koniocellular layer or K layer (45, 46) (Fig. 20). We shall deal with the short wavelength sensitive system in another chapter (Webvision: S-cone pathways) and so will say little more about these ganglion cells here.

About the Authors

S-Cone Pathways

Helga Kolb

Created: May 1, 2005; Updated: May 4, 2007.

General Characteristics

Over the last few years, psychophysicists, electrophysiologists, geneticists, and anatomists have concluded that there is something unique about the short wavelength system compared with the two longer wavelength systems in the visual system.

There are differences in the genetic structure and locus of the S-cone visual pigment compared with the L- and M-cone pigments (1), yet the S-cones are common to all vertebrate retinas and always form a consistent 8-10% of the cone photoreceptor population (2, 3) (Fig. 1). The S-cones are, however, very few in the fovea center, thus causing a so-called S-cone blind spot (4), but they peak in number on the foveal slope at about 12% of the population (Fig. 2).

The short wavelength system has a lower spatial and temporal resolution than the other two cone systems (5, 6) but is probably the only system to truly carry color information through the retina (7, 8).

The pathways for transmitting information from the short-wavelength cones to ganglion cells appear to be different from the midget pathways for the medium- and long-wavelength cones. As we have discussed in a previous chapter, the latter two chromatic pathways are via midget bipolar and midget ganglion cell connections related to a single spectral type of cone, either L-cone or M-cone.

Blue Cones

Of the three spectral types of cone found in the normal human retina, only the S-cone or blue cone can be distinguished from the others in the mosaic. Using special antibodies generated against cone opsins, which are the visual pigments contained within the cone, it is possible to selectively stain the short-wavelength-sensitive pigment (or blue pigment)-bearing cones (Fig. 3) (9, 10).

Before the development of the antibody though, the S-cones were recognizable by staining with fluorescent dyes like Lucifer yellow (11) or from careful quantitative light microscopy of monkey and human retinas (12).

They are distinguished from other cones in the fovea by their larger inner segment diameter and their occurrence in a different mosaic than the the more numerous, hexagonally packed L- and M-cones. Thus, the S-cones seem to break up the regular hexagonal array into small distorted patches of the other cones (Fig. 1).

In vertical sections of human retina, the S-cone is recognized by having a longer inner segment that sticks further into subretinal space than neighboring cones (Fig. 4). It also has a narrower "waist" at the outer limiting membrane than neighboring cones and often sits adjacent to another cone cell body without intervening rods. Pedicles belonging to S-cones project deeper into the outer plexiform layer (OPL) and have a smaller or unusually shaped pedicle compared with other cone pedicles (Fig. 4 and Fig. 5) (13, 14).

In peripheral retina, S-cone pedicles are bilobed in shape, with synaptic invaginations and ribbons separated to the two lobes (Fig. 6). They do not exhibit the long telodendria typical of other cone pedicles, so they remain rather isolated from gap junction contacts, with L- or M-cones at the level of the OPL (14).

S-Cone Bipolar Cell

The S-cone pedicle is only contacted by a special S-cone bipolar cell, which was originally described by Mariani (15) and shown later to be selectively stainable with antibodies to the peptide cholecystokinin (16). This bipolar

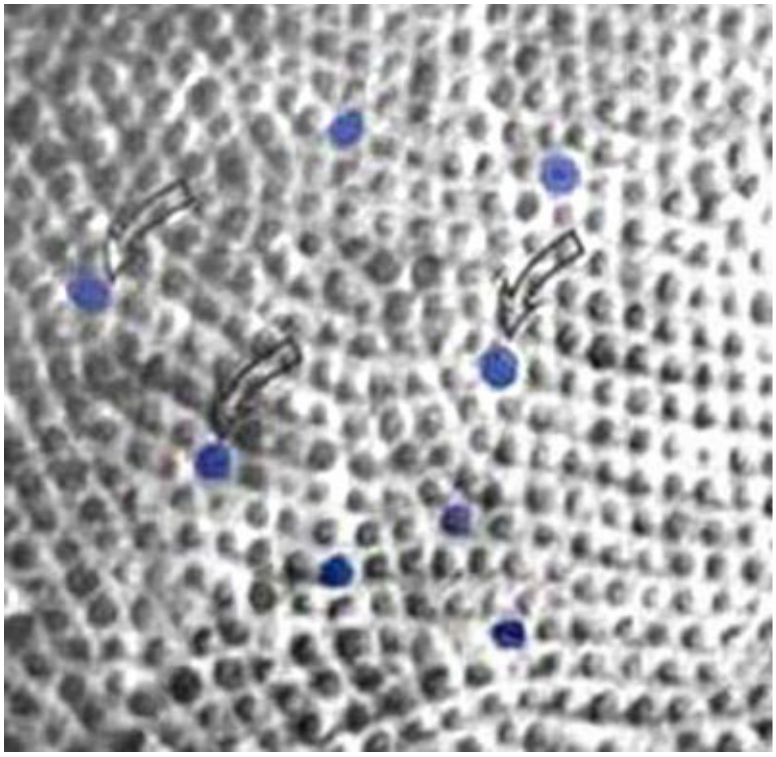

Figure 1. Cone mosaic in the fovea where the S-wave or blue cones are evident by size and density differences.

is not like other midget bipolar cells, although in the central retina, it is related mostly to a single S-cone (16). It differs primarily in its axonal ending in the inner plexiform layer (IPL), from the regular midget bipolar cells that contact M- and L-cones. The S-cone bipolar axon ends deep in the IPL with a long-ranging terminal that runs among the rod bipolar axon terminals in stratum 5 (Fig. 7).

The S-cone bipolar cell makes an invaginating ribbon junction with the cone pedicle as well as a basal junction type of contact (Fig. 6, violet profile, sb). A small number of additional fine bipolar dendrites make basal junction contacts only (Fig. 6, green profile, fb) and so belong to some other kind of diffuse bipolar type, possibly one called GBB, a giant bistratified type (Fig. 7) (17). The HII horizontal cells make many of the lateral element contacts with the S-cone in both lobes (Fig. 6, orange profiles, HII). A small number of contacts come from HI cells (Fig. 6, red profiles, HI) (13).

S-Cone Horizontal Cell

Originally, there was thought to be only one type of horizontal cell in the primate retina—a long-axoned cell type that connected with cones at its dendrites and rods at its axonal endings (18-20). However, in 1980 a second type of horizontal cell was described (21) and proposed to be more concerned with S-cones than the original long-axoned HI type. The HII cell was distinguished on its bushy dendritic tree with fine irregular dendrites and without clear clusters destined for cones (Fig. 8a, compare H1 and H2 cells morphology). Electron microscopy finally showed that the HII type of horizontal cell indeed sent many dendritic processes to the few S-cones in its dendritic field and lesser concentrations of processes to overlying M- and L-cones. The short axons of these HII cells contact S-cones exclusively (Fig. 8b) (13). Intracellular recordings from H2 horizontal cells in monkey retina have proved conclusively that this horizontal cell is blue sensitive and an important element of the S-cone pathway in the primate retina (22).

It has been demonstrated that horizontal cells produce negative feedback to cones (23-25) and are engaged in center-surround generation in bipolar cells and color opponent responses in horizontal cells of animals with

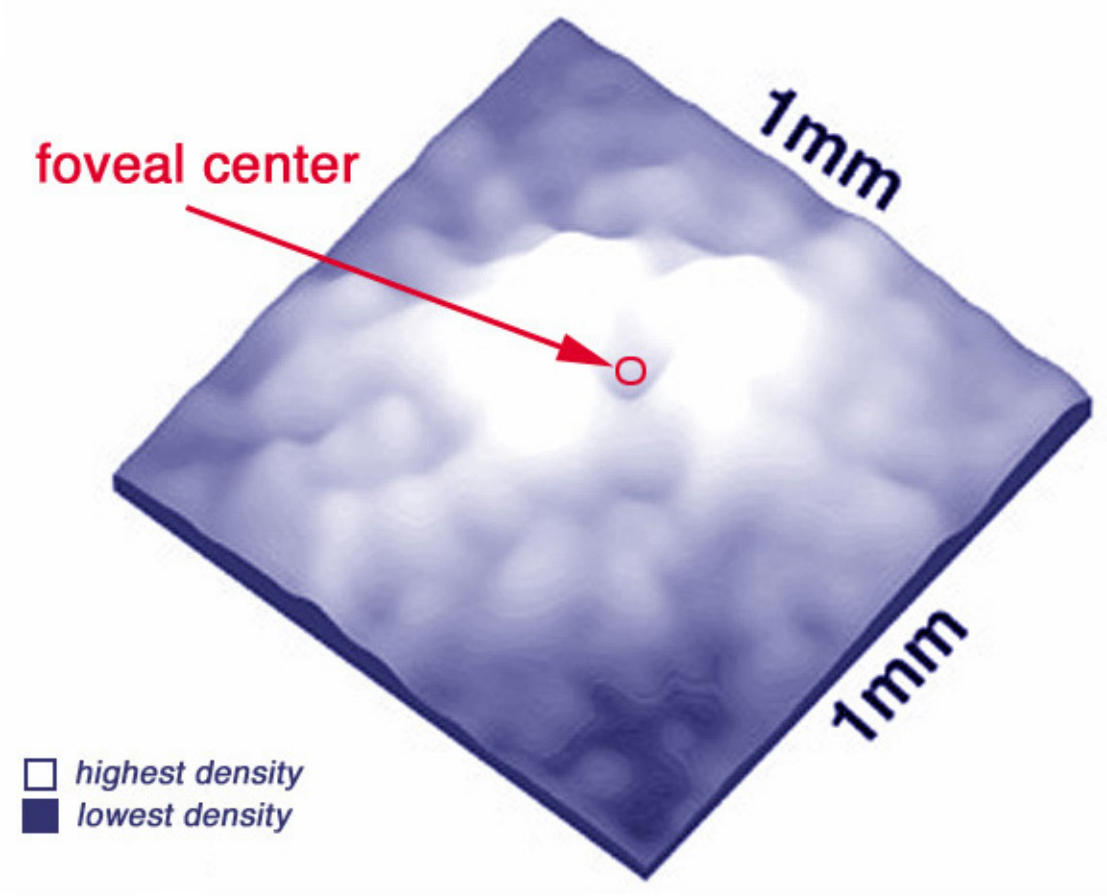

Figure 2. 3D map of the blue or S-cone density around the foveal center. The peak density occurs on the foveal slope. From Ahnelt and Kolb (9).

good color vision (24). In the case of the HI and HII horizontal cells of the primate retina, it has been difficult to demonstrate color opponency in intracellular recording and dye-markings (22), although anatomically, we know there is color selectivity of their contacts (13). Dacey and coauthors (22) concluded that HII cells, which of course make contact with L- and M-cones as well but are primarily concerned with S-cones, do not engage in feedback signals with the longer wavelength cones. However, it is possible that HII cells feed back only to their S-cones, thereby forming opponency in the S-cones themselves and their S-cone bipolar cells. This should result in an opponent S-cone bipolar S-ON, L-/M-OFF (blue ON/yellow OFF) channel that could be carried straight to the ganglion cells (Fig. 9).

S-Cone Ganglion Cell

Early electrophysiological investigation of monkey retinal ganglion cells indicated that blue/yellow opponency was carried primarily by an S-cone ON-center ganglion cell type with a much larger receptive field center than is typical of the L- or M-cone color and spatially opponent midget ganglion cells (26). The S-cone ganglion cell did not appear to have a spatially antagonistic receptive field structure. Instead, the yellow opponency was coextensive with the center of the receptive field. Interestingly, there are very few recordings of the opposite type of ganglion cell, i.e., yellow-ON and blue-OFF.

The morphology of the blue-ON/yellow-OFF ganglion cell has been known since Dacey and Lee (27) made intracellular recordings and staining of these ganglion cells in monkey retina. It turns out to be a relatively small-

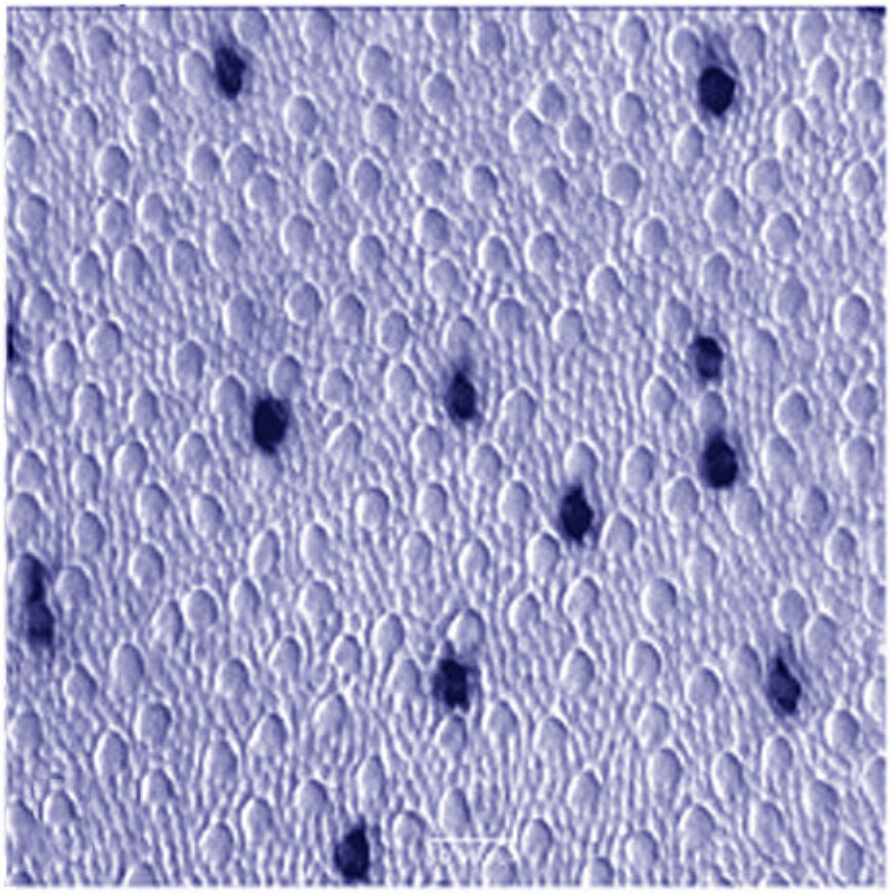

Figure 3. Blue or S-cones can be marked with anti-S-cone pigment antibodies. From Ahnelt and Kolb (9).

field bistratified ganglion cell (28) with its major dendritic branching in stratum 5 of the IPL and a small tier of dendrites in stratum 1 of the IPL (Fig. 10).

Circuits for the S-Cone Pathways in the Primate Retina

Hypothetical wiring diagrams of the S-cone pathway through the primate retina in comparison with the L- and M-cone midget pathways are shown in Fig. 11. The S-cone bipolar would carry ON signals to the lower dendrites of the bistratified ganglion cell, which may be the dominant input. It is possible, though, that the bipolar is already S-ON and yellow-OFF, in response to the HII cell influence, as mentioned above. Then both ON and OFF spectrally antagonistic components would drive the ganglion cell. However, the yellow-OFF response could also be complemented by an OFF bipolar that contacts L- and M-cones as well, making synapses upon the upper dendrites of the bistratified ganglion cell (Fig. 11).

The equivocal existence of the OFF S-cone channels (29, 30) in the retina could be because only a small number of S-cone OFF ganglion cells are present, and they are difficult to record. Very recent preliminary recordings and markings of an OFF-blue cone ganglion cell indicate that it is a small-bodied, wide-field cell type with thin dendrites in S5 of the IPL (31). Wiring of such a cell type must involve amacrine circuitry to get blue-OFF and yellow-ON signals to the ganglion cell (Fig. 11).

Feedback Loops in the Retina

Helga Kolb

Created: May 1, 2005; Updated: May 4, 2007.

General Characteristics

At every level of the retina, there are reciprocal or feedback loops in the circuitry so that certain neurons can interact laterally within the same layer, vertically from one layer to the other, and indeed from the brain to the retina. The intra-layer feedback loops are typically provided by neurons that use inhibitory neurotransmitters, such as GABA, and have a function in sharpening the image by adding lateral inhibition or antagonism to receptive fields of the neurons, whereas the feedback loops between the layers or from the brain are less clear in function. The latter loops tend to use neuromodulators as their transmitters and thereby have a more generalized effect on groups of neurons, or on the state of excitability of the neuron chains (adaptation, for example).

Feedback in the Outer Retina

As mentioned in previous chapters, it has been well demonstrated in turtle and fish retinas that cones receive an antagonistic reciprocal feedback message from horizontal cells (1), which serves to provide a restricted concentric receptive field for the individual cones (Fig. 1 and Fig. 2). Evidence for feedback synapses have been difficult to demonstrate, either electrophysiologically or morphologically, in the cones of the mammalian retinas. However, the rod axon terminals of HI horizontal cells ending in the rod spherules are seen to make small punctate chemical synapses, consisting a small cluster of vesicles at a single dense projection in the membrane, upon both the rod spherule (Fig. 2) and upon the rod bipolar cell dendrite (not illustrated) in human retina (2). A similar-appearing small cluster of vesicles is occasionally seen in horizontal cell dendrites in the cone pedicle triads in human retina as well (Fig. 3).

In the inner plexiform layer, many amacrine cell types probably provide feedback information to bipolar axon terminals. One we know something about is the reciprocal synapses from the wide-field rod amacrine A17 upon the rod bipolar axon terminal. It is intriguing that this IPL input/output synaptology between the rod bipolar and A17 amacrine parallels the input/output of the photoreceptor and horizontal cell at the outer plexiform layer (OPL) and suggests some necessity of the rod system, in the mammalian retina at least, to be in repetitive feedback loops all through the retina (Fig. 4).

Where A17 is a **rod** system bipolar cell feedback amacrine cell, A4, A13, and wide-field amacrines like A19 are **cone** system feedback amacrine cells. Similar to A17 cells of the rod system, these amacrine cells are probably also GABAergic. The amacrine cell feedback loop seen below occurs commonly at the midget bipolar axon terminal in the human retina in close proximity to the ribbon synapse of the related midget ganglion cell (Fig. 5).

It is possible that feedback (reciprocal) synapses, in these cases, are involved with phasic or transient components of these cell response characteristics. They may sharpen and speed up otherwise slow potential responses of the bipolar cell by feedback to the bipolar before output to the ganglion cell (see an animation of the feedback synapses).

Interplexiform Cells

A neuron in the retina of just about every species studied, including humans, links the two plexiform layers by receiving synaptic input in the IPL and having synaptic output upon neurons of the OPL. It is known as the interplexiform cell, an **IPC**. The interplexiform cell, first described by Gallego (3) in the cat retina, has been studied extensively in the goldfish retina by Dowling and coauthors (4) and now also in the cat and the human

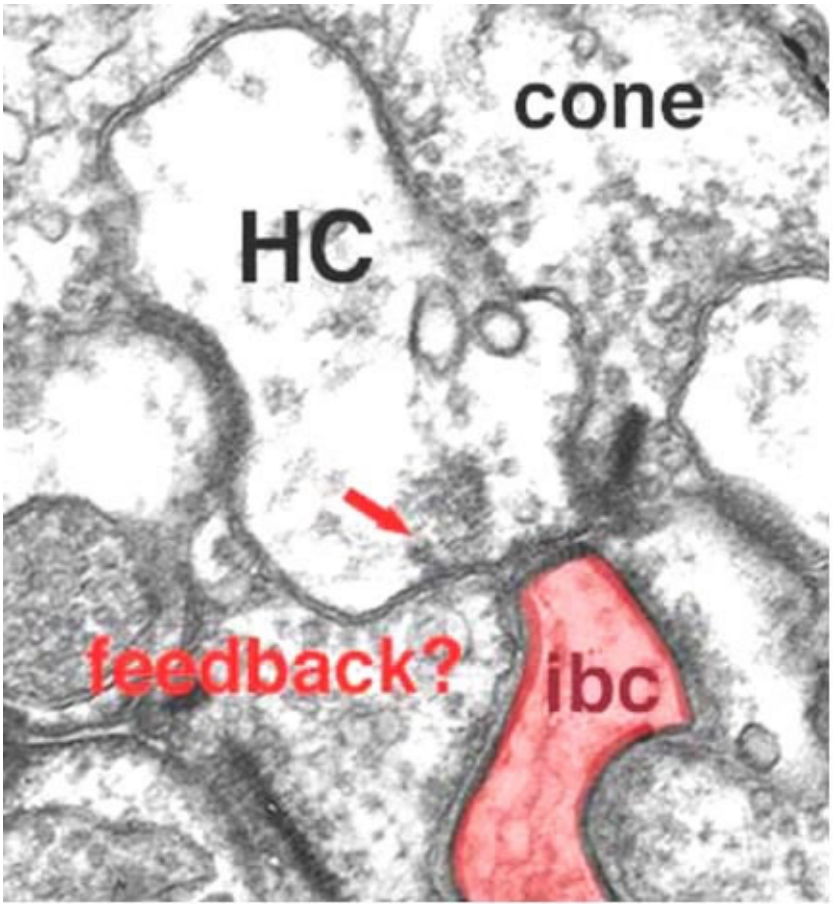

Figure 1. Electron micrograph of a cone pedicle.

retinas (2, 5, 6). In cat and human retinas, such interplexiform cells are medium field and tristratified in branching pattern in the inner plexiform layer. Either from the cell body or from one of the dendrites in stratum 1 of the IPL, processes ascend through the inner nuclear layer to the outer plexiform layer. There they run for a short distance (Fig. 6 and Fig. 7).

Electron microscopy has been performed on examples of this type of IPC in cat and human retinas. They get input from amacrine cells of unknown type and make some synapses upon rod and cone bipolar axons (5, 7) with their inner plexiform layer branches. Through the inner nuclear layer and into the outer plexiform layer, processes of IPCs cell make numerous conventional synapses upon rod and cone bipolar cell bodies and dendrites (Fig. 8).

In both cat and human, the interplexiform cell has processes that touch cone pedicles but make rather unspecialized junctions at this site, so we have been reluctant to call these synapses. The interplexiform cell, just described in the human and cat, is known to be GABAergic. This differs considerably from the interplexiform cell of the fish retina, where it is known to be dopaminergic (8). In the fish retina, the dopaminergic interplexiform cell is known to have synapses in the OPL, primarily upon horizontal cells. Thus, it seems that the fish interplexiform cell has a rather different role to play in the retina compared with the GABAergic interplexiform cell of the human (Fig. 9).

Dopaminergic Cells in Mammals

In both human and cat retinas, there exists a dopaminergic amacrine cell, called A18, which we think is involved in the rod system pathways of the IPL and particularly with the rod amacrine AII cells (see previous chapters).

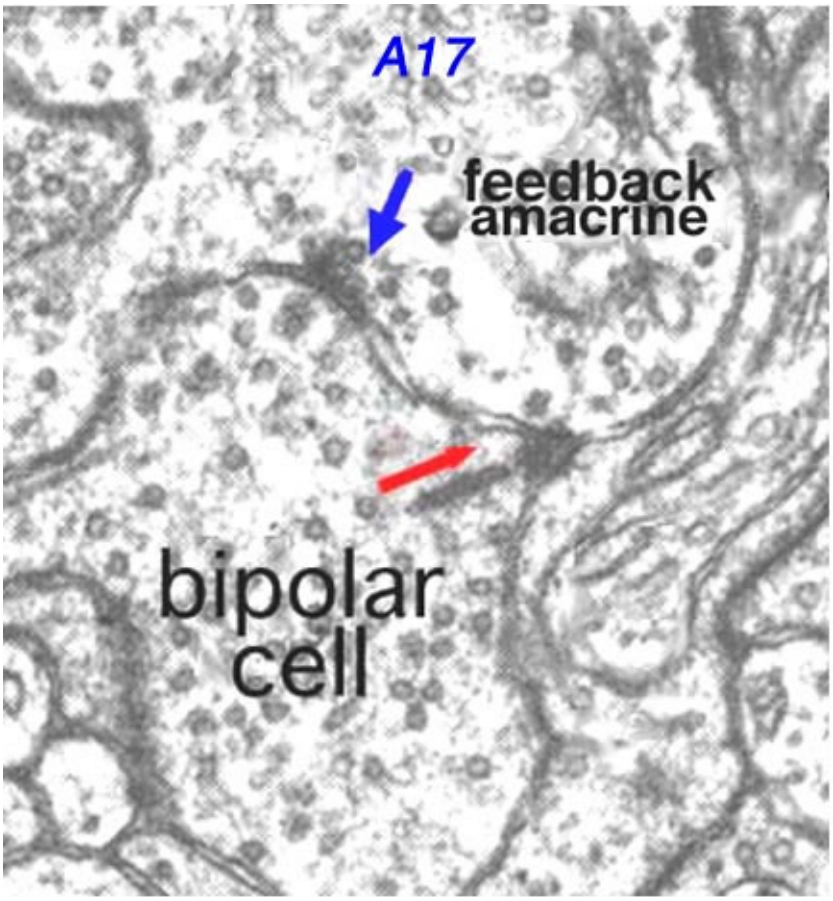

Figure 4. Electron micrograph of a reciprocal synapse of a rod amacrine cell (A17) upon a rod bipolar axon terminal.

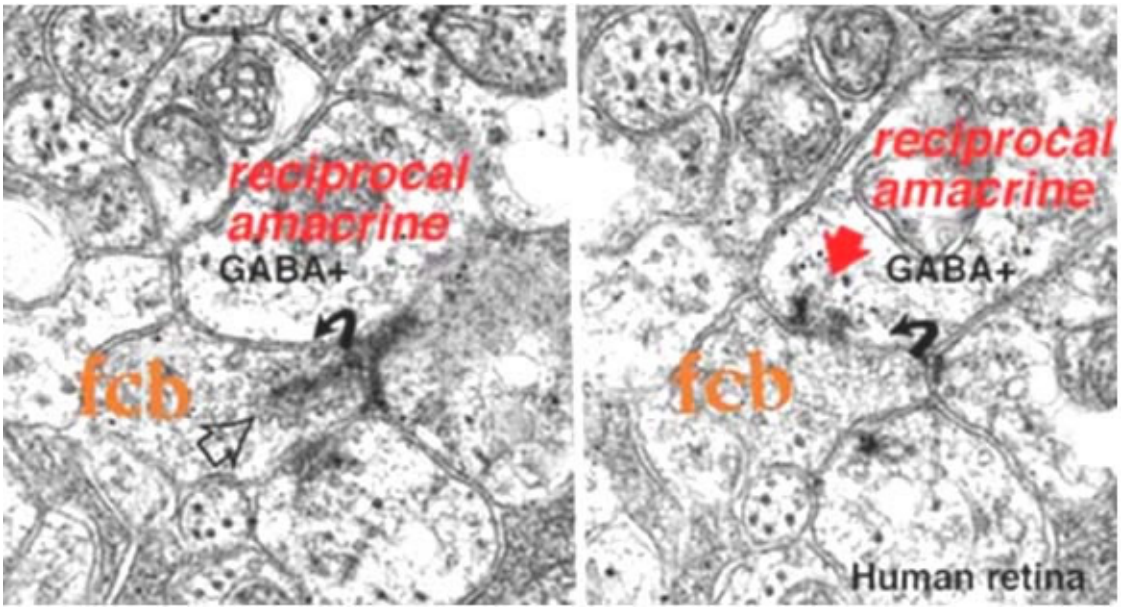

Figure 5. Electron micrograph of a reciprocal GABAergic synapse.

However, sometimes these A18 cells can be seen to have processes ascending from their cell bodies or from their plexus of dendrites in stratum 1 of the innerplexiform layer, to pass up to the outer plexiform layer. In these layers, dopaminergic processes may be presynaptic to horizontal cells in the human retina (9). In the cat retina,

however, we have seen these ascending dopaminergic processes (marked by their content of Toh immunoreactivity) to be presynaptic to the conventional IPC of the cat, i.e., the cell described above (10, 11) (Fig. 10 and Fig. 11).

Centrifugal Fibers in Mammalian Retinas

Centrifugal fibers arising in brain nuclei and passing back to the retina have been noted sporadically in mammals but with few details and no ideas about which brain centers they might derive from. Centrifugal fibers are particularly well developed in the avian retina (12-14). A few centrifugal fibers were described in the monkey retina by Polyak (15) and later by Honrubia and Elliot (16). According to Polyak (15), the centrifugal fibers in monkey have varicose, bulbous terminals that end in the inner plexiform layer close to amacrine cell bodies. In the human retina, they have been followed across the nerve fiber layer into the inner nuclear layer before disappearing (17) (Fig. 12).

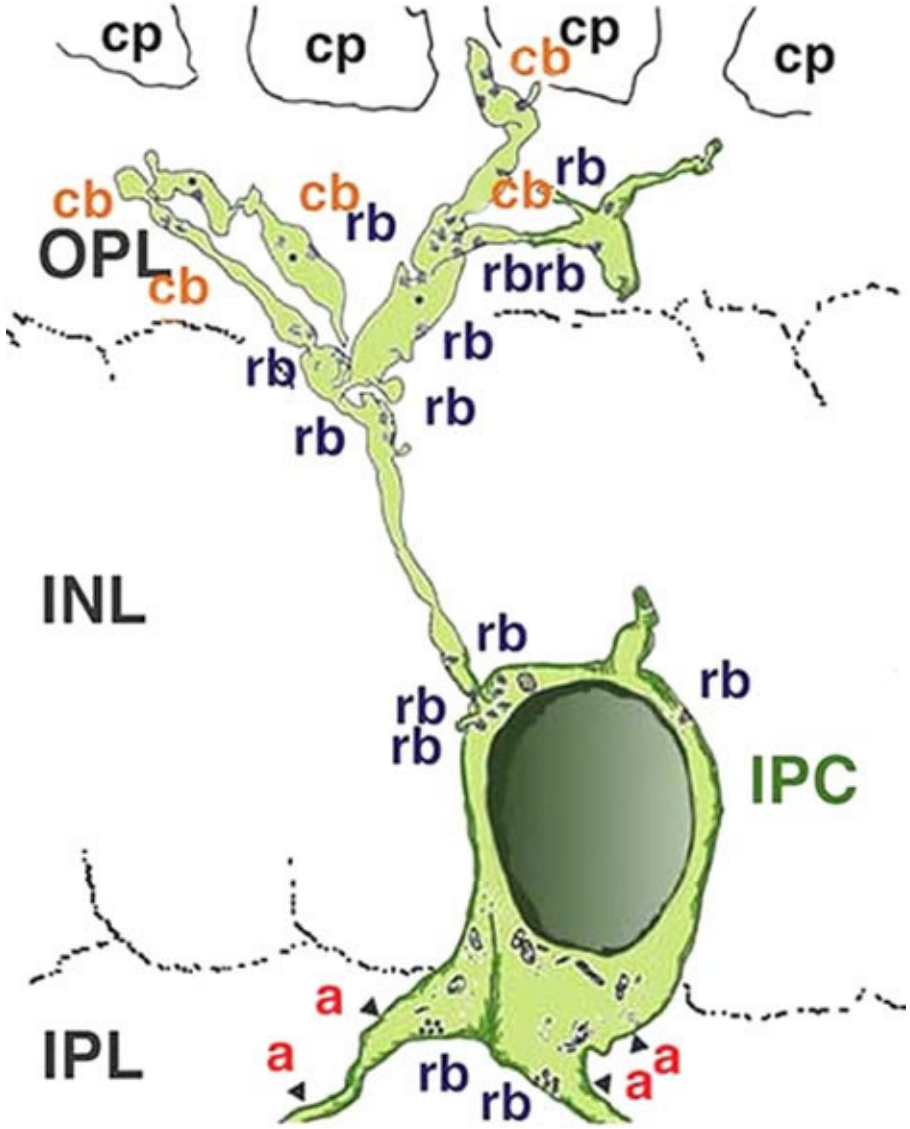

Figure 9. Summary diagram of the organization of the interplexiform cell in human retina.

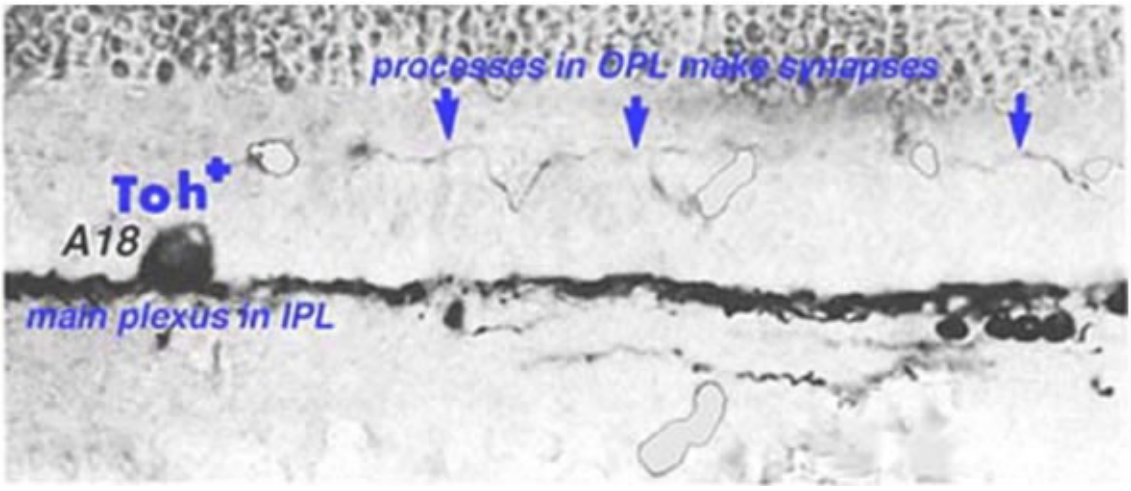

Figure 10. Light micrograph of a dopaminergic cell.

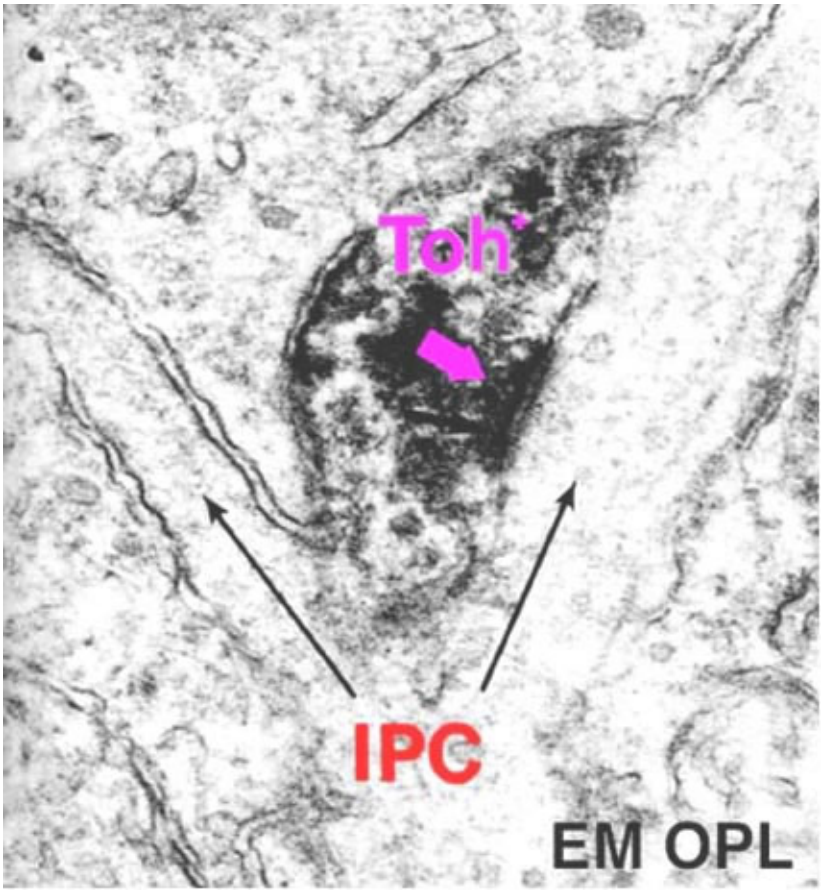

Figure 11. Electron micrograph of a dopaminergic cell.

Recently, it has been discovered that centrifugal axons arising in the hypothalamus project to various parts of the brain, including the retina in the macaque monkey. Interestingly, these axons contain histamine (18). The histamine-immunoreactive axons run from the optic nerve head in a broad circular band around the far side of the fovea in temporal retina and appear to return to the optic disc (see Fig. 13). Many of these axons branch extensively and emerge out of the nerve fiber layer into the inner plexiform layer. Sometimes the histaminergic axons are associated with retinal blood vessels. It will be extremely interesting to discover whether these histamine-containing centrifugal fibers have interactions with amacrine or other cells of the retina, similar to what is proposed for centrifugal fibers in other species.

In the fish retina, we know that centrifugal fibers use the hormones FMRF amide and luteinizing hormone-releasing hormone as neurotransmitters (19). They synapse in the fish directly upon cell bodies of the dopamine interplexiform cell (20). In turtle retina, only three to six efferent fibers that are immunoreactive to the peptide MET-enkephalin are known to enter the retina and pass up to the amacrine cell area. These fibers originate in the caudal mesencephalon, but their function and action in the retina are still unknown (21).

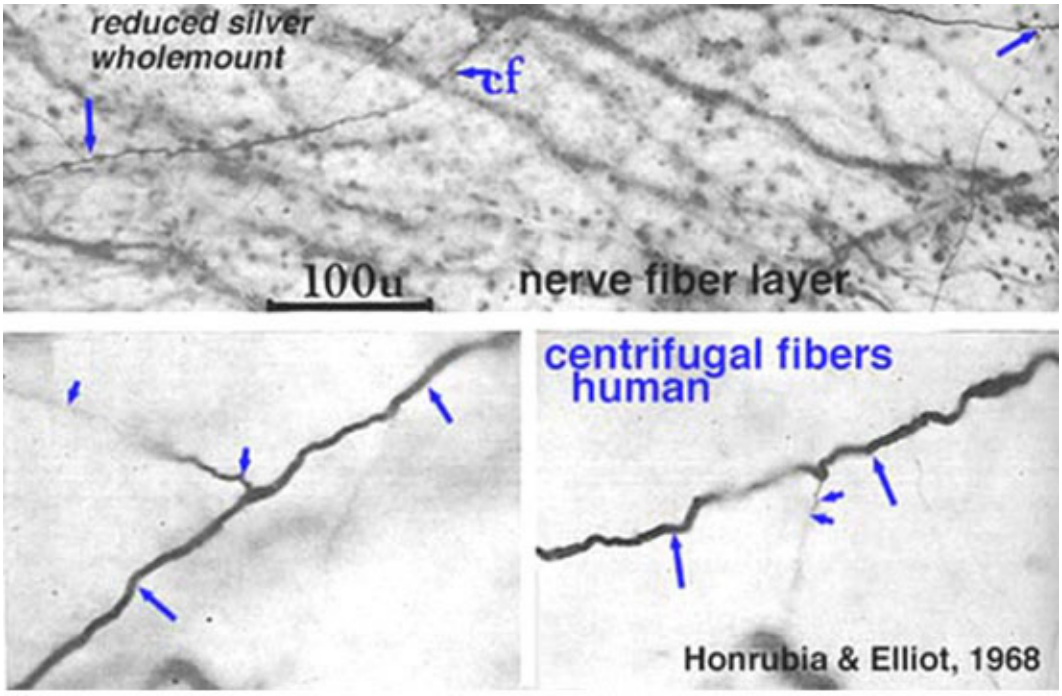

Figure 12. Centrifugal fibers in human retina.

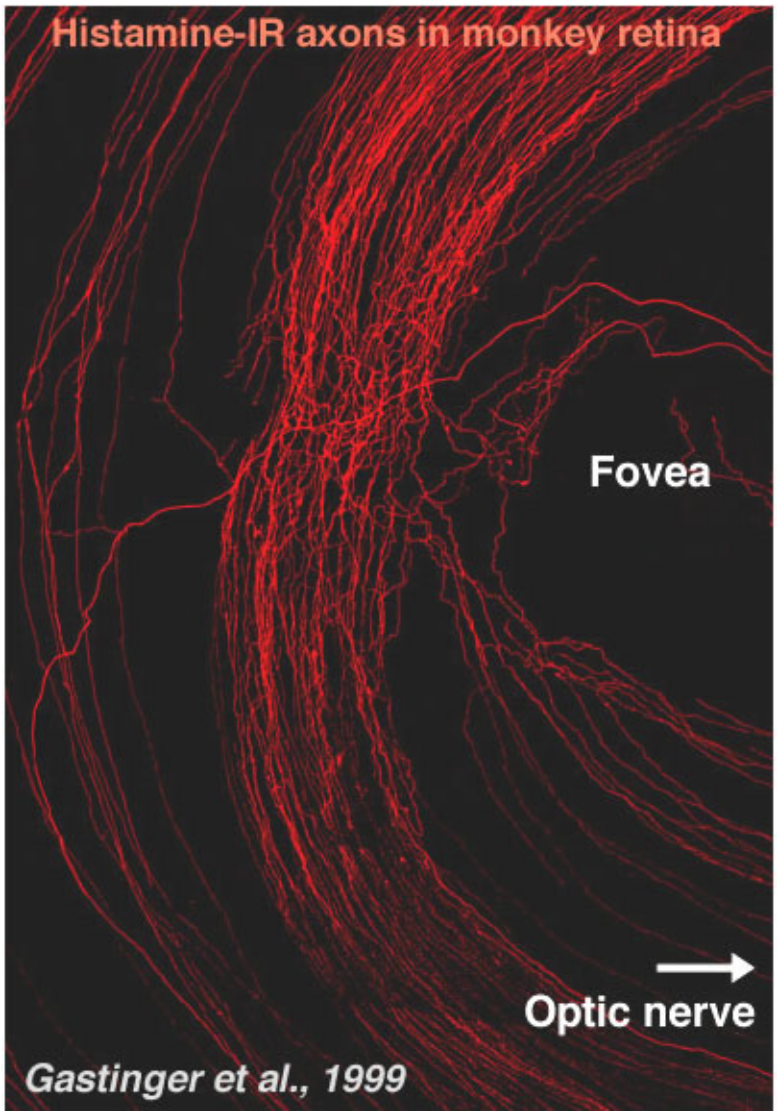

Figure 13. Photomontage of histamine-immunoreactive axons from the area temporal to the fovea. In this region, most histamine-IR axons made collateral branches in the optic fiber layer that continued around the fovea and returned to the optic disc. One large axon passed through this dense network of collaterals and ultimately made an orthogonally projecting branch to the inner plexiform layer. In the parafovea, a few of the smaller collaterals terminated in the inner plexiform layer, and the remainder ended in small swellings in the optic fiber layer.

Myriad roles for gap junctions in retinal circuits

Stuart Trenholm, Ph.D.[1,*] and Gautam B. Awatramani, Ph. D[2,†]

Created: September 20, 2019.

Abstract

Gap junctions are recognized in the electron microscope as dense starchy areas of opposed membrane between two cells. Small tracer molecules such as Neurobiotin pass through the gap junction pore, marking interconnected cells. Electrical signals pass through these junctions, extending the region of neuronal data collection, modifying the dynamic properties of the signal, and synchronizing impulse generation. In the retina, circuits comprised of many neuronal types transform information within the visual environment into a series of highly processed, simplified spike trains that are relayed to higher visual areas. Retinal signal processing relies on intricate interactions between specific cell types, which are mediated by both chemical and electrical synapses. In the field, great strides have been made in understanding the diversity of retinal cell types, of which there are likely at least 100 unique types, and how they connect to form cell-type-specific circuits. Here, we provide an overview of electrical coupling in the retina and outline the varied roles that gap junctions play in processing information in healthy and diseased states.

Introduction

The retina is built from approximately 100 distinct neuronal cell types, which reside in specific retinal layers and connect with one another to form intricate microcircuits (1-5). These circuits serve to extract principle features of the visual world, which get parsed into distinct visual channels via different retinal ganglion cell types. These differentially processed visual signals are then relayed out of the retina to a large number of higher visual areas (6, 7). Interestingly, microcircuits in the retina are connected through both chemical synapses and bi-directional electrical synapses formed by gap junctions. The rich interactions between electrical and chemical synapses enable circuits to operate in highly flexible and dynamic ways. Moreover, as the strength of gap junctions can be modified over a variety of timescales, they can reconfigure retinal microcircuits on both a millisecond time-scale as well as over the course of the day/night cycle. In addition, gap junctions exert their effects over a range of spatial scales, synchronizing activity at the sub-cellular level as well as across wide swaths of the retina. Given these diverse roles for gap junctions in retinal signal processing, it is not surprising that electrical synapses also play many roles in disease states. Finally, despite the advances outlined here regarding our understanding of the various roles for gap junctions in retinal signaling, it is likely that we are still only scratching the surface in identifying the full repertoire of their functional roles.

Gap junctions in the retina and how they affect receptive field size

The vertebrate retina contains five principal neuron classes: photoreceptors (rods and cones), horizontal cells, bipolar cells, amacrine cells and ganglion cells. For each class of neuron, we describe electrical and chemical synaptic connectivity patterns (**Figure 1**). For electrical synapses, when known, we outline the connexin

† About the authors

subtypes involved in forming gap junctions and describe their biophysical properties. Also, whenever possible, we describe the strength of gap junctions between pairs of neurons, represented as either the junctional conductance or the coupling coefficient (i.e. the change in membrane potential of a post-junctional cell divided by the change in the membrane potential in a pre-junctional cell when then membrane potential of the pre-junctional cell is altered).

Despite the characterizations of coupling strength that we will outline below, it is important to keep in mind that the conductance through a gap junction is not static, and changes to the conductance can have significant effects on the roles that electrical synapses play in neuronal circuits. For instance, modifying the strength of gap junction coupling can significantly alter the receptive field size of retinal neurons by modifying the strength and extent of their excitatory receptive field surround. For many neurons in the retina, light adaptation or circadian rhythm can modulate the strength of electrical coupling and thus alter receptive field sizes. Changes to coupling strength could also modify other roles for gap junctions in retinal circuits. While molecular mechanisms underlying changes in coupling strength have been studied in detail (8), in the following section we focus on the functional outcomes of modifications in coupling strength on receptive field size.

Photoreceptors

Vision starts in rod and cone photoreceptors, as photons are converted into an electro-chemical signal (See Webvision chapter Phototransduction in Rods and Cones). Photoreceptors make glutamatergic synapses with horizontal and bipolar cells (ionotropic sign conserving synapses with horizontal cells and OFF bipolar cells; metabotropic sing-inverting synapses with ON bipolar cells). Photoreceptors also form both homologous (i.e. cone-cone and rod-rod) and heterologous (rod-cone) electrical synapses (**Figure 2**) (9-17).

Cone gap junctions contain connexin 36 (Cx36) in mammals (**Figure 3**) (18-21) and Cx35 in zebrafish (22), while the connexin involved in rod electrical synapses has not been definitively identified (22-24), and coupling between rods and cones appears to rely on Cx36 (25). Photoreceptor gap junctions are localized around the axon terminal of cones (11, 16, 26-28).

Based on physiological recordings, it appears that homologous photoreceptor coupling is stronger than heterologous coupling. The junctional conductance of cone-cone and rod-rod gap junctions appears to be bidirectionally symmetrical and in the range of 200-800 pS (**Figure 4**) (12, 14, 15, 27, 29), with a coupling coefficient of around 0.15 (14, 30). The junctional conductance of rod-cone gap junctions has been reported to be bidirectionally symmetrical and in the range of 40-200 pS (31), with a coupling coefficient of around 0.04 (32). From tracer dye experiments where the dye is injected into cones, it appears that being coupled to rods is more common than being coupled to only cones or to both rods and cones, and some cones may be uncoupled (13). In contrast, from tracer dye experiments where the dye is injected into rods, rod-rod coupling seems to be more common than rod-cone coupling and some rods may be uncoupled (15).

Circadian rhythm, and not light adaptation, appears to be the main controller for altering the strength of electrical coupling in photoreceptors in fish and mouse retinae (33). Psychophysical experiments in humans have indicated that cone coupling appears to be unaffected by light adaptation, but effects of circadian rhythm have not been tested (12). In contrast, light adaptation, not circadian rhythm, appears to modulate electrical coupling strength between salamander photoreceptors (31). Altering the strength of gap junctions can modify the receptive field size of photoreceptors. For instance, cones have larger receptive fields during states in which rods and cones are more strongly electrically coupled (33). Similarly, rod receptive fields are also expected to be larger when they are more strongly coupled, and coupling decreases trial-to-trial variability in their responses to dim flashes (15). Finally, heterotypic gap junctions allow cone responses to pass into rods (34), and rod responses to pass into cones (**Figure 5**) (13, 35-37), meaning that increases in electrical coupling should extend the range of light intensities over which a given rod or cone can respond, and at least for cones such coupling could result in increased reliability of threshold responses.

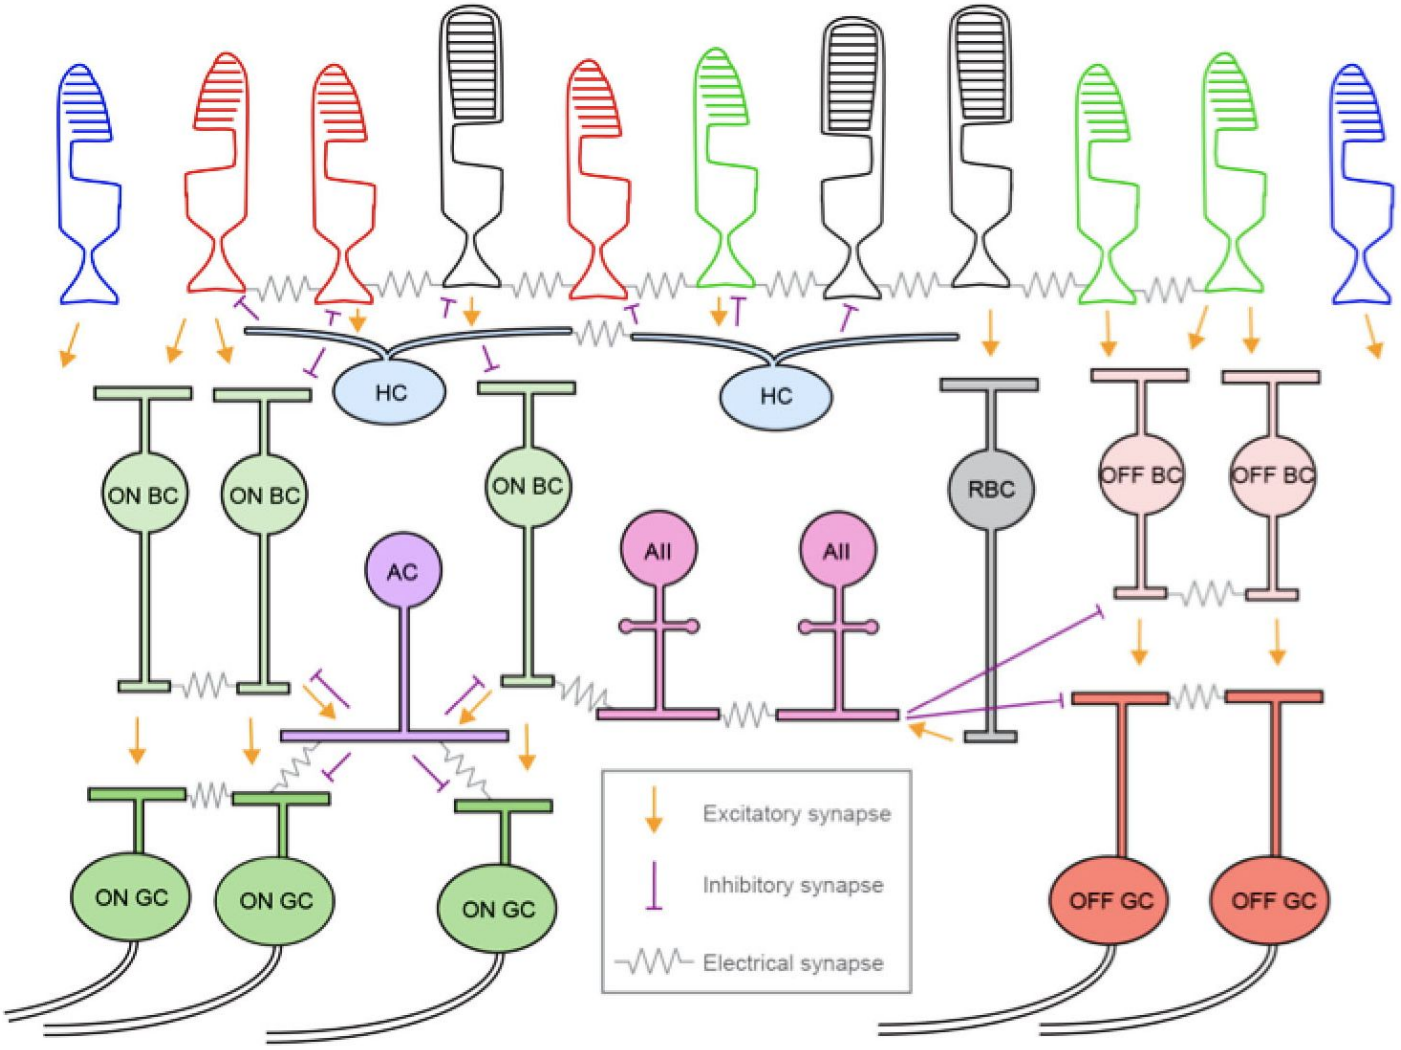

Figure 1. *Retinal anatomy and synaptic connectivity.* A schematic of the vertebrate retina. Photoreceptors (top), showing rods (black), and cones, colored according to wavelength. Note that blue cones may be uncoupled (14, 27). Horizontal cells (HC, blue), ON bipolar cells (ON BC, green), OFF bipolar cells (OFF BC, light red), and rod bipolar cells (RBC, gray) are shown in the middle, as are AII amacrine cells (pink), as well as a generic amacrine cell (AC, purple). ON and OFF ganglion cells (ON GC, green; OFF GC red) are on the bottom. Taken from Trenholm and Awatramani (2017) (197).

Horizontal cells

Horizontals receive glutamatergic inputs from photoreceptors, and in turn provide negative feedback to photoreceptors and possibly feedforward inhibition to bipolar cells (See Webvision chapter S-potentials and Horizontal cells). The mechanisms of feedback interactions are still actively being studied (38). Additionally, horizontal cells are densely interconnected with gap junctions (**Figure 6**) (26, 39).

Horizontal cell gap junctions can be either axoaxonic or dendrodendritic. In mouse, Cx57 is present in both types of gap junctions (**Figure 7**) (40, 41), while Cx50 is localized in axonal gap junctions (42). In rabbit A-type horizontal cells, Cx50 localizes in dendritic gap junctions (43), and Cx57 is found in axonal gap junctions in B-type horizontal cells (44). In zebrafish, horizontal cell gap junctions appear to be comprised of Cx52.6, 52.9 and 55.5 (45, 46).

Coupling between horizontal cells appears to be very strong, with a bidirectional and symmetrical junctional conductance of > 1ns and with a coupling coefficient of 0.5 or greater in cultured horizontal cells (47-50). From

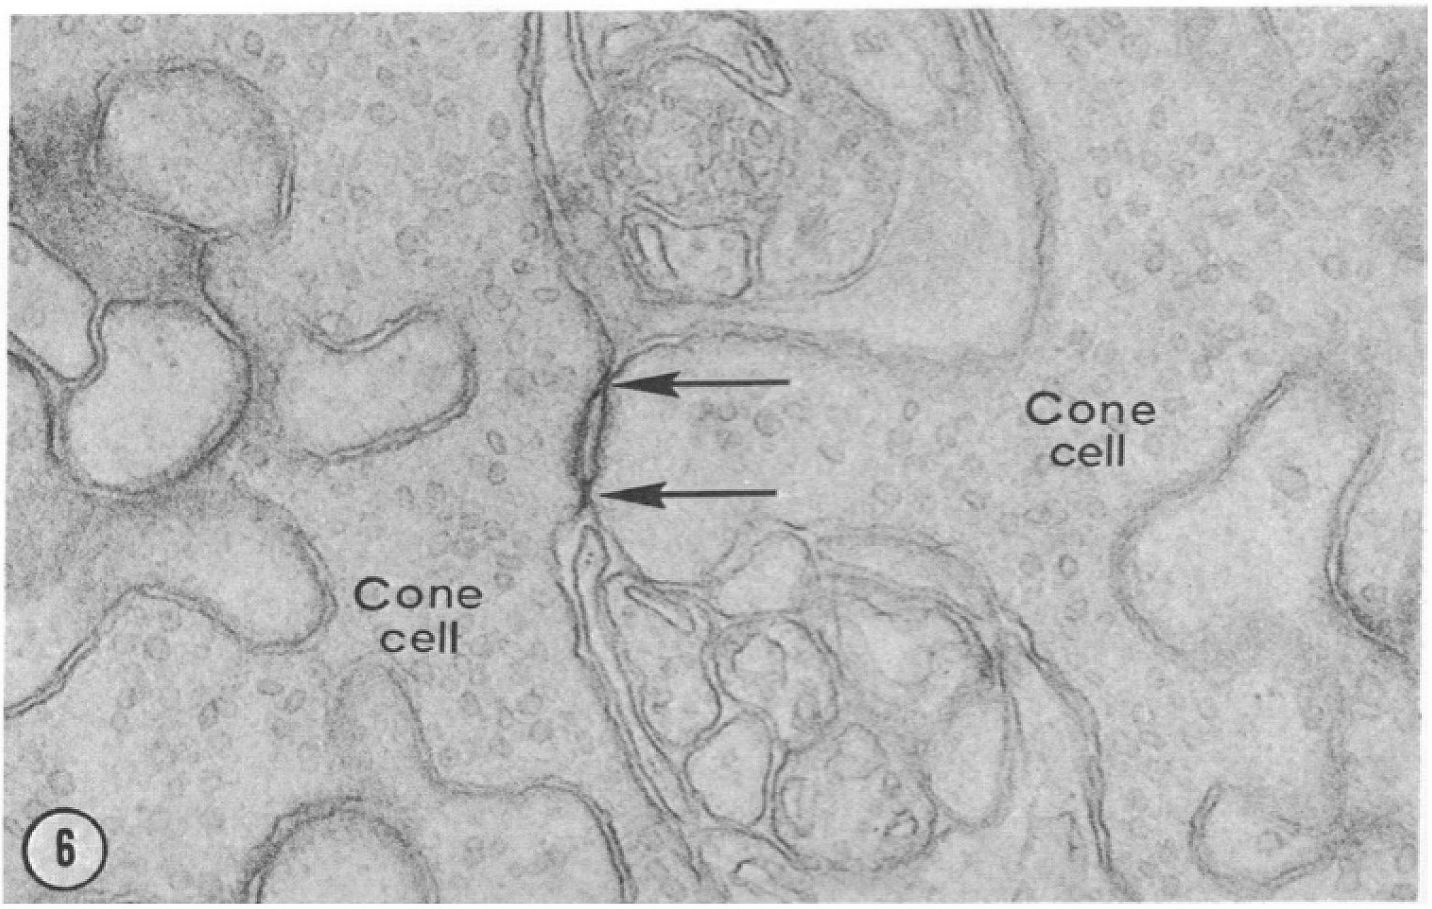

Figure 2. *Gap junctions between cone photoreceptors*. Electron micrograph of a tangential retinal section showing two gap junctions (black arrows) between cone photoreceptors in macaque retina. Magnification: x 55000. Taken from Raviola and Gilula (1973) (16).

remarkable tracer dye experiments, where dye is injected into a single horizontal cell, it has been found that dye can spread into more than 1000 surrounding horizontal cells extending across a distance of over 1 mm (**Figure 8**) (51).

In horizontal cells, light adaptation appears to be the main factor controlling the strength of gap junction coupling (52, 53). Horizontal cell coupling has been shown to exhibit a tri-phasic relationship depending on luminance levels: tracer coupling experiments show minimal coupling in the dark adapted or "dark-suppressed" state; tracer coupling is greatly increased in medium light levels, during the so-called "light-sensitized" state; tracer coupling is very weak during the light adapted state (**Figure 9**) (51).

Horizontal cell coupling seems to strongly affect receptive field size (54), with receptive fields being approximately three times larger in the light-sensitized state (51). Consistent with this finding, knocking out Cx57 in mice decreases the size of horizontal cell receptive fields (**Figure 10**) (55).

As horizontal cells provide negative feedback to photoreceptors, it has been posited that they might be responsible for generating inhibitory surround receptive fields in downstream ganglion cells (56, 57) in which case modifying horizontal cell coupling strength would modify ganglion cell receptive field size. However, the effect of horizontal cell feedback on ganglion cell surround responses remains uncertain, and at least in some cases horizontal cells do not drive significant surround responses in ganglion cells (58-60). Additionally, despite reducing horizontal cell receptive field size, knocking out Cx57 has little effect on ganglion cell spatial tuning and on visual acuity in mice (61). In contrast, horizontal cells might play a role in temporal tuning of ganglion cells. For instance, it has been suggested that strong electrical coupling might functionally remove horizontal

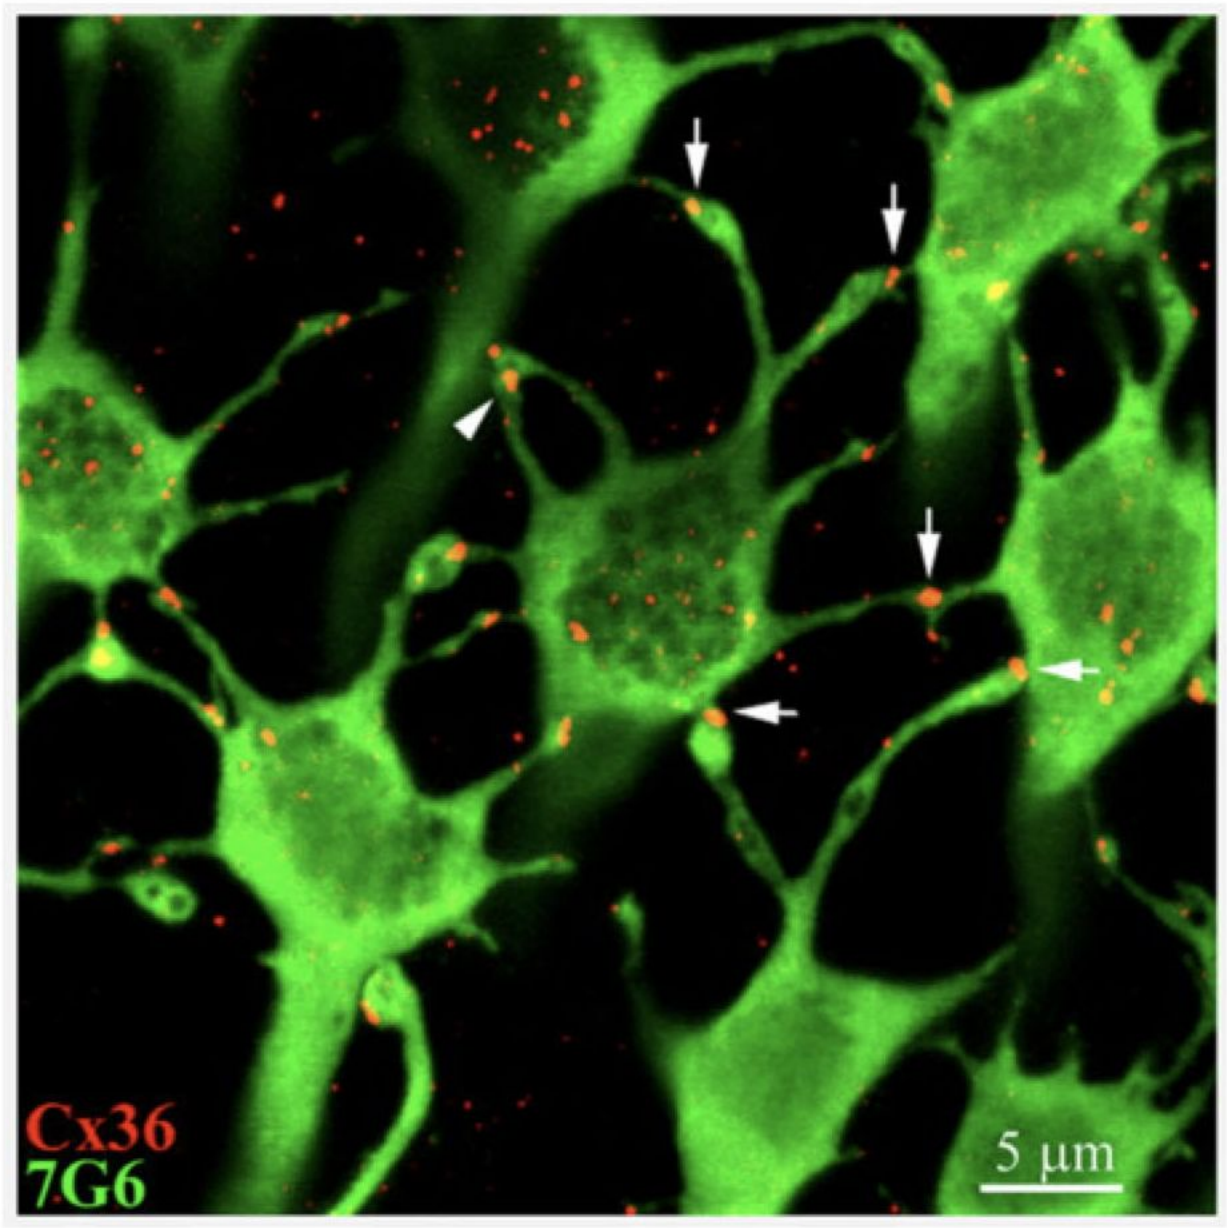

Figure 3. *Connexin 36 is present in telodendria contacts between pedicles of adjacent cones.* Connexin 36 (Cx36, red) is localized at contact points (white arrows) between neighbouring cone terminals (7G6, green, cone arrestin antibody) in macaque retina. Taken from O'Brien et al. (2012) (21).

cells from the retinal circuit, by effectively shunting their input current from photoreceptors. In such a situation, modifying coupling strength could switch the retina from a mode of short integration time in daylight conditions to a mode of long integration time in nightlight conditions (62). In another study, horizontal cell feedback to photoreceptors was shown to differentially affect transient and/or sustained portions of ganglion cell responses (58), and this could provide another mechanism whereby changes in horizontal cell coupling could affect temporal tuning in ganglion cells.

Bipolar cells

Bipolar cells, of which there are at least 10 types (63), pass photoreceptor signals onto amacrine and ganglion cells at glutamatergic synapses (See Webvision chapter Bipolar Cell Pathways in the Vertebrate Retina).

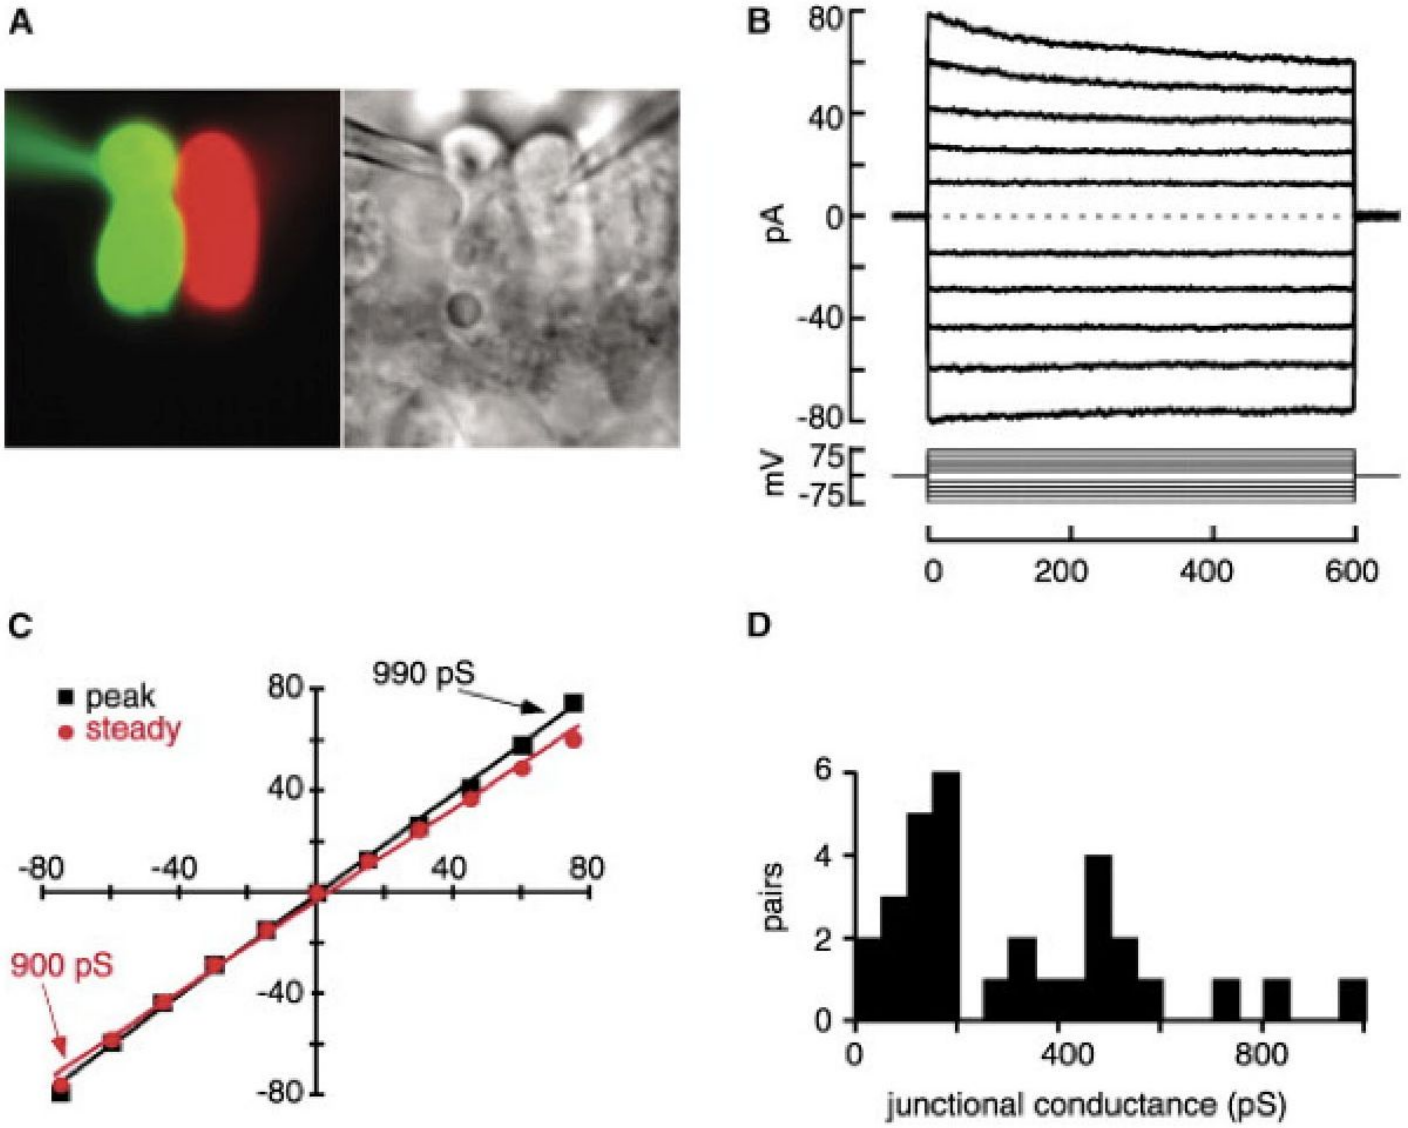

Figure 4. *Paired whole-cell voltage clamp recordings from ground squirrel retina*. **A**, Patch pipette recording from a pair of cones, labelled in green and red, in a retinal slice preparation (shown in grey on the right). **B**, Changing the resting voltage in one cell (*bottom*) results in transjunctional currents in the neighbor (*top*). **C**, Conductance is plotted for both peak and steady state transjunctional currents to a variety of membrane changes in the pre-junctional cell (x-axis represents mV; y-axis represents pA). **D**, Distribution of measured junctional conductances for different pairs of cells. Taken from Devries et al. (2002) (12).

Additionally, bipolar cells can be electrically coupled to other bipolar cells and amacrine cells. Most commonly, bipolar cells are coupled to AII amacrine cells (**Figure 11**) (64), though recent work shows that certain ON cone bipolar cells form gap junctions with non-AII amacrine cells (59, 65). See Webvision chapter on AII amacrine cells.

Gap junctions between bipolar cells can be localized in dendrites (66) or axon terminals (67, 68), though gap junctions between ON cone bipolar cells and AII amacrine cells are localized in the bipolar cell axon terminal (69). In mouse retina, bipolar cell gap junctions contain either Cx36 or Cx45 (**Figure 12**) (18, 70-73).

Bipolar cell to bipolar cell gap junctions are bidirectional and symmetrical, with a junctional conductance of around 1 nS and a coupling coefficient of around 0.3 (**Figure 13**) (66, 74-77).

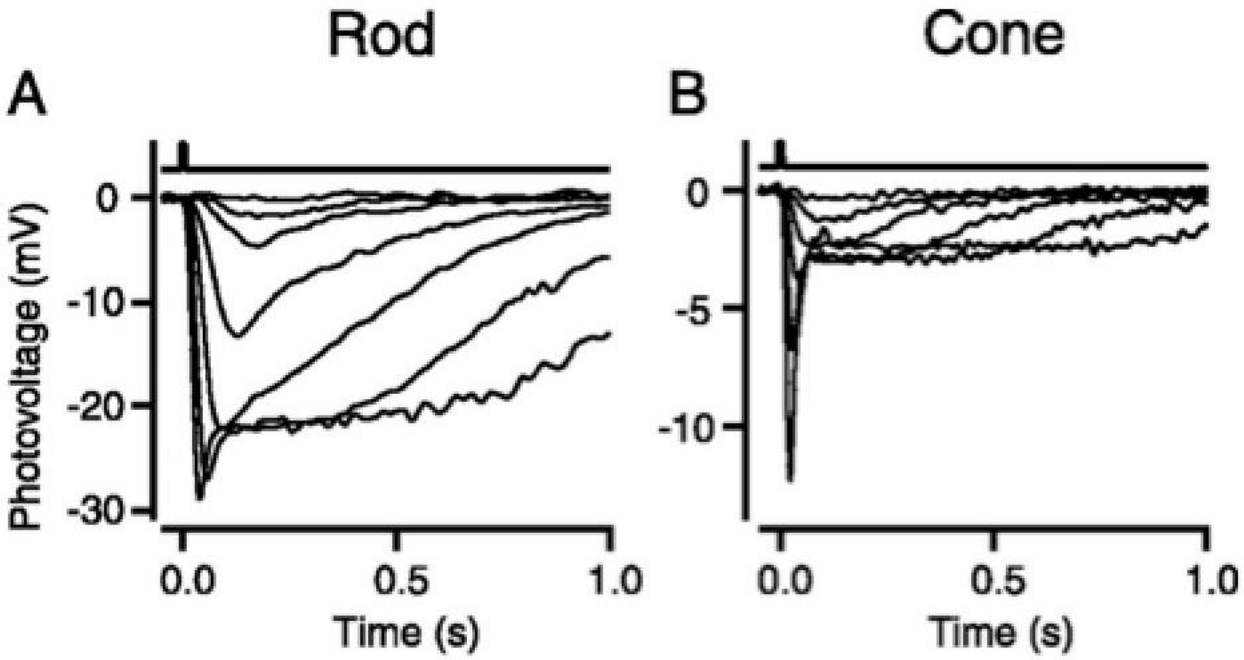

Figure 5. *Rod-generated signals measured in rods and cones of macaque*. **A**, Photovoltage responses from a rod for flashes of increasing brightness (from 0.3 to 803 photons um^{-2}). **B**, Photovoltage responses from a cone for flashes of increasing brightness (from 2.0 to 3874 photons um^{-2}). Slow, rod-like responses are present in cones at dim light levels. The stimulating wavelength is 500 nm. Taken from Hornstein et al. (2005) (13).

ON cone bipolar cells form gap junctions with AII amacrine cells that are bidirectional but asymmetric, though this measured asymmetry is likely an artifact of differences in input resistance. Between ON cone bipolar cells and AII amacrine cells the junctional conductance is approximately 1 nS, with a coupling coefficient between 0.3-0.6 (**Figure 14**) (64, 70, 78-80).

The gap junction conductance between electrically connected bipolar cells increases in the light adapted state, at least as shown in goldfish for Mb-1 bipolar cells (66). While it has been suggested that bipolar cell coupling can result in increased receptive field sizes, which some studies have found to be significantly larger than dendritic field sizes (74, 75, 81), but also see (82), to our knowledge the effect of changing light adaptation state on bipolar cell coupling and receptive field size has never been directly tested. Furthermore, since previous work has shown that light adaptation can produce antagonistic surround receptive fields in bipolar cells (83), such surround inhibition would be expected to counteract excitatory surround responses provided via gap junction inputs from neighbouring cells, thus limiting the ability of gap junction coupling to expand receptive field size. As such, while bipolar cell gap junctions appear to enhance their ability to integrate spatially separated stimuli and preferentially enhance their signaling of low contrast stimuli (84), further study is required to define the effect of light adaptation on the strength of gap junction coupling for bipolar cells, and for examining whether such changes effectively modify receptive field size.

Amacrine cells

Amacrine cells, of which there are more than 45 types (5, 85), provide inhibition, via GABA or glycine release, to bipolar cells, other amacrine cells and ganglion cells. Some amacrine cells can also co-release acetylcholine (86-88), dopamine (89), or glutamate (90). Many amacrine cells form homologous gap junctions (78, 79, 91-93), and heterologous gap junctions with bipolar cells – as described above – and ganglion cells (94, 95). AII amacrine cells form gap junctions with one another in their dendritic arbors (**Figure 15**) (69). It seems likely

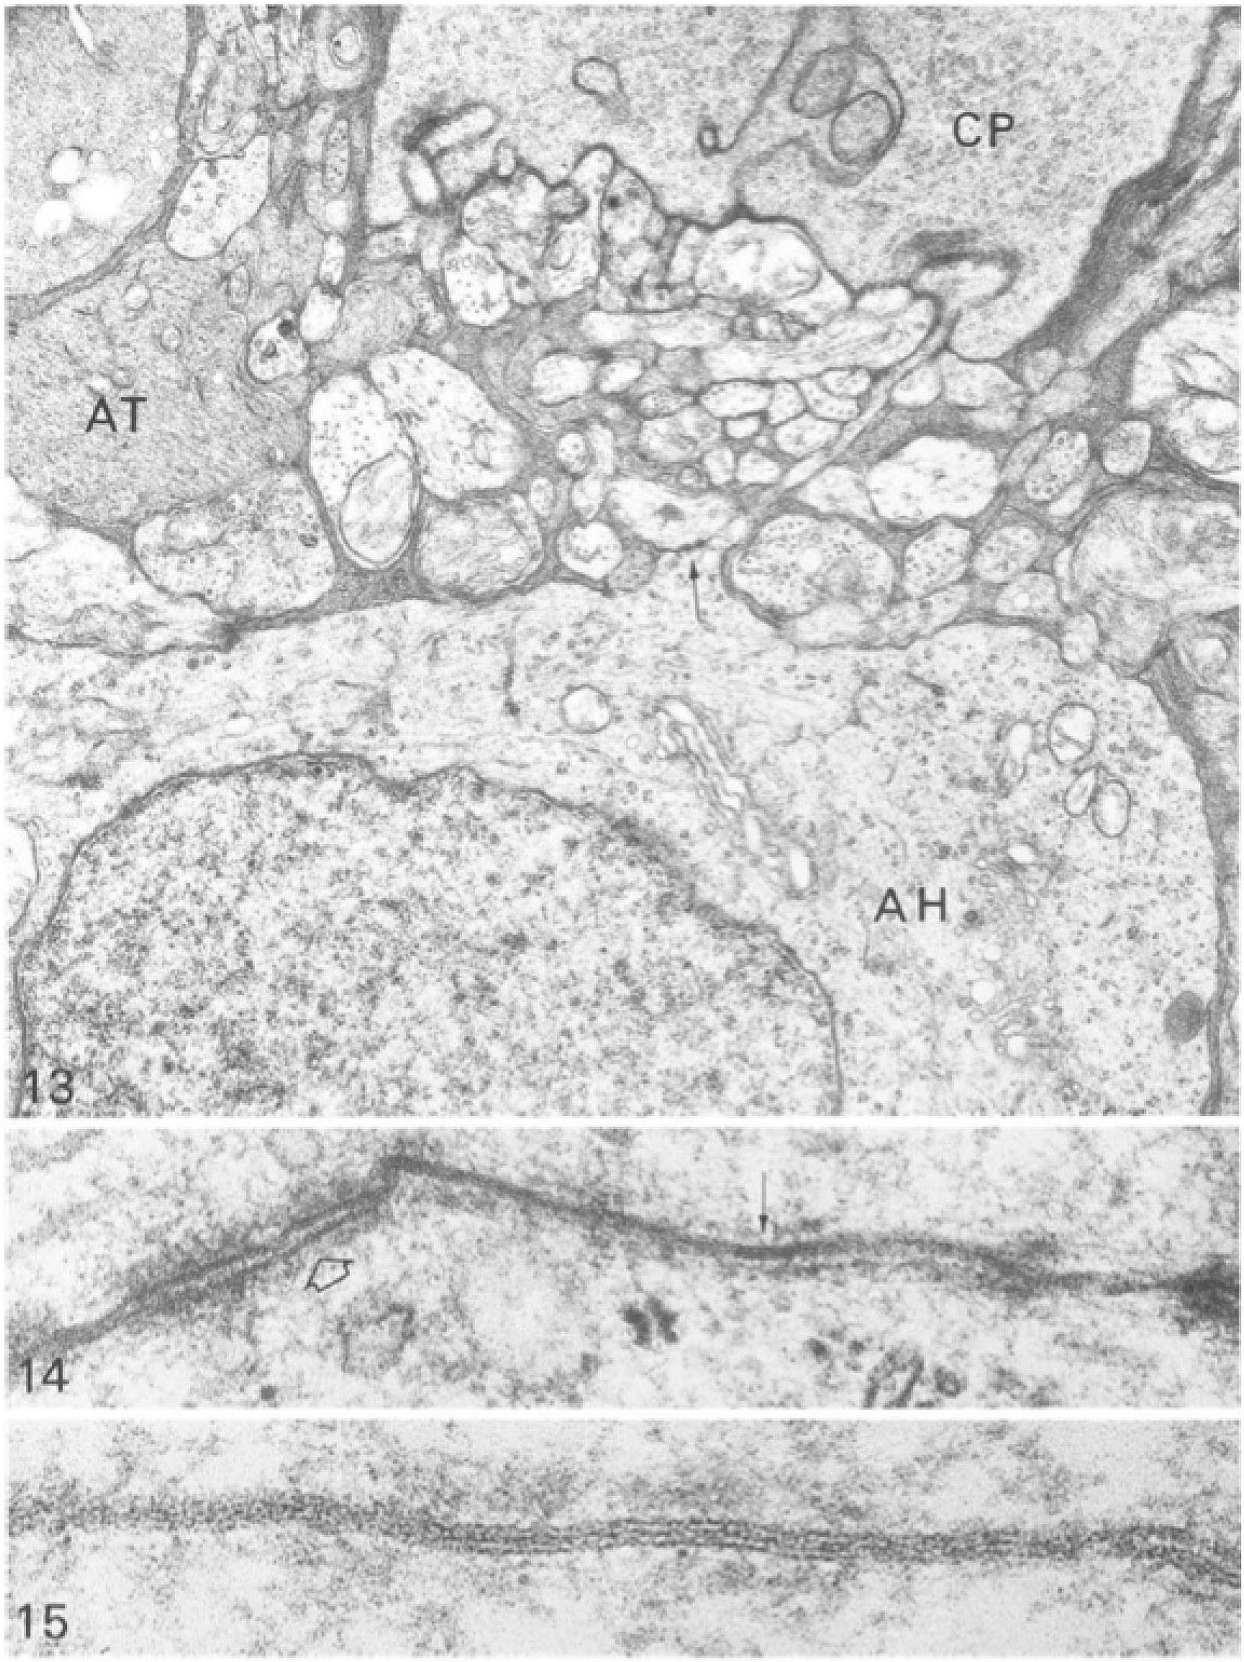

Figure 6. *Gap junctions between horizontal cells*. **13**, An electron micrograph of an A-type horizontal cell (AH), an axon terminal tract (AT) and a cone pedicle (CP) from cat retina, revealing a small gap junction (black arrow) on the horizontal cell dendrite. Magnification: x 18000. **14**, A gap junction (small arrow) between two A-type horizontal cell processes, as well as a macula adherens (large arrow). Magnification: x 90000. **15**, A higher resolution view of gap junctions between two A-type horizontal cell dendrites. Magnification x 180000. Taken from Kolb (1977) (26).

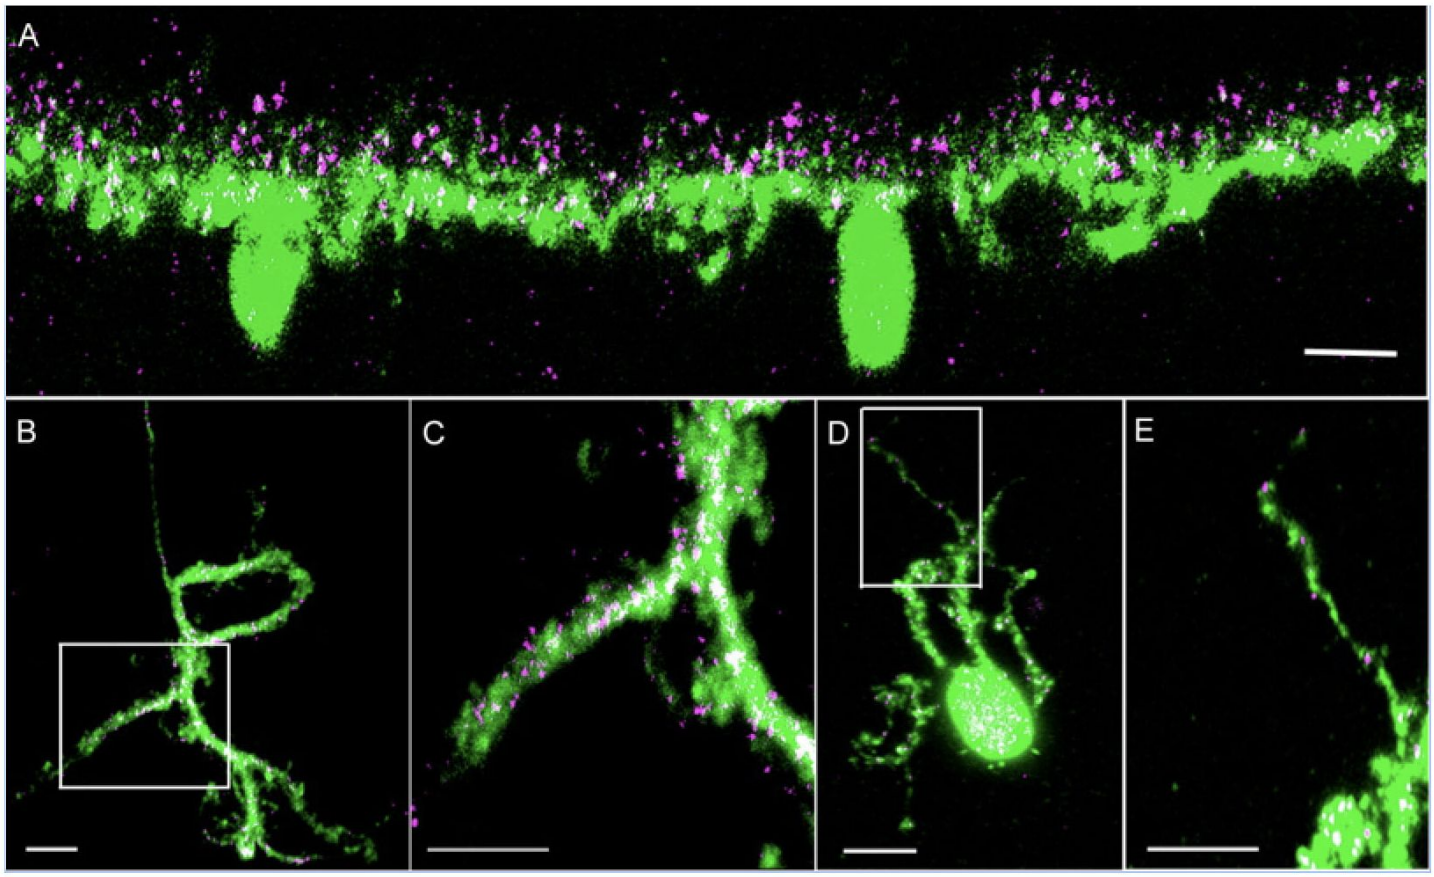

Figure 7. *Cx57 is localized in the processes of mouse horizontal cells*. **A**, Calbindin (green) stained horizontal cells in a retina slice, co-labelled for Cx57 (purple) revealing dense Cx57 expression in horizontal cell processes. **B**, An isolated horizontal axon terminal. **C**, A higher magnification view of the area outlined in (B). **D**, An isolated horizontal cell body and processes. **E**, A higher magnification view of the area indicated in (D). Scale bars: 20 μm in A, B, D; 10 μm in C, E. Taken from Janssen-Bienhold et al. (2009) (41).

that other amacrine cell types also make dendrodendritic gap junctions with amacrine and ganglion cells, as this is often the only location where their processes overlap.

AII amacrine cells appear to form gap junctions with ON cone bipolar cells with Cx36. Coupling between AII amacrine cells is bidirectional and symmetric, with a junctional conductance of ~700 pS and a coupling coefficient of ~ 0.3 (**Figure 16**) (78).

Other amacrine cell types form gap junctions with amacrine or ganglion cells with electrical synapses comprising either Cx36 or Cx45 (96, 97). nNOS-2 amacrine cells, which are the main source of nitric oxide in the mouse retina, have been shown be extensively interconnected with what appear to be Cx45 containing gap junctions, and exhibit a bidirectional and symmetrical conductance, with a junctional conductance that was modeled to be very large (4.4 nS, **Figure 17**) (98). The measured coupling coefficient for nNOS-2 amacrine cell gap junctions was ~0.08 (98).

Light adaptation state appears to strongly control coupling strength in amacrine cells (94). Similar to horizontal cells, tracer coupling experiments indicate that AII amacrine cells exhibit minimal coupling during both very dim and bright conditions, and strong coupling during mid light conditions (**Figure 18**) (94).

Such changes in coupling strength appear to strongly influence receptive field size, as AII amacrine cell receptive fields can be 2-3 times larger than their dendritic fields in the light-sensitized state (94). However, a direct relationship between coupling strength and receptive field size does not appear to hold across all amacrine cell

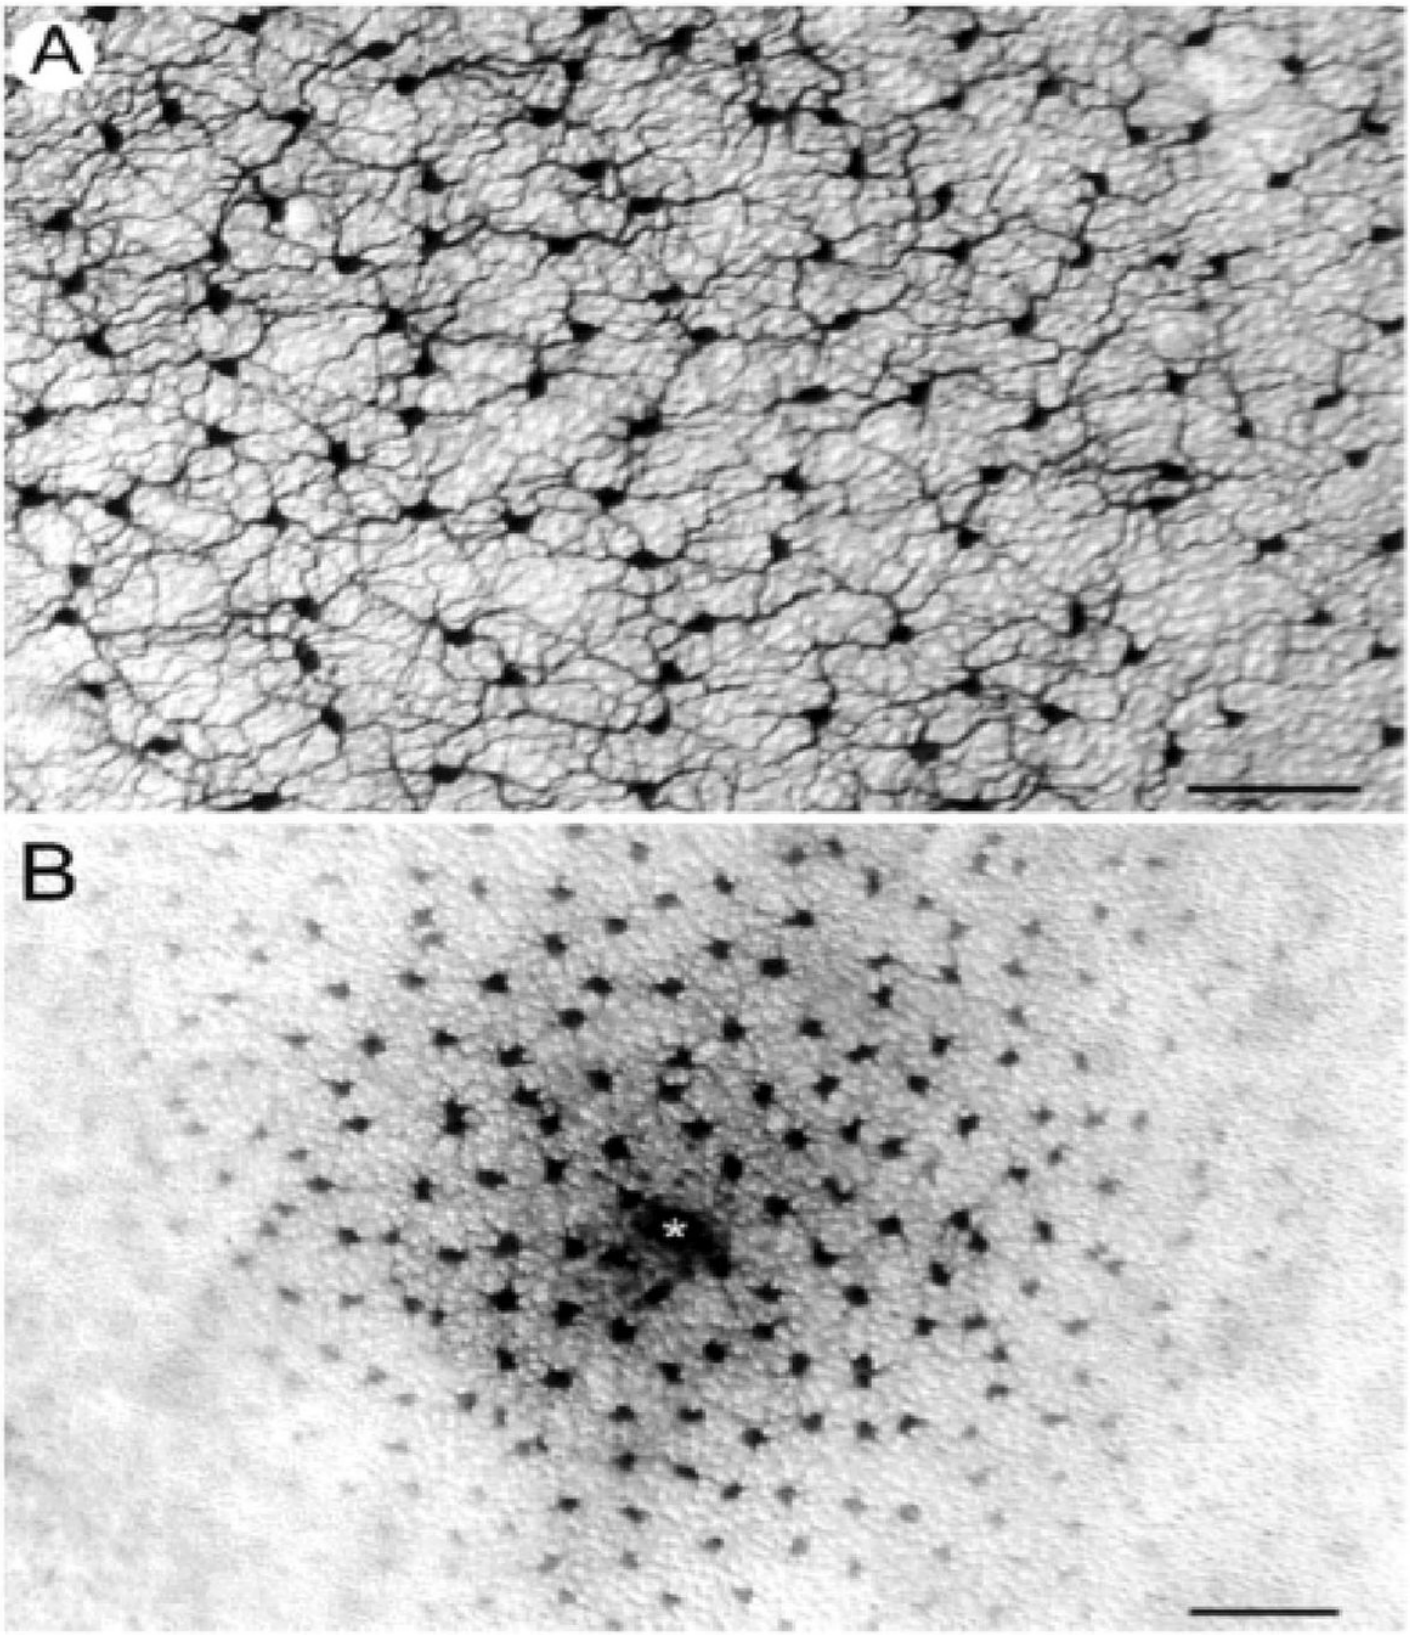

Figure 8. *Extensive tracer coupling in horizontal cells in the dark-adapted rabbit retina.* **A**, Neurobiotin injected into A-type horizontal cell spread into over 1000 neighboring cells, spanning across a distance of over 2 mm (a more restricted view is shown here). **B**, Neurobiotin injected into a B-type horizontal cell spread into over 200 neighboring cells. Scale bar, 50 μm. Taken from Xin and Bloomfield (1999) (51).

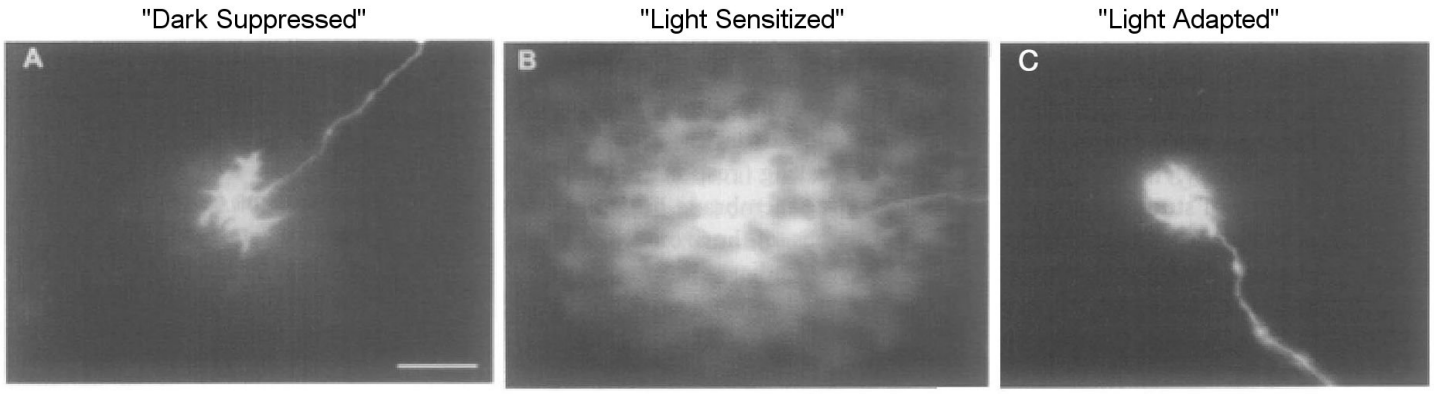

Figure 9. *Triphasic adaptation of horizontal cell tracer coupling.* Injecting Lucifer yellow dye into a single H1 horizontal cell in goldfish retina results in little tracer coupling in dark adapted ("Dark Suppressed") retina (**A**), extensive tracer coupling in the "Light Sensitized" state (**B**), and little if any tracer coupling in the "Light Adapted" state (**C**). Taken from Baldridge (2001) (198).

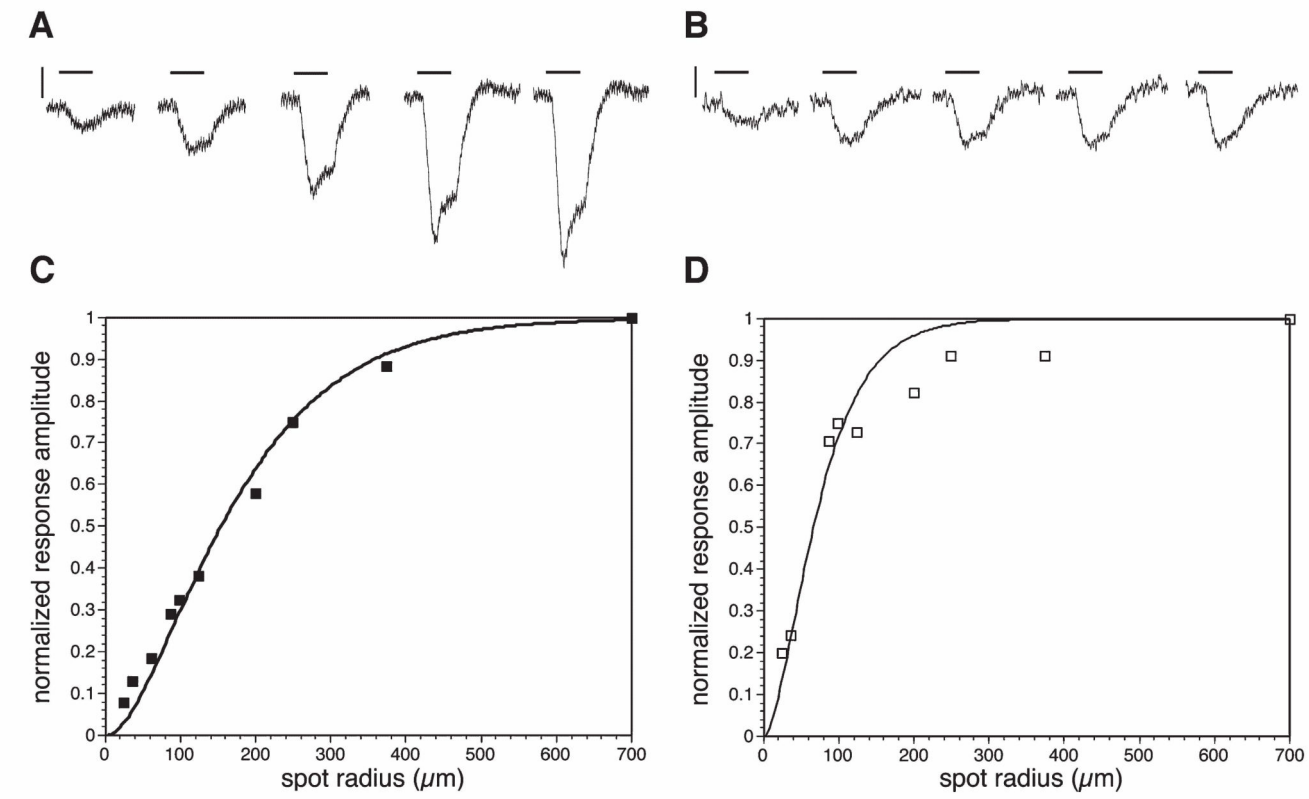

Figure 10. *Spatial integration is impaired in horizontal cells in Cx57 KO mouse retina.* **A**, Spots of light of increasing radii (40, 90, 200, 375, and 700 μm) were presented to a horizontal cell and membrane voltage responses are shown (scale bar, 2 mV). **B**, The same experiment as in (A), but in Cx57 KO retina. **C**,**D**, Response amplitude vs. spot size is plotted for wild type (C) and Cx57 KO (D) horizontal cells. In Cx57 retina, horizontal cells reach their peak response amplitude at small spot sizes. Note that response amplitude is also significantly decreased in Cx57 knockout, as seen in panels A and B. Taken from Shelley et al. (2006) (55).

types. For instance, unlike AII amacrine cells, work with some other types of amacrine cells did not indicate a strong effect of light adaptation on receptive field size, despite the fact that tracer coupling experiments showed light-adaptation dependent changes in tracer coupling patterns (**Figure 19**) (94). Why the effect of gap junction coupling on receptive field size does not appear consistent across all amacrine cell types remains unclear, though it could have to do with the fact that the dendrites of some amacrine cell types appear to perform local

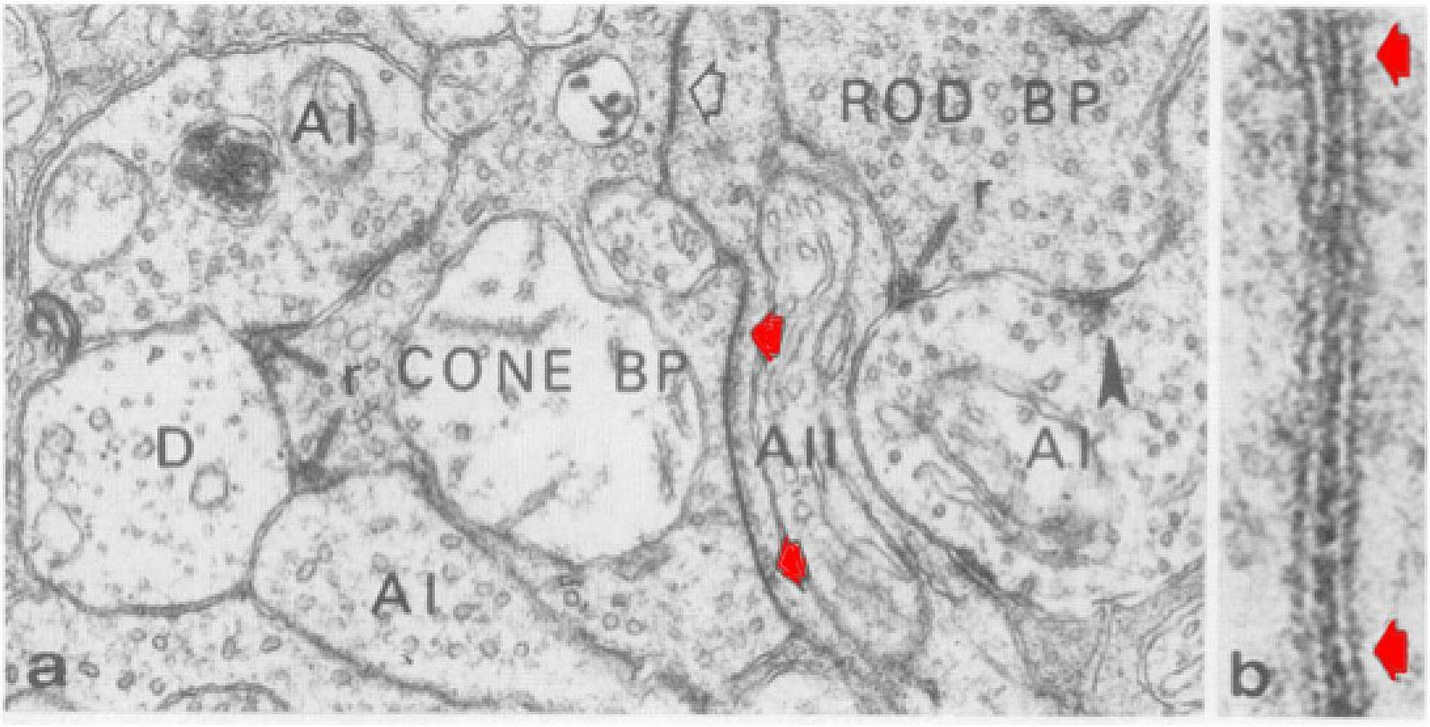

Figure 11. Gap junctions between a cone bipolar cell and an AII amacrine cell. **a** An electron micrograph from a section of cat retina showing a cone bipolar cell (CONE BP), that makes extensive gap junctions connections (red arrows) with an AII amacrine cell. Also seen are bipolar cell ribbon synapses (r) onto a ganglion cell dendrite (D) as well as a synapse of an AI amacrine cell making a synapse (arrowhead) on a rod bipolar cell (ROD BP). AI is also known as A17. Magnification: x 33000. **b** A higher resolution view of a gap junction between a bipolar cell and an AII amacrine cell. Magnification: x 250000. Taken from Kolb and Famiglietti (1974) (64).

computations (99), which might therefore not require global changes in receptive field size for changes in junctional conductance to have an effect on circuit function. Another possibility for the difference of light adaptation on amacrine cell coupling could be differential regulation by dopamine. Indeed, gap junction coupling of A8 amacrine cells, which are coupled to both ON and OFF bipolar cells with Cx36 gap junctions, does not appear to be modulated by dopamine receptor D_1 activation, in contrast to AII amacrine cells (100). Finally, in mouse nNOS-2 amacrine cells, there appears to be a remarkable self-regulation between light activation and coupling state. nNOS-2 cells are extensively electrically coupled in the dark-adapted retina, whereas upon light activation they produce nitric oxide which in turn decouples the network (98). Whether this light-activated decoupling affects receptive field size remained to be tested.

Ganglion cells

Ganglion cells, of which there are upwards of 30 types (101-103), receive excitatory glutamatergic input from bipolar cells and inhibitory GABAergic and glycinergic input from amacrine cells, and send their signals, via the optic nerve, to multiple higher visual areas (6, 7) (See Webvision chapter Visual Responses of Ganglion Cells). Ganglion cells also form dendrodendritic gap junctions with amacrine cells and other ganglion cells (**Figure 20**) (91, 95, 104-108).

Ganglion cell gap junctions are frequently comprised of connexin 36 (**Figure 21**) (96, 109-111), though some contain connexin 45 (109) and possibly also connexin 30.2 (109).

Ganglion cell to ganglion cell coupling appears to be exclusively homologous, with no coupling between different ganglion cell types (95, 105, 112, 113), though possibly there are exceptions (114). Furthermore, distinct ganglion cell subtypes have unique coupling patterns (Figure 22) (95). Less is known about ganglion cell-

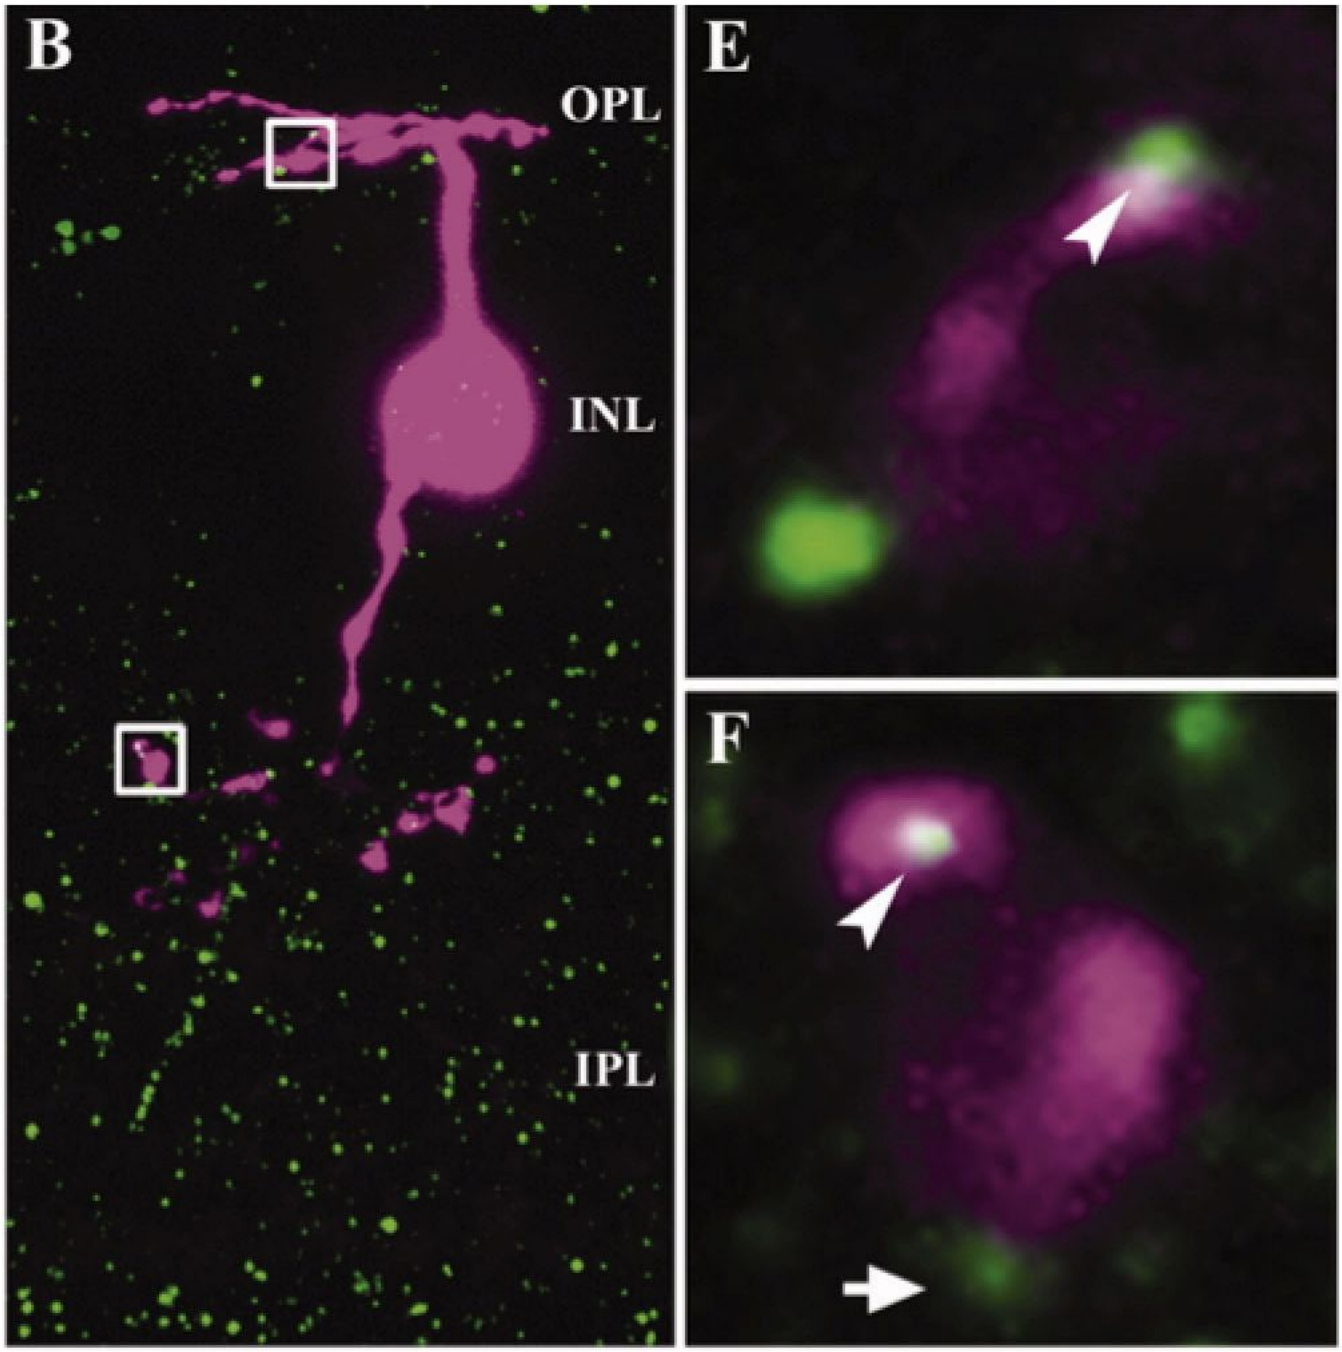

Figure 12. *Connexin 45 is present on certain bipolar cells*. **B**, An Alexa-594 filled type 1 cone bipolar cell in mouse retina (magenta) stained for Cx45 (green). Overlap between a bipolar cell dendrite and Cx45 (**E**), and a bipolar cell axonal bouton and Cx45 (**F**) are show for regions outlined in (B). Taken from Hilgen et al. (2011) (72).

amacrine cell coupling, though tracer coupling work suggests that specific ganglion cells form gap junctions with specific types of amacrine cells (**Figure 22**) (95).

Gap junctions between ganglion cells are bidirectional and have a symmetrical junctional conductance of around 1 nS and a coupling coefficient of around 0.15 (**Figure 23**) (106, 113).

In ganglion cells, light adaptation appears to control coupling strength, with coupling being reduced in the dark adapted state and increased in the light adapted state (at least as has been shown for OFF α cells in the rabbit retina (115); though this may not be the case for all ganglion cell types (111)). Interestingly, while increased

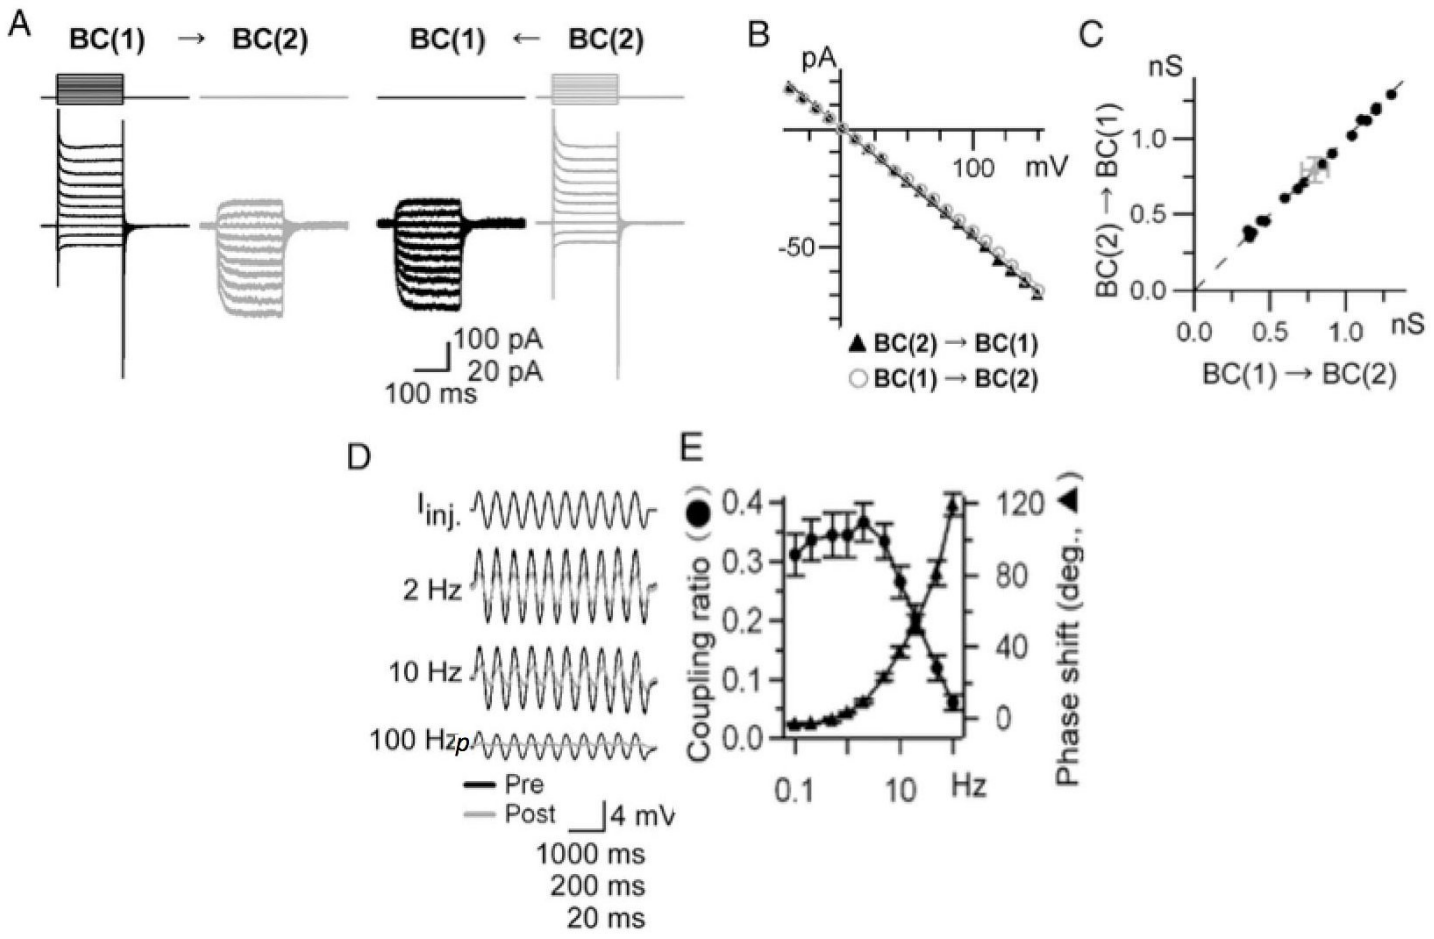

Figure 13. *Biophysical properties of gap junctions between bipolar cells*. **A**, A pair of Mb1 bipolar cells in goldfish retina were voltage clamped at -60 mV, and voltage steps (-100 to +90 mV) were applied to one cell in the pair while currents were measured in the other cell. **B**, The junctional I-V curves from the experiment shown in (A). **C**, Bidirectional junctional conductance plotted for 16 pairs of cells. **D**, Example voltage responses (both pre and postjunctional) to sinusoidal current injections into a prejunctional cell (20 pA peak to peak current injection) at various frequencies. **E**, Coupling ratio (i.e. coupling coefficient) and phase shift plotted against frequency. Taken from Arai et al. (2010) (66).

coupling strength does not seem to alter the size of the classical (spiking) receptive field (115, 116), gap junction inputs from neighboring cells endow electrically coupled ganglion cells with extensive subthreshold excitatory surround receptive fields (113). Furthermore, for many ganglion cells, receptive field size actually decreases in light adapted conditions (117-119), likely due to a strengthening of inhibitory surround responses arising from either horizontal and/or amacrine cells. For instance, it was found that for mouse ON and OFF α-like ganglion cells (59) and directionally selective ganglion cells (60), surround inhibition in ganglion cells is provided by wide-field amacrine cells, and this surround inhibition appears to be activated only at light intensities that activate cones. In this bright light, amacrine-cell-mediated surround inhibition is thought to rely on electrical coupling between a wide-field amacrine and ON cone bipolar cells. Knocking out Cx36 eliminates the bright light induced reduction in receptive field size of α-like ganglion cells (59). As such, classical receptive field size in ganglion cells appears to be most strongly controlled by amacrine cell mediated surround inhibition: one recent study suggests that horizontal cells may only contribute as little as ~15% to the surround inhibition of ganglion cells (58).

Much less is known about the properties of ganglion cell-amacrine cell coupling. Nonetheless, the gap junction strength appears to be strong enough such that current injected into one ganglion cell can pass via gap junctions

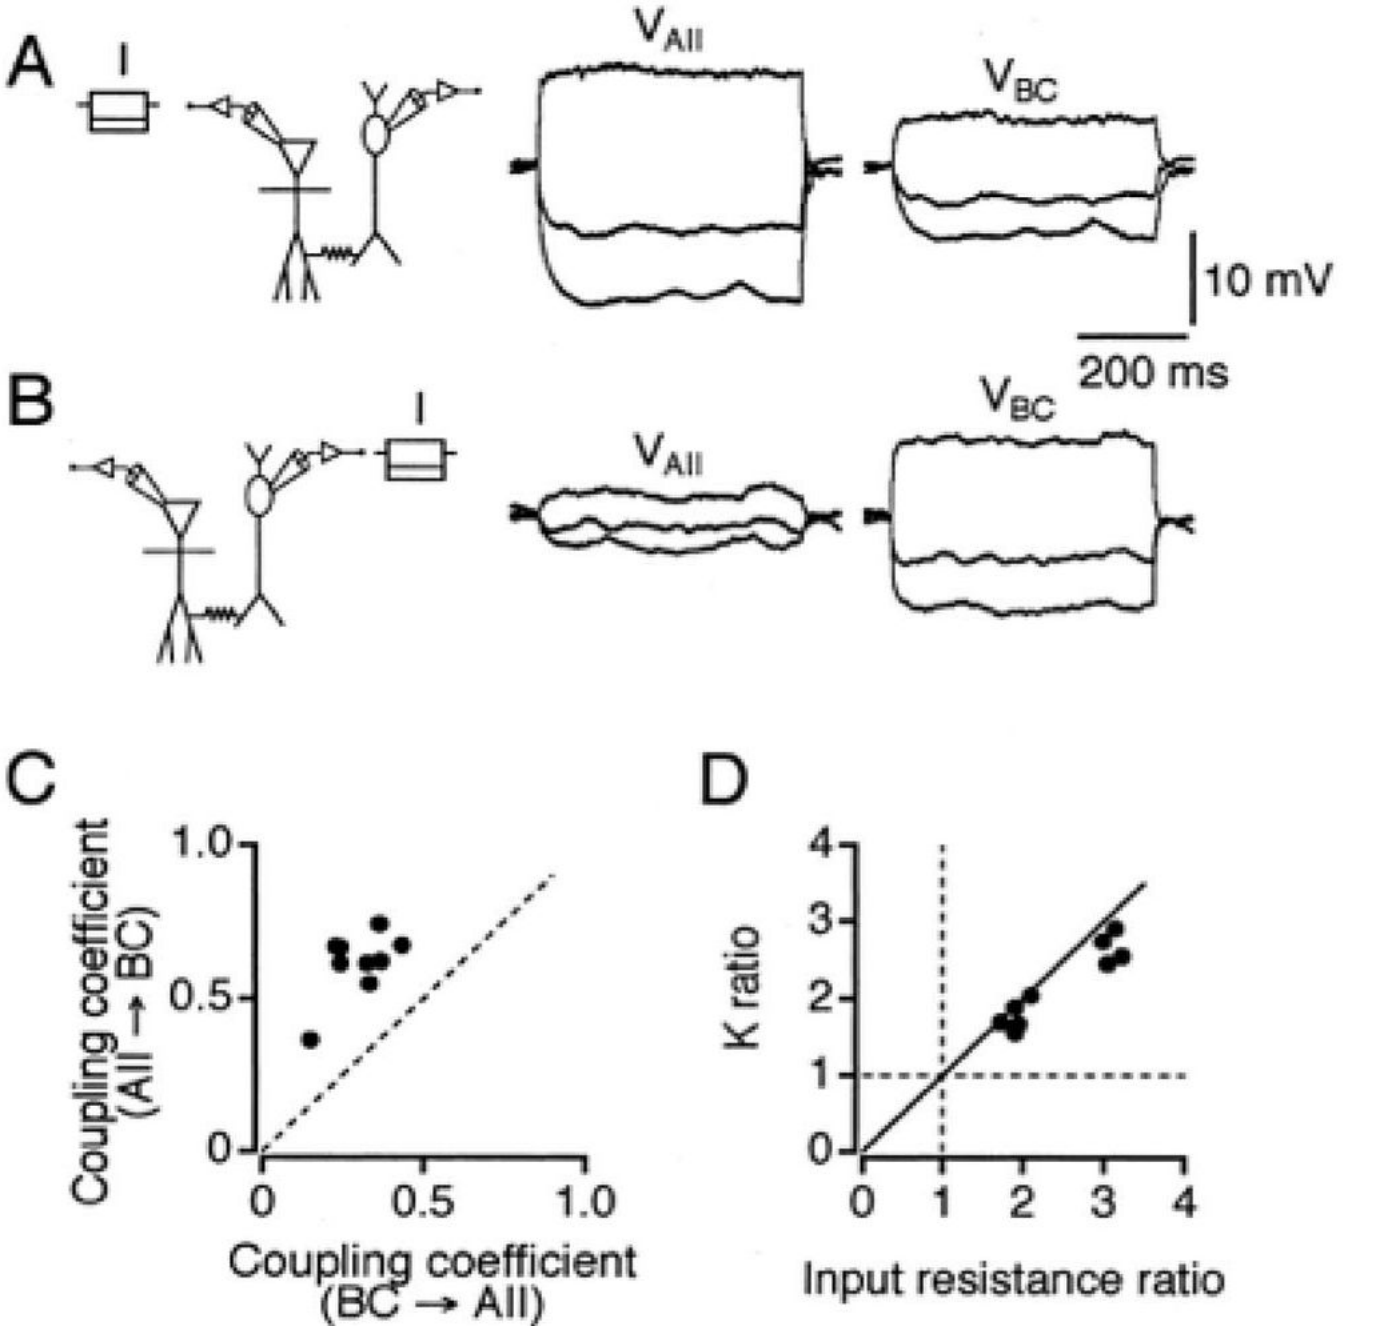

Figure 14. *Coupling coefficient of gap junctions between ON bipolar cells and AII amacrine cells.* **A**, Paired current clamp recording from an ON bipolar cell and an AII amacrine cell in rat retina, with current pulses (-50, -25 and +50 pA) applied to the AII amacrine cell. **B**, The same experiment but with current pulses (-20, -10 and +20 pA) applied to the bipolar cell. **C**, Plotting the reciprocal coupling coefficient suggests asymmetric coupling. **D**, Compensating for differences in input resistance between ON bipolar cells and AII amacrine cells results in a more symmetrical coupling coefficient between pairs of cells. Taken from Veruki and Hartveit (2002a) (199).

into an amacrine cell, and then via additional gap junctions into a nearby ganglion cell, driving measurable responses in the indirectly coupled ganglion cell (**Figure 24**) (120).

Gap junctions and scotopic vision

In dark (scotopic) light conditions, when rods are the active photoreceptor, gap junctions are critical for passing rod-mediated signals throughout the retina. In the classical rod pathway, rods form glutamatergic synapses with

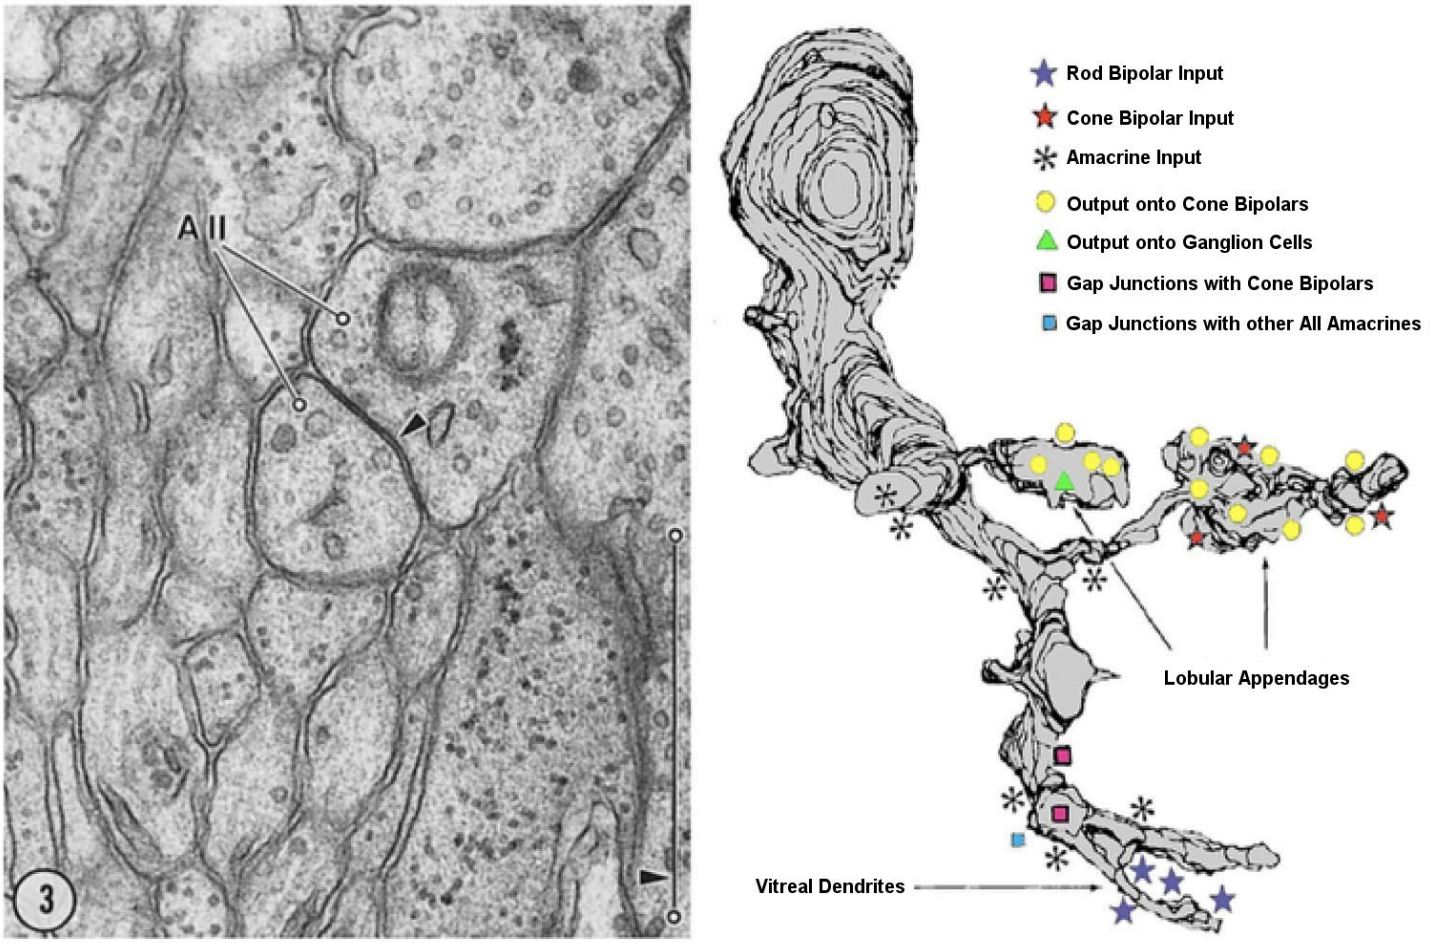

Figure 15. *Electrical synapses between AII amacrine cells. Left*, an electron micrograph showing a gap junction (arrow) between a pair of AII amacrine cells in rabbit retina. Magnification: x27000. *Right*, reconstruction of a portion of an AII amacrine cell indicating the location of different types of synaptic inputs and outputs. Adapted from Strettoi et al. (1992) (69).

rod bipolar cells, which in turn form glutamatergic synapses with AII amacrine. These AII amacrine cells then transfer rod-generated signals to the ON cone bipolar cells, via gap junctions with ON cone bipolar cells. In addition, AII amacrine cells also make glycinergic synapses with OFF bipolar cells (**Figure 25 A**) (64, 79, 80, 121-124). In the second route, rod signals pass directly into cones, via rod-cone electrical synapses, and are thus passed onto the inner retina (**Figure 25 B**) (36, 122, 125, 126). In the third route, some rods appear to form glutamatergic synapses with OFF bipolar cells, and pooling of signals between electrically coupled rods has been hypothesized to increase sensitivity of this pathway (**Figure 25 C**) (17, 127, 128).

Consistent with an important role for gap junction signaling during rod-mediated scotopic vision, knocking out Cx36 greatly impairs rod-mediated responses in the inner retina (**Figure 26**) (70, 122, 126). Additionally, gap junctions between certain types of amacrine and ganglion cells could also aid in high-sensitivity detection of dim light (129).

Gap junctions are thought to play another important role in rod signaling by allowing rods to increase their signal-to-noise ratio. Intrinsic noise in photoreceptors is unique to individual cells, whereas gap junctional coupling allows light-evoked signals to be shared, resulting in more effective detection of relatively weak signals and a decrease in response variability. Note however that these gains may result in a loss of absolute sensitivity and resolution in dim conditions (12, 13, 15, 32, 130-132). A final possible role for gap junctions in rod signaling relates to the nature of synaptic transmission between rods and rod bipolar cells. There appears to be significant

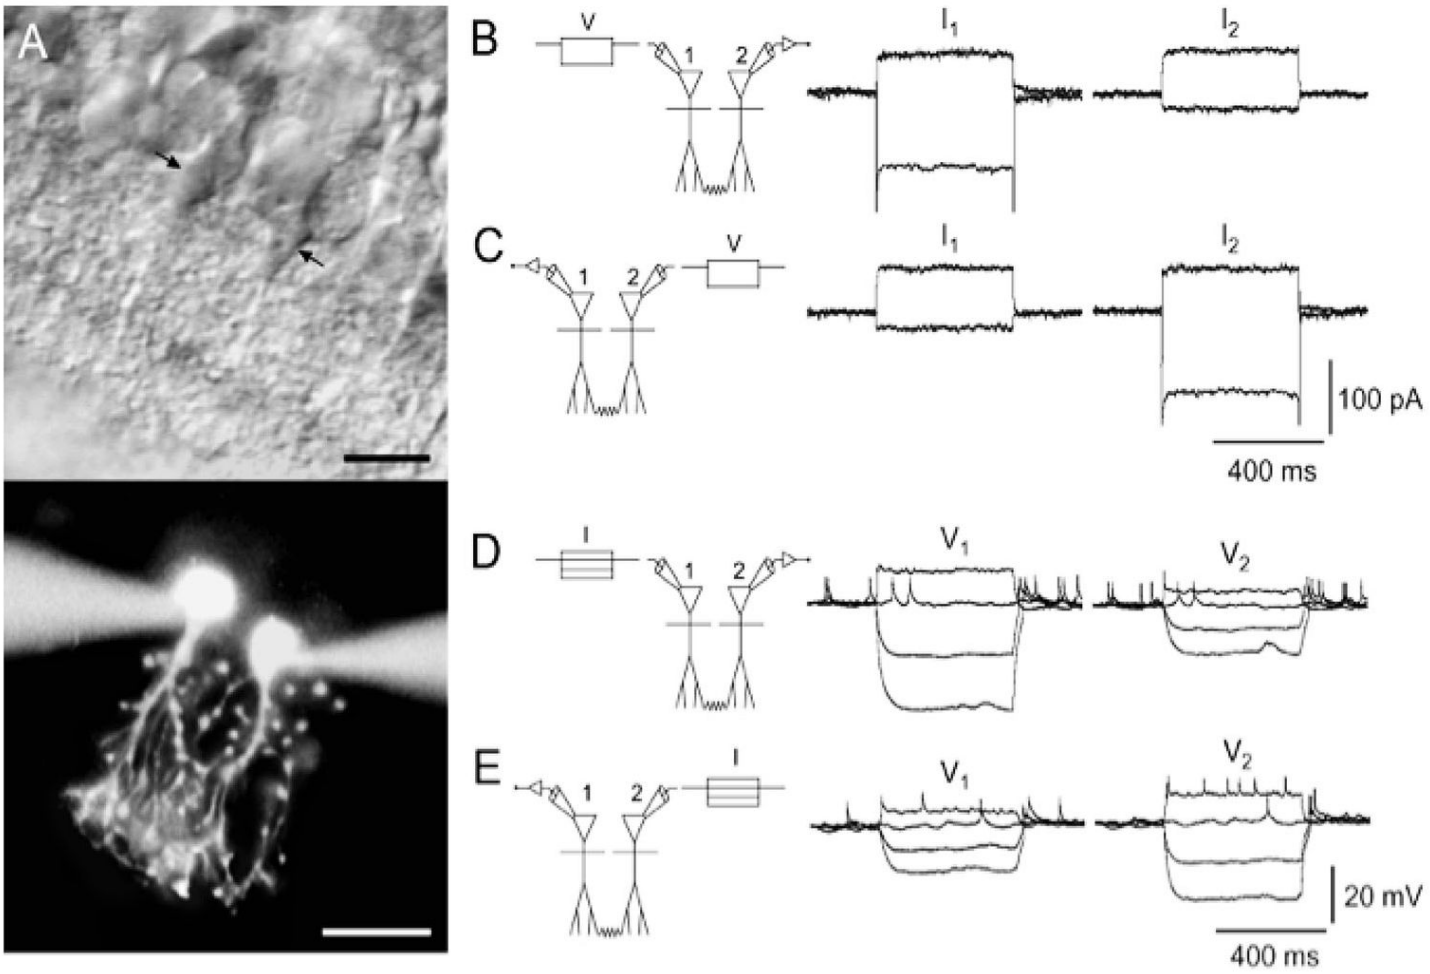

Figure 16. *Properties of electrical synapses between AII amacrine cells*. **A**, A paired recording from AII amacrine cells in a slice from rat retina (top view, DIC; bottom view, fluorescence from Lucifer yellow delivered via the patch pipettes). **B**,**C**, Paired voltage clamp recordings, with cells held at -60 mV, and voltage steps (-30 mV and +10 mV) injected into one of the cells while current is monitored in the other cell. **D**,**E**, Paired current clamp recordings when current steps (-50, -25, 0 and +25 pA) are injected into one of the cells while voltage is monitored in the other cell. Taken from Veruki and Hartveit (2002b) (78).

signal clipping (i.e. saturation of synaptic transmission) between rods and rod bipolar cells, and it has been posited that electrical coupling between rods could allow spatially-restricted visual stimuli to activate several rods, via junctional spread, and that this activated group of rods would then more effectively activate bipolar cells (133).

Gap junctions and synchrony

One of the best described roles for gap junctions in the CNS is that they can synchronize activity between coupled cells (134, 135). Classical work in the retina revealed that neighboring retinal ganglion cells exhibit significant spike synchrony (136-139). Subsequent studies verified that electrical synapses are responsible for driving diverse types of fine-scale synchrony between ganglion cells, in many species (112, 116, 140-143).

Correlations between neighbouring pairs of ganglion cells are generally classified, based on temporal characteristics, as either narrow, medium or broad (**Figure 27**) (140, 142, 144). Narrow synchrony occurs within ± 2 ms, with a trough in the cross-correlogram at 0 ms delay. Medium correlations have a cross-correlogram peak at 0 ms delay, and occur somewhere between 2-10 ms (144), ~ 25-50 ms (140), and less than 100 ms (142). Broad correlations generally exhibit a 0 ms delay peak in the cross-correlogram, and occur on a timescale of

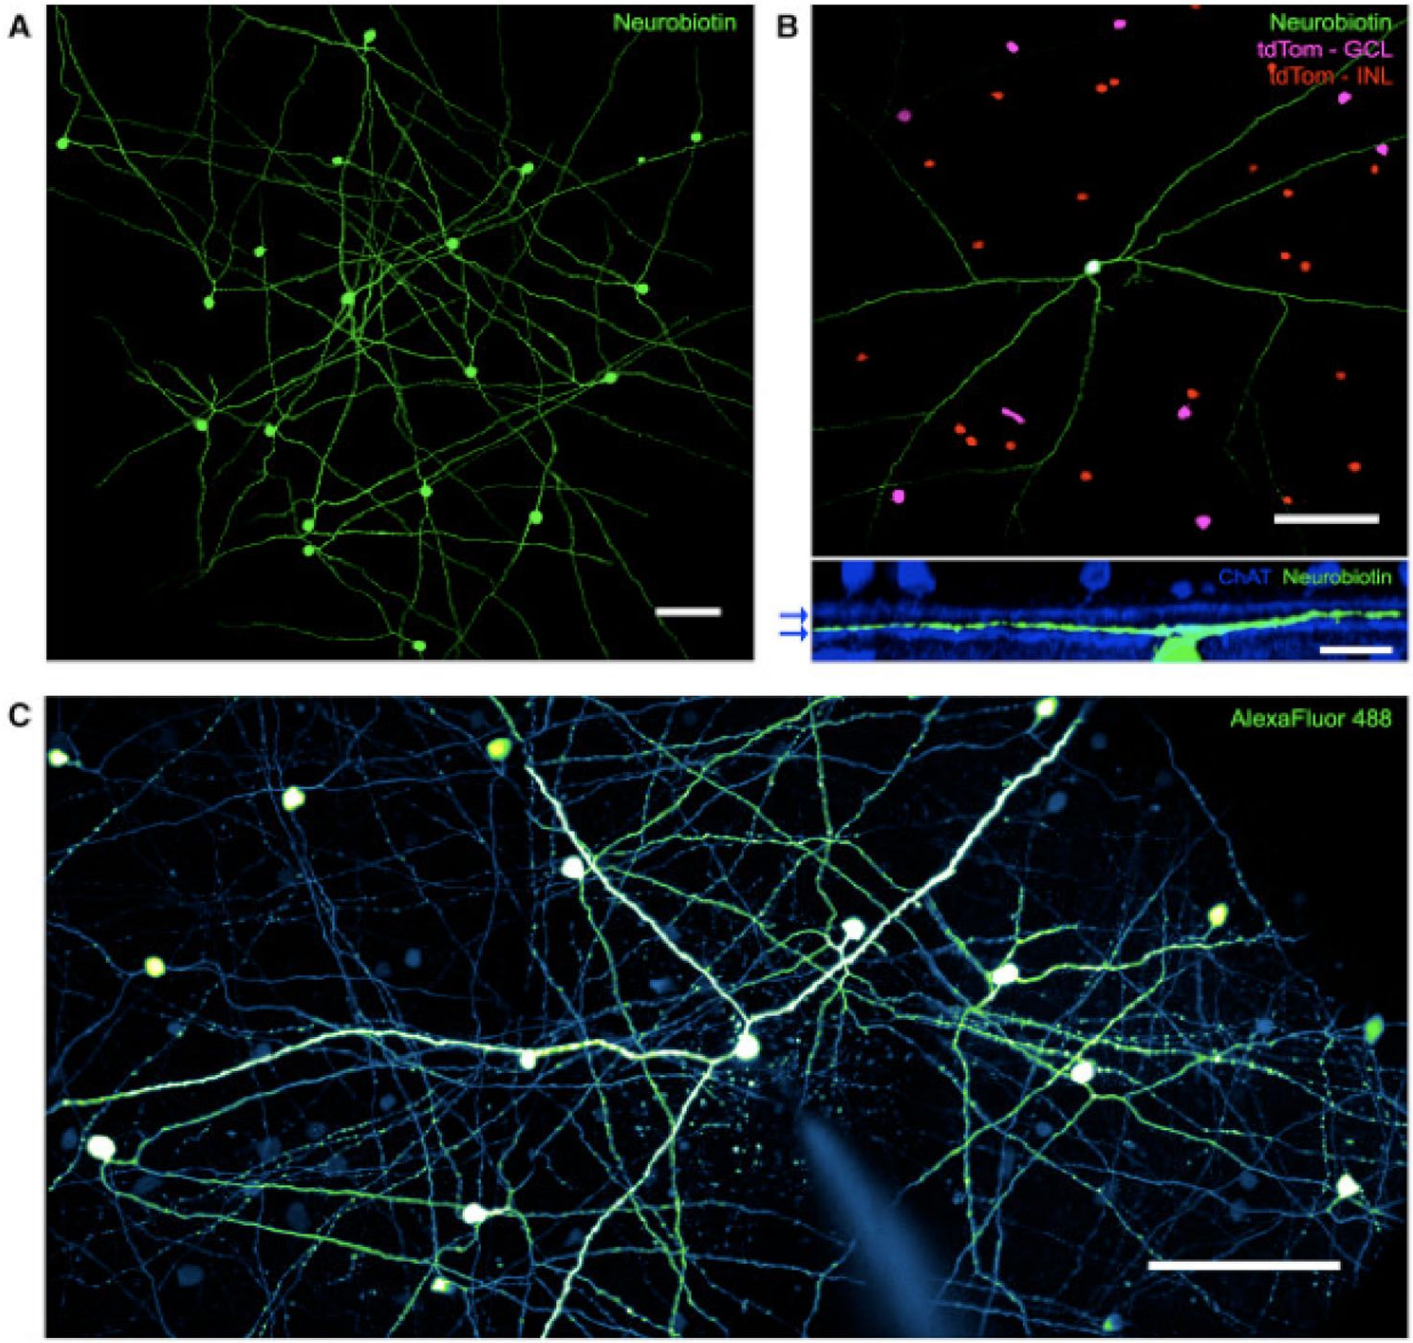

Figure 17. *Tracer coupling between nNOS-2 amacrine cells in mouse retina*. **A**, Tracer coupling when a single amacrine cell in the center of the field of view was injected with Neurobiotin (green). **B** (*top*), Injecting an nNOS-2 amacrine cell with Neurobiotin in the presence of the gap junction blocker meclofenamic acid results in no neighbouring cells being tracer coupled. Red and pink cells indicate the positions of nearby nNOS-2 amacrine cells in both the ganglion cell layer (GCL, pink) and the inner nuclear layer (INL, red). **B** (*bottom*), Side projection of a Neurobiotin (green) filled nNOS-2 amacrine cell co-stained with choline acetyltransferace (ChAT) which labels starburst amacrine and helps to delineate the inner plexiform layer. **C**, A 2-photon image from an acute retinal preparation showing that Alexa Fluor 488 (green), delivered to a single nNOS-2 amacrine via a patch pipette, can spread throughout the coupled network. Blue represents tdTomato transgenically labelled nNOS-2 amacrine cells. Taken from Jacoby et al. (2018) (98).

around 50 ms (144), greater than 50 ms (140) and greater than 100 ms (142), though between pairs of ON and OFF ganglion cells, broad correlations can exhibit a trough at 0 ms, indicative of a slow anti-correlation (137, 138, 144).

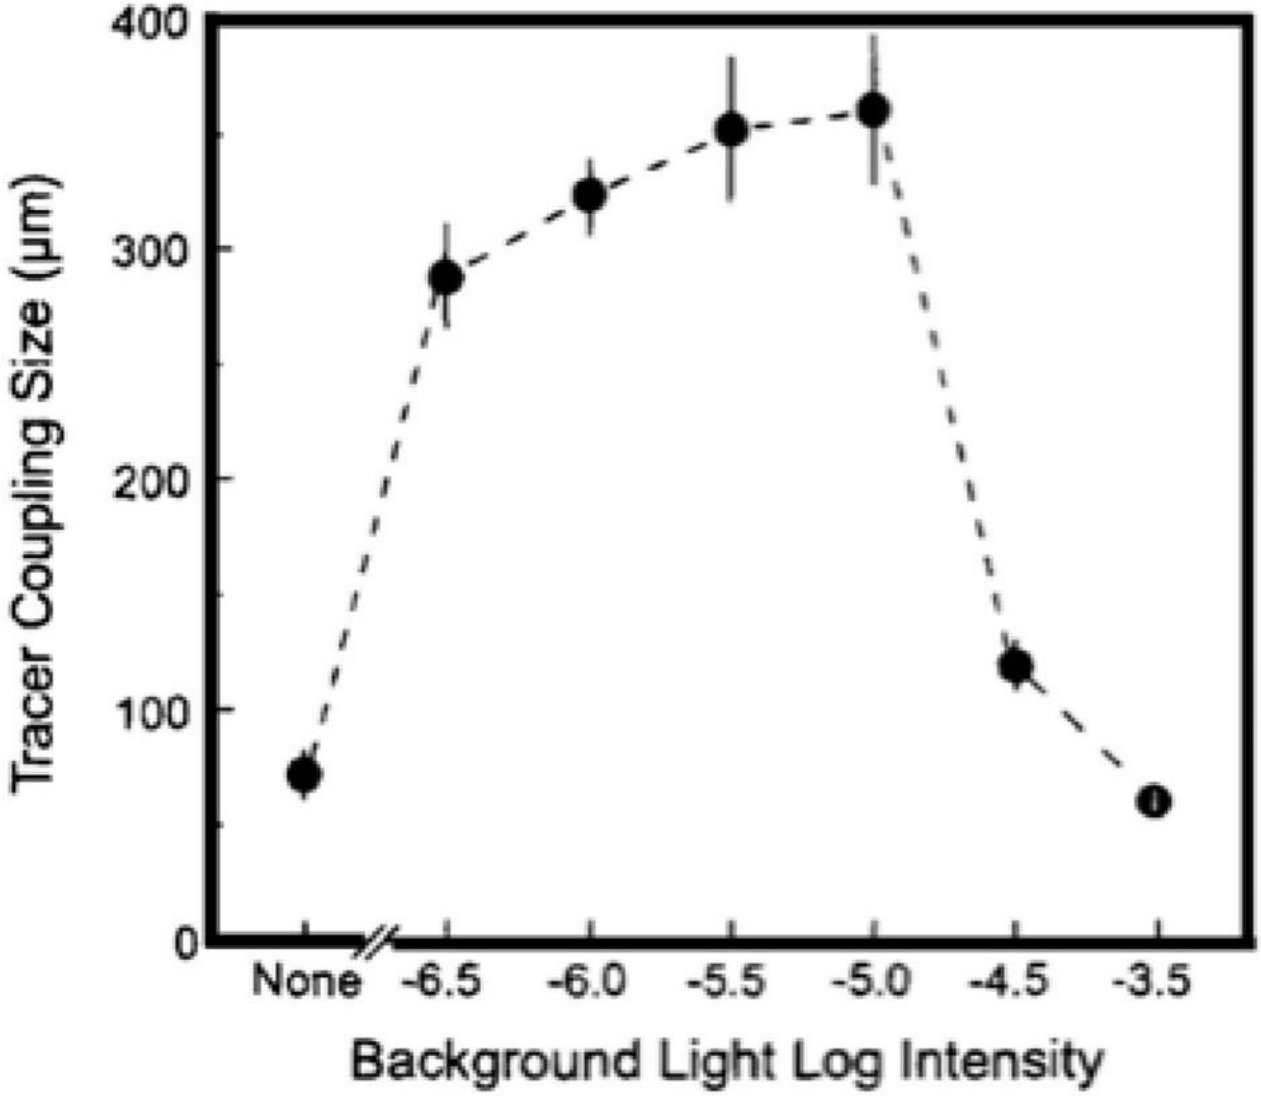

Figure 18. *Coupling between AII amacrine cells in rabbit retina is controlled by illumination conditions*. The average extent of tracer coupling in AII amacrine cells when Neurobiotin was injected into a single AII amacrine cell at different background intensities of light. Taken from Bloomfield et al. (1997) (200).

Pharmacological and genetic knockout experiments have been performed to tease apart the role of electrical and chemical synaptic transmission in these different types of ganglion cell correlations. Pharmacological studies indicate that narrow and medium correlations are unaffected by a cocktail of chemical synaptic blockers, but are inhibited by application of gap junction blockers (140). Cx36 knockout experiments have indicated that broad correlations may also rely upon gap junction signaling (142). Based on these studies, it is thought that broad correlations arise initially in photoreceptors. In contrast, medium correlations are thought to be generated when pairs of ganglion cells are indirectly coupled via an amacrine cell (116, 140, 142, 144, 145), and narrow correlations form between reciprocally coupled ganglion cells (106, 111, 112, 116, 139, 140, 142, 143). In the rest of this section, we mostly focus on homologous coupling between ganglion cells and narrow correlations.

It is thought that narrow spike synchrony arises when one neuron fires an action potential and thus biases spike firing in its neighbor within a short time window. However, as gap junctions act as low-pass filters which significantly reduce the amplitude of action potential mediated signals as they pass across the junction **(Figure**

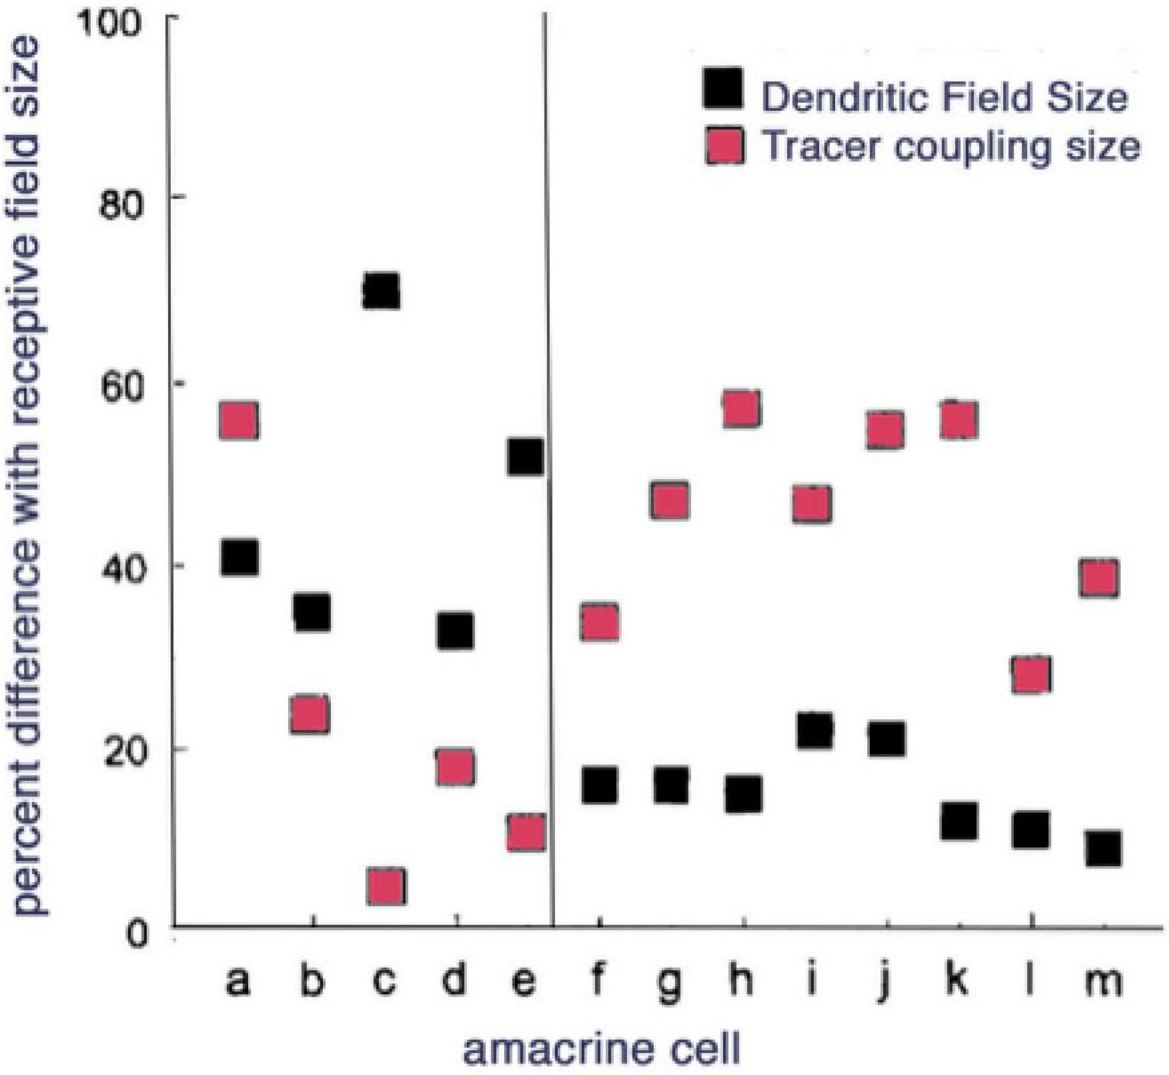

Figure 19. *Relationship between tracer coupling and receptive field size in rabbit amacrine cells.* A scatterplot comparing how different the receptive field size is from the dendritic field size (black squares) and the extent of tracer coupling (pink squares). Cells to the left of the dotted vertical line are AII amacrine cells and have receptive fields closer in size to their tracer coupled networks than their dendritic fields, whereas the non- AII amacrine cells to the right of the vertical line have receptive fields that more closely align with their dendritic fields. Taken from Bloomfield and Xin (1997) (200).

28) (134, 135, 146), it was not immediately evident how such small signals can generate such robust synchrony (120).

While it has been suggested that an action potential in one ganglion cell can directly drive a spike in a coupled neighbour (112), more direct experimental evidence indicates that action potentials in one ganglion cell practically never drive suprathreshold responses in coupled ganglion cells (143). Consistent with this finding, early work in the field suggested that a spike in one ganglion cell will directly drive a spike in a coupled neighbor with a success rate of less than 5% (139). Furthermore, the classical receptive field of ganglion cells is not significantly increased by the presence of gap junctions (but see also112, 113, 116). Why is a spike in one ganglion cell ineffective in directly driving spikes in a neighour? It turns out that in ganglion cells, coupled spikelets – at least when measured with a patch-pipette at the post-junctional soma – are small in amplitude (**Figure 23**; ~ 1 mV), though they do arrive with little delay (< 1 ms) (113). As such, coupling between ganglion cells is similar to coupling between most other neurons in the CNS, in which spiking in a pre-junctional neuron

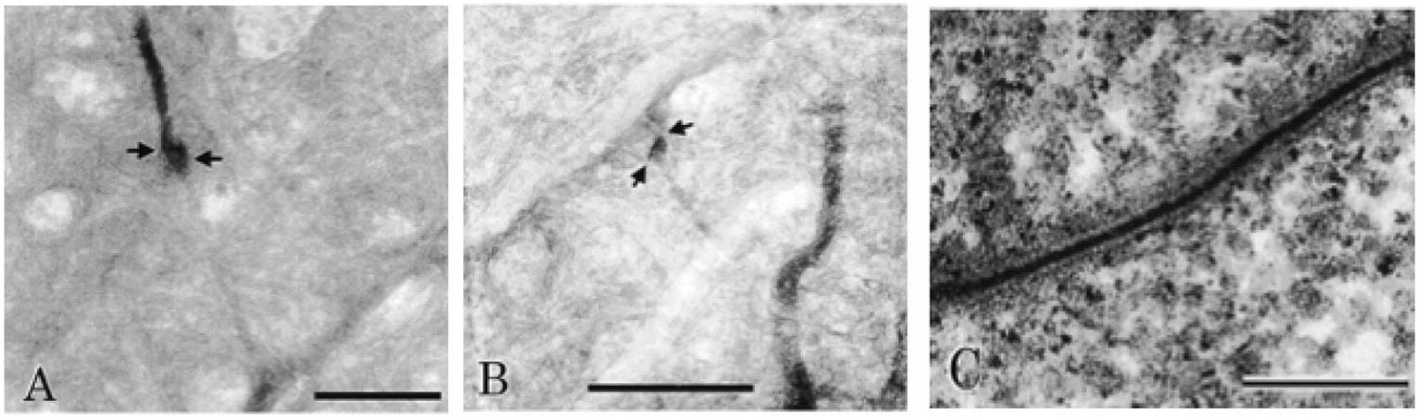

Figure 20. *Dendrodendritic gap junctions between ganglion cells*. **A**,**B**, Electron micrographs showing dendrodendritic gap junctions between Neurobiotin coupled alpha ganglion cells in rat retina. **C**, High resolution view of a gap junction between dendrites of coupled ganglion cells. Scale bars: A,B, 10 μm; C, 200 nm. Taken from Hidaka et al. (2004) (106).

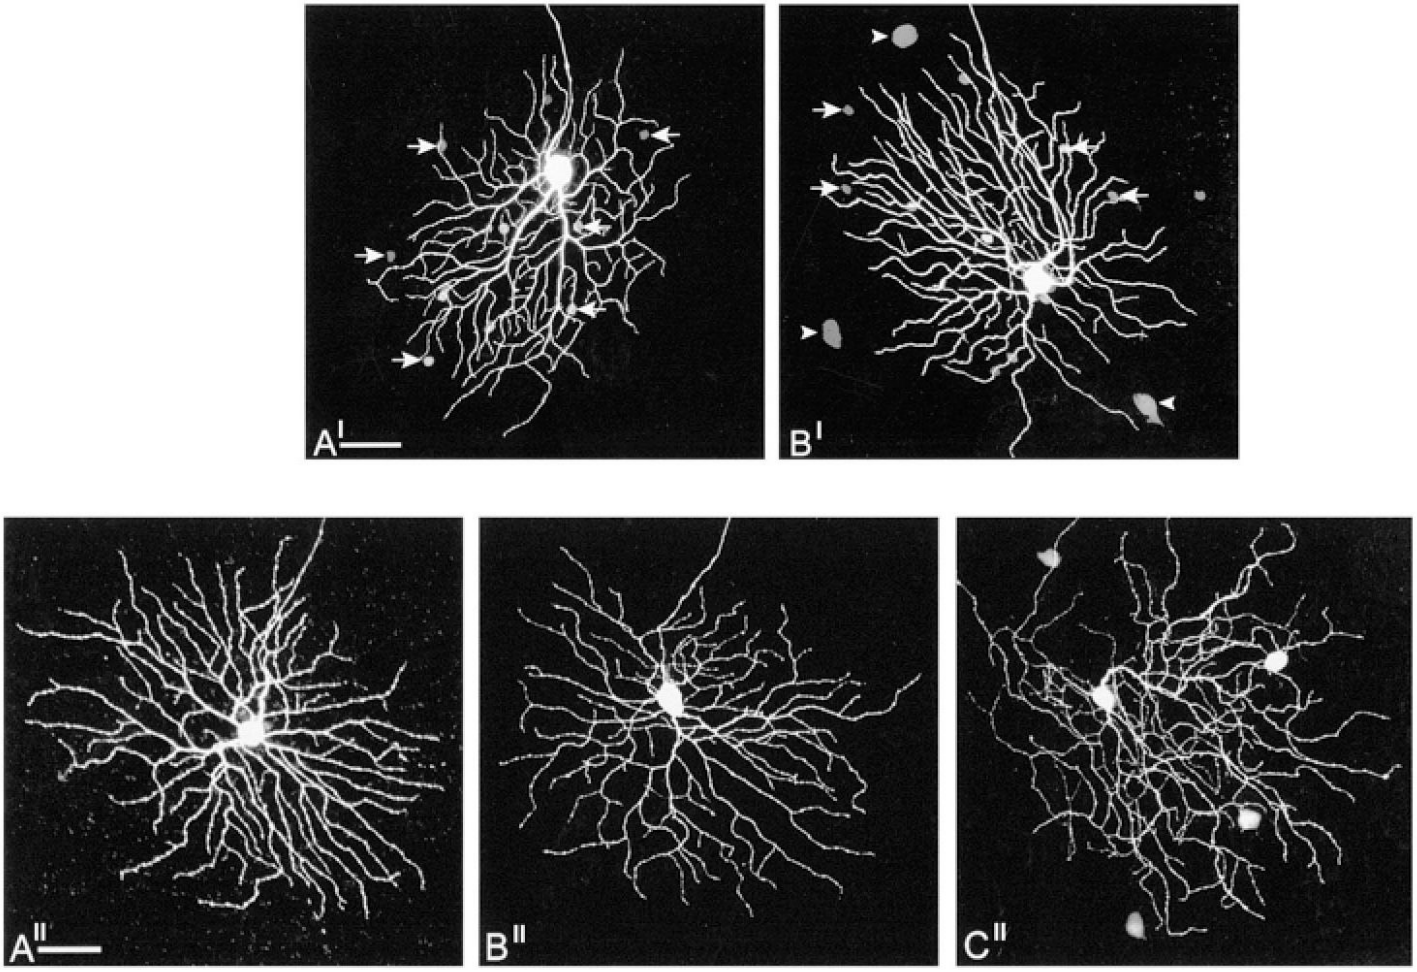

Figure 21. *Tracer coupling from certain ganglion cell types is dependent on Cx36*. $\mathbf{A^{I}}$, Neurobiotin injected into an ON alpha ganglion in wild type mouse retina cell results in tracer dye labelling the somata of neighbouring amacrine cells (white arrows). $\mathbf{B^{I}}$, Neurobiotin injected into an OFF alpha ganglion cell in wild type mouse retina results in tracer dye labelling the soma of neighbouring amacrine cells (white arrows) and ganglion cells (arrowheads). $\mathbf{A^{II}}$, $\mathbf{B^{II}}$, Neurobiotin injected into a pair of OFF alpha ganglion cells in Cx36 KO retina shows no tracer coupling. $\mathbf{C^{II}}$, Neurobiotin injected into a bistratified ganglion cell shows tracer coupling to neighbouring ganglion cells in the Cx36 KO retina. Adapted from Schubert et al. (2005a) (201).

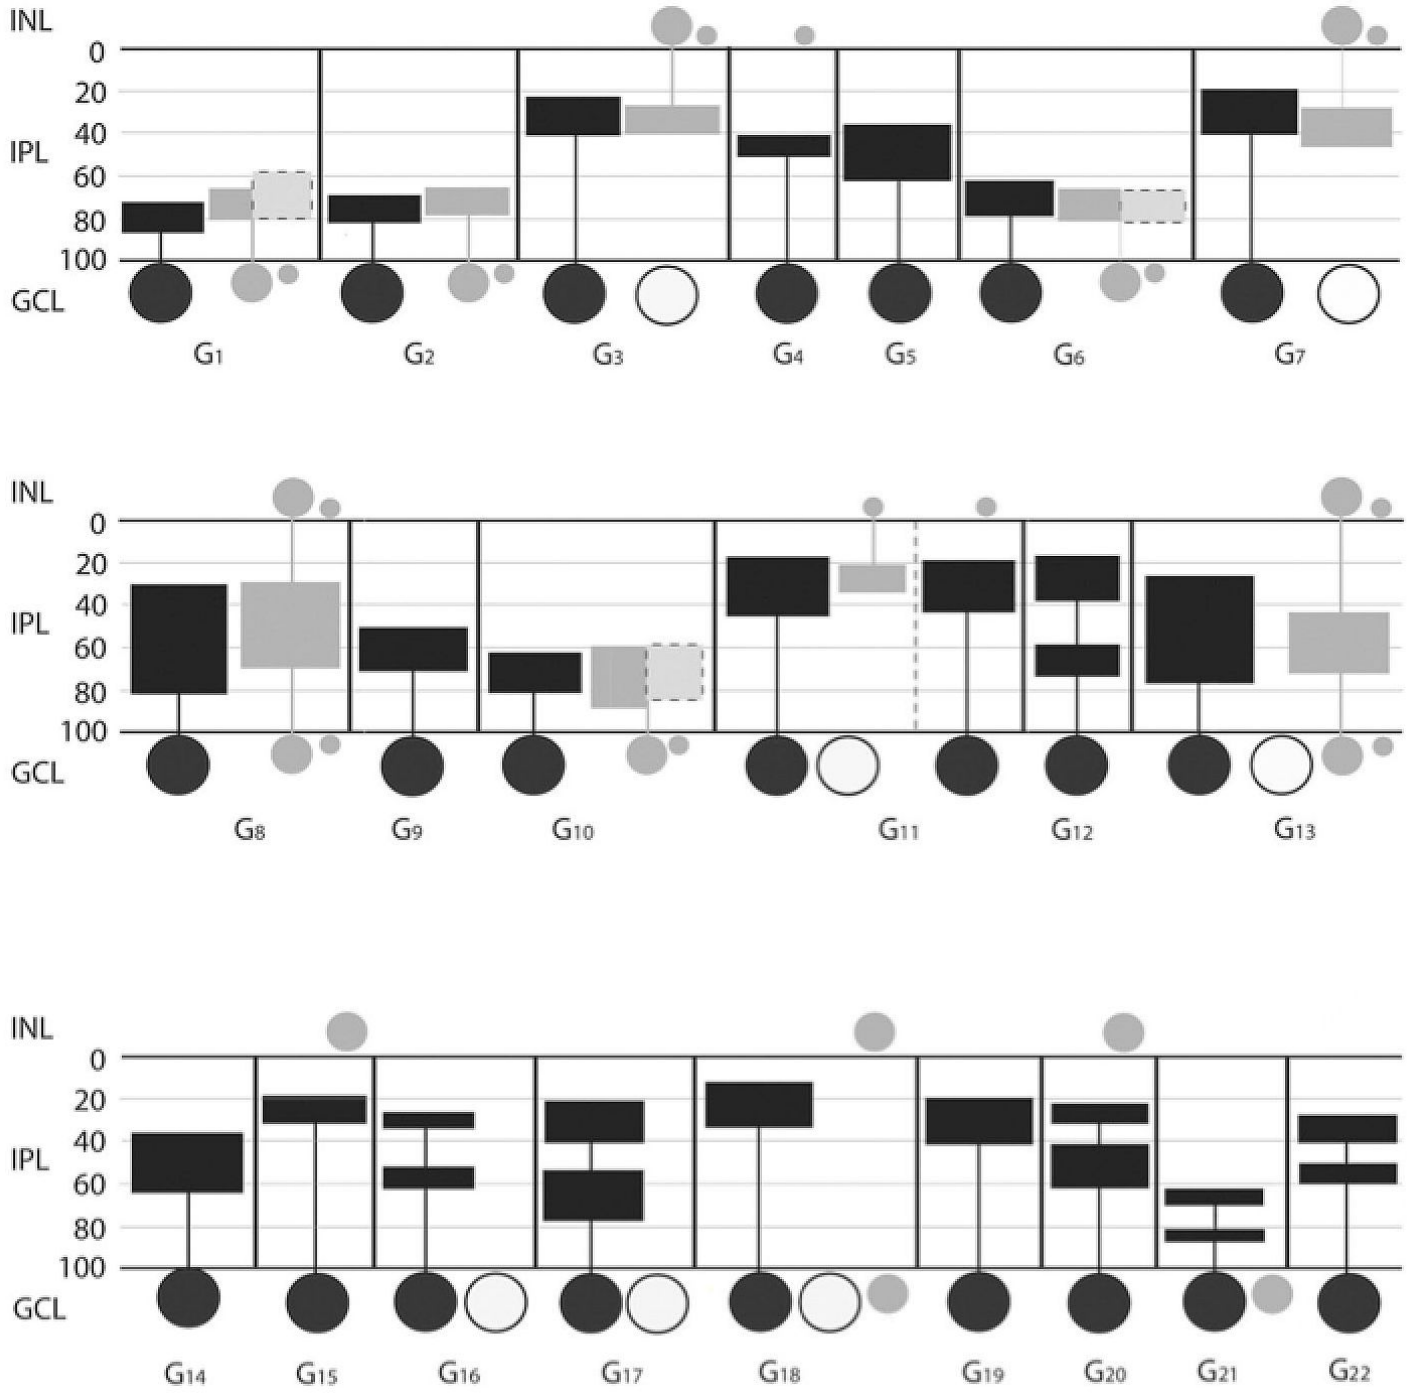

Figure 22. *Diverse coupling patterns of different retinal ganglion cell types.* Schematic outlining differential coupling patterns (as determined via tracer coupling experiments) of 22 types of ganglion cells in the mouse retina. Dendritic stratification patterns in the inner plexiform layer (IPL) for each ganglion cell (black) and its coupled amacrine cells (grey) are shown. Large unfilled circles in the ganglion cell layer indicate tracer coupled ganglion cells. Filled grey circles represent coupled amacrine cells (the size of the circle varies depending the soma size, and if also labelled, amacrine cell dendrites/axons are shown). Taken from Völgyi et al. (2009) (95).

only drives subthreshold activity in post-junctional neighbors (134). How then do subthreshold coupled spikelets drive synchronous activity in coupled ganglion cells?

ON-OFF directionally selective (DS) ganglion cells have been an ideal model for studying how coupled spikelets can drive synchrony via non-linear dendritic signaling. DS ganglion cells generate Na^+-channel dependent, TTX-sensitive dendritic spikes that trigger action potentials with high reliability (147, 148). There are at least

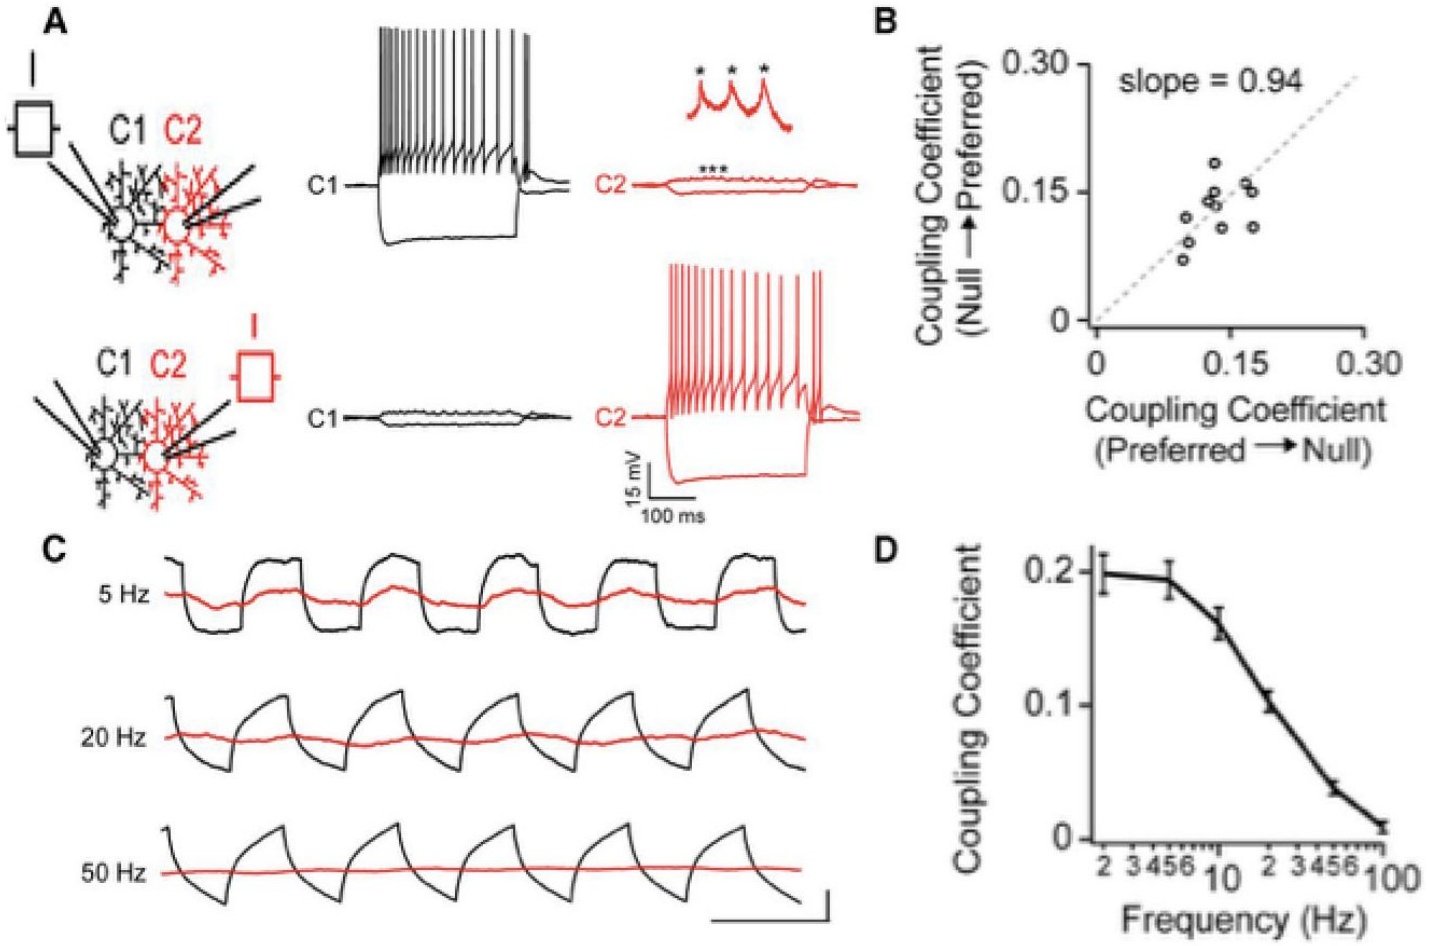

Figure 23. *Properties of gap junctions between ganglion cells in mouse retina*. **A**, Paired current clamp recordings, in which current steps (-200 and +120 pA) were injected into one cell while, membrane responses were monitored in the other cell. The 'I' and current steps in the diagram indicates which cell of the pair is having current injected into it. **B**, Bidirectional coupling coefficient is plotted for 11 pairs of cells. **C**, The membrane responses of both cells when current pulses of different frequencies where injected into one cell (black) and the voltage responses in the postjunctional cell (red) were monitored. **D**, The coupling coefficient is plotted for different frequencies of current injections. Taken from Trenholm et al. (2013a) (113).

four types of ON-OFF DS ganglion cells, coding the cardinal directions (149). For reasons that are not entirely clear, only ON-OFF DS cells that prefer superior motion in the visual field (ventral motion on the retina) exhibit homologous electrical coupling in the adult mammalian retina, at least in rabbit and mouse retinas (**Figure 29**) (105, 113, 150).

Interestingly, when coupled spikelets were simulated via current injection at the soma (with a patch pipette) in coupled DS ganglion cells, they did not significantly modulate action potential timing, raising the possibility that their site of action was in the dendrites (143). Furthermore, coupled spikelets do not appear large enough to directly initiate dendritic spikes themselves. It turns out that to drive spike synchrony in neighbouring cells, coupled spikelets must interact non-linearly with chemical synaptic inputs in the overlapping dendrites of neighbouring ganglion cells (143). Flashing light at a shared location of receptive overlap between a pair of neighboring coupled ganglion cells drives significant spike correlations, whereas flashing two spots of light at two different spatial locations to activate the same pair of ganglions at the same time but with non-overlapping chemical synaptic inputs, does not drive significant correlations (**Figure 30**) (143).

Despite its prevalence, it remains unclear what role correlated ganglion cell activity plays in higher visual processing. One hypothesized role is that it could enhance synaptic transmission in retinorecipient cells. In the

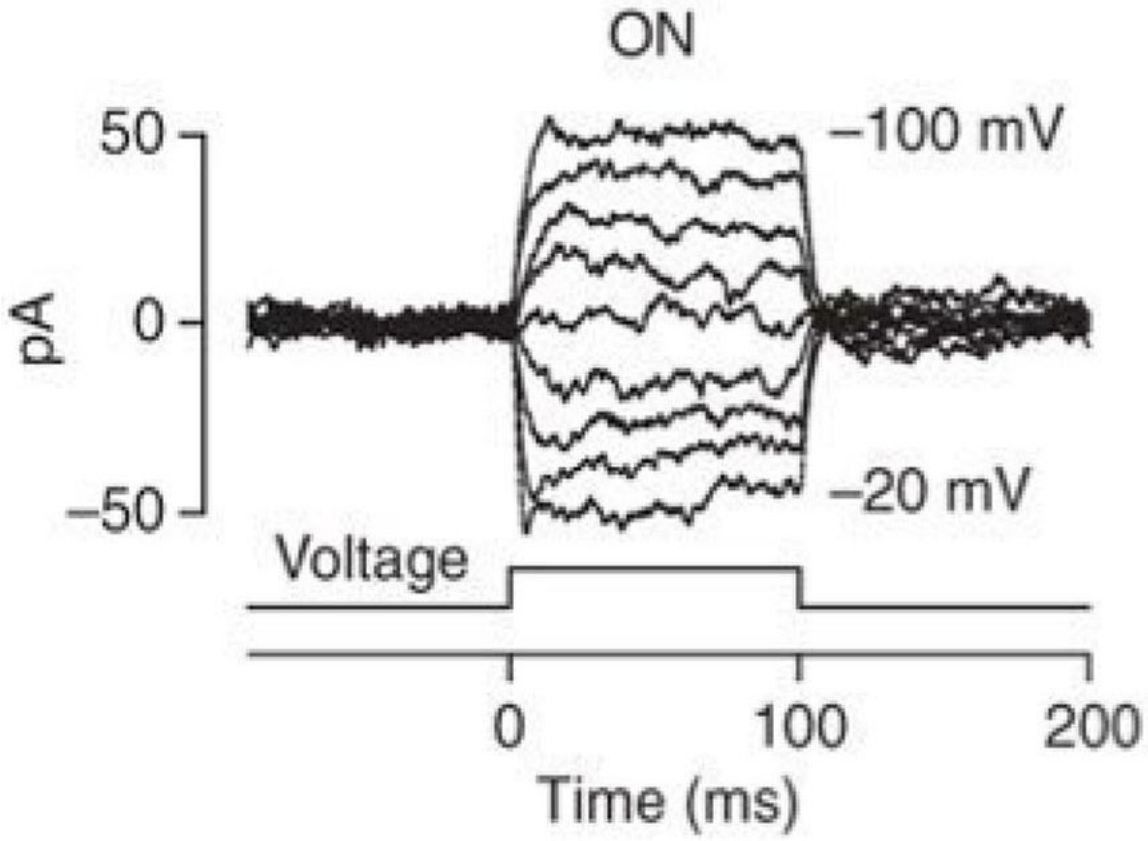

Figure 24. *Properties of gap junctions between ganglion cells and amacrine cells in primate retina.* **A**, Coupling mediated currents in an ON parasol cell when the membrane potential of a neighbouring ON parasol cell was changed from -100 to -20 mV in 10 mV steps (from a holding potential of -60 mV). This coupling current was present despite minimal dendritic overlap between neighbouring ON parasol ganglion cells, and no tracer coupling between ganglion cells, thus suggesting that the coupling was indirect via an amacrine cell. Taken from Trong and Rieke (2008) (120).

lateral geniculate nucleus (LGN), retinal inputs with short inter-spike intervals greatly increase synaptic efficacy (151, 152). Considering that multiple neighbouring ganglion cells converge onto individual LGN relay neurons (153-156), ganglion cell synchrony appears to be a highly plausible strategy for effectively driving LGN neurons. Another hypothesized role for ganglion cell synchrony is that it enhances bandwidth of the optic nerve (145, 157). Since correlated ganglion cell spikes tend to occur when light activates overlapping areas between neighbouring ganglion cell receptive fields (**Figure 31**) (145, 157), correlated activity contains unique spatial information which could subsequently be decoded separately from uncorrelated activity.

Furthermore, since the strength of narrow gap junction mediated ganglion cell correlations appears to decrease with increasing spike rates (143, 158), though an inhibitory mechanism may sometimes concomitantly lower spike rates and reduce medium-scale gap-junction mediated synchrony (159), correlated ganglion cell activity could relay information to downstream targets independent from spike rate (**Figure 32**). Whether these types of parallel decoding strategies are actually implemented in higher visual areas remains to be examined.

Aside from the above described forms of synchrony, which tend to be restricted to neighbouring retinal neurons, gap junctions also appear to play an important role in synchronizing activity across wide regions of the retina. Classic work with paired recordings revealed the presence of long-range correlated activity in the retina across distances larger than 20 degrees of visual space (160). Such synchrony appeared to arise when pairs of distally located ganglion cells were responding to a visual image that fell upon their receptive fields as well as the space in between them (160). More recent work has shown that this long-range synchrony arises from gap junction

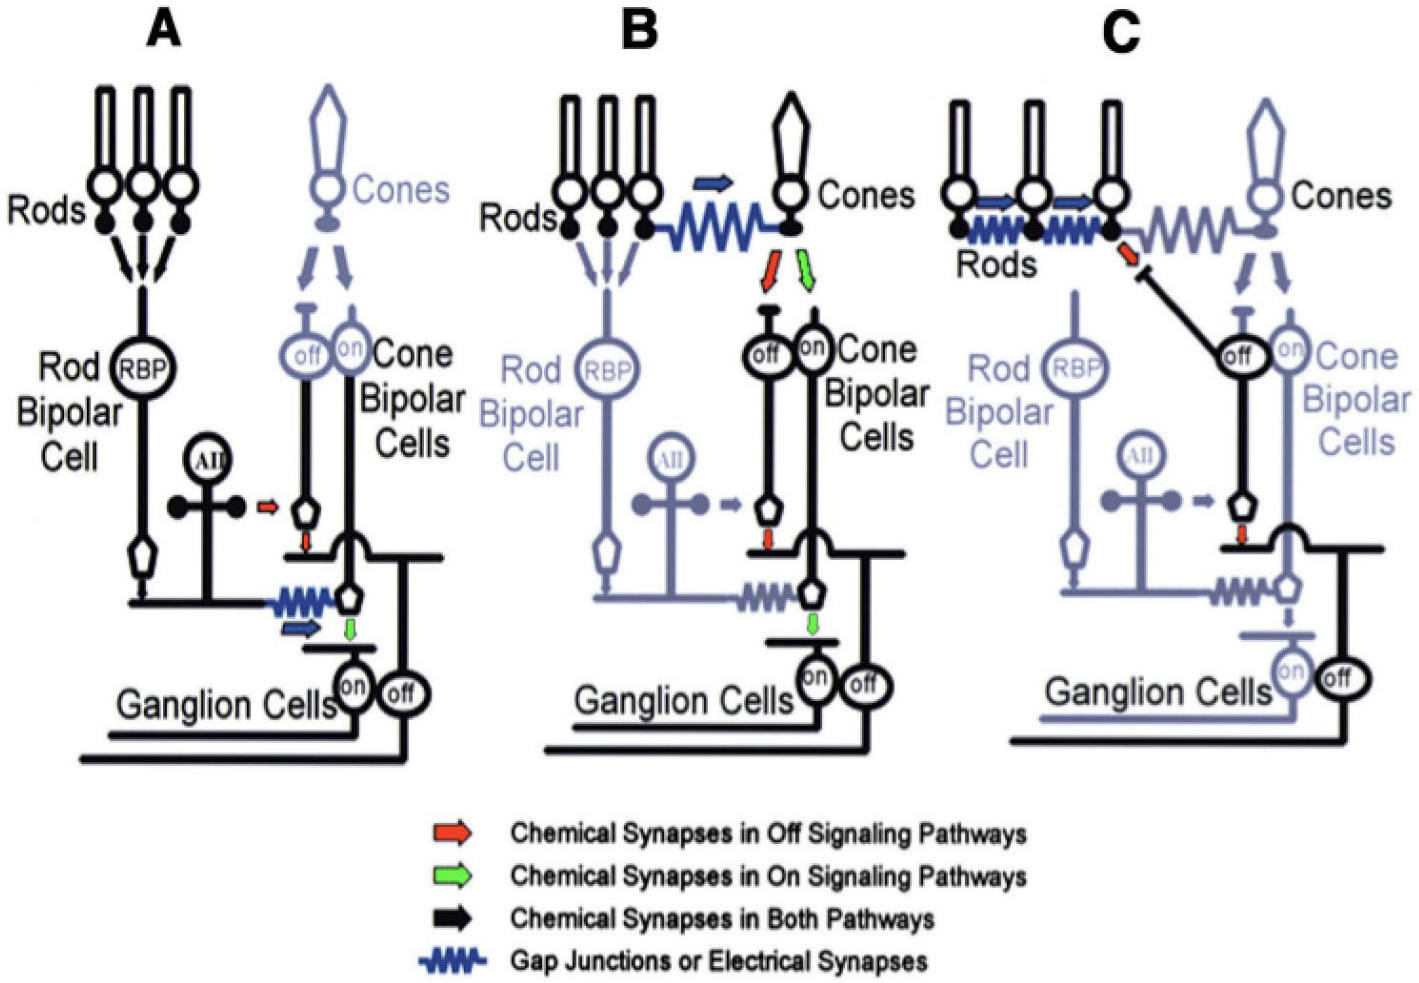

Figure 25. *Three rod vision circuits in the mammalian retina.* **A**, Rod signals pass to rod bipolar cells, then onto AII amacrine cells, and then onto bipolar and ganglion cells. **B**, Rod signals pass into cones via gap junctions. **C**, Rods directly synapse onto OFF bipolar cells. Taken from Deans et al. (2002) (70).

connectivity between ganglion cells, likely via an intermediary widefield amacrine cell (161). Remarkably, as was originally hypothesized (160), this long-range synchrony appears to play an important behavioral role in an animal's ability to bind together distal portions of the same visual image (161).

Gap junctions and moving visual stimuli

The classical view of the excitatory retinal signaling pathway is of a vertical circuit from photoreceptors to bipolar cells to ganglion cells. Placing gap junctions between neighbouring cells adds a lateral excitatory connection to this vertical pathway. Unsurprisingly, adding such a lateral excitatory pathway endows retinal circuits with distinct advantages when it comes to processing moving visual stimuli.

Motion sensitivity

Lateral gap junction connectivity, in both bipolar cells and ganglion cells, has been shown to selectively modify and enhance responses to moving stimuli. In mouse retina, it has been shown that gap junction inputs to bipolar cells (which can represent > 30% of their excitatory synaptic input), can endow bipolar cells with supralinear spatial summation, which selectively enhances processing of spatio-temporally correlated inputs (i.e. stimuli moving in a coherent direction). This results in enhanced responses to motion in retinal ganglion cells **(Figure**

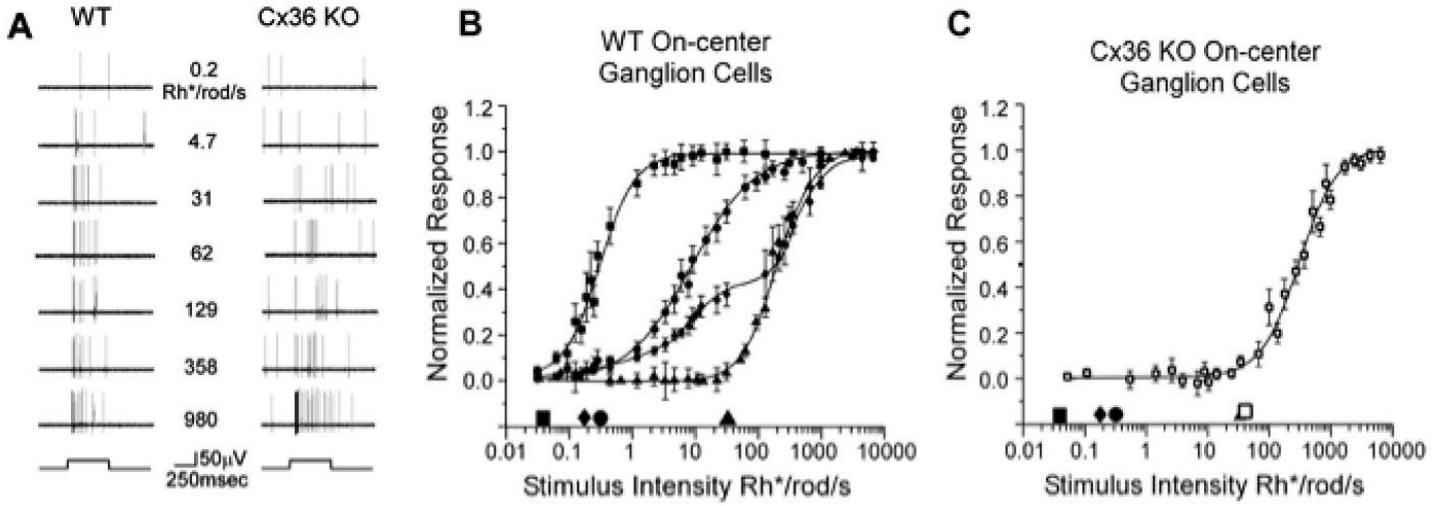

Figure 26. *Cx36 containing gap junctions are required for rod-mediated signals to pass to ganglion cells*. **A**, Example of spiking responses from ON ganglion cells in wild type (WT, left) and Cx36 KO mouse retina (right) to a series of flashes of different intensities. **B**, Ganglion cells in wild-type retina were grouped into 4 different categories based on their stimulus response profiles, with many cells being activated by dim flashes. **C**, In Cx36 retina, all ganglion cells resembled the least sensitive group identified in wild type retina. Taken from Deans et al. (2002) (70).

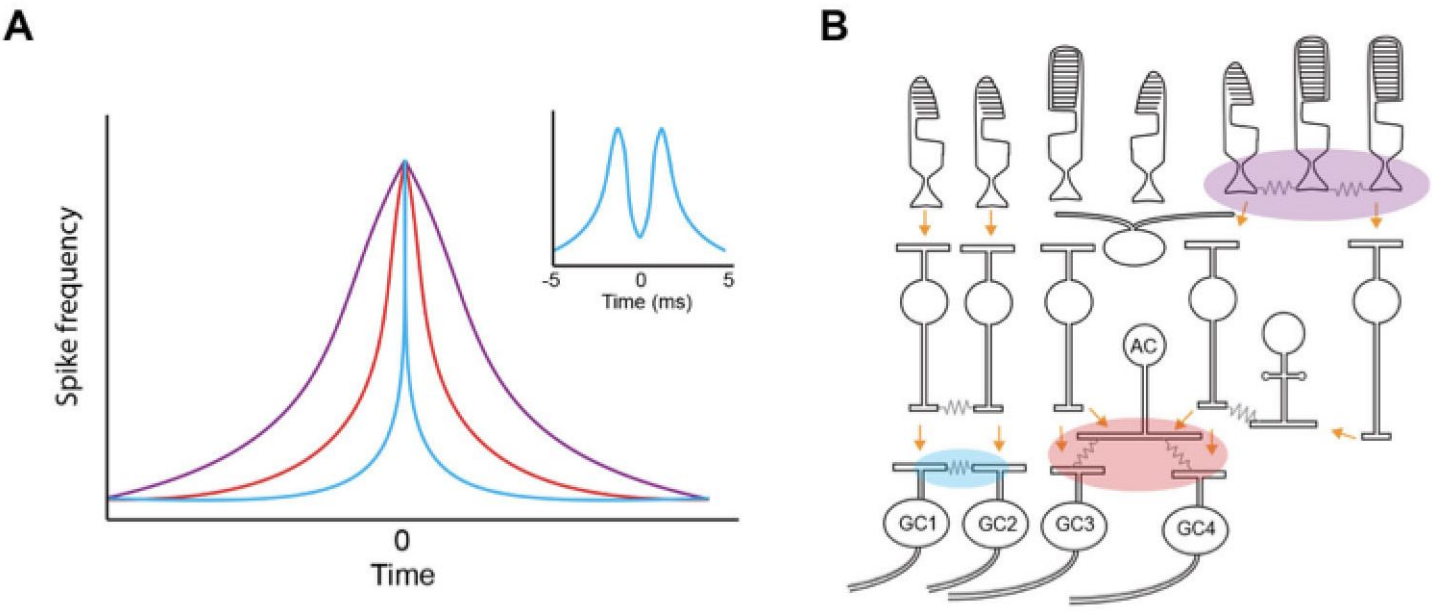

Figure 27. *Correlated spike activity in pairs of retinal ganglion cells*. **A**, Schematic cross-correlogram outlining broad (purple), medium (red) and narrow (blue) spike correlations between pairs of retinal ganglion cells. The inset shows a zoomed in view of the narrow correlations, with a trough in the cross-correlogram at 0 ms delay. **B**, Schematic of the retinal synaptic locations where broad (purple), medium (blue) and narrow (red) correlations are thought to arise. Taken from Trenholm and Awatramani (2017) (197).

33) (84). Related work has been done in primate retina, in which bipolar cell gap junction coupling appears to contribute to motion sensitivity of parasol ganglion cells (162). The general principles underlying motion facilitation in gap junction networks in bipolar cells appears to be similar to that described in more detail in a later section on ganglion cells (163).

Finally, in mouse retina, at low light levels, homologously coupled direction selective ganglion cells have broader tuning curves than their uncoupled counterparts. As such, gap junction connectivity appears to allow these cells

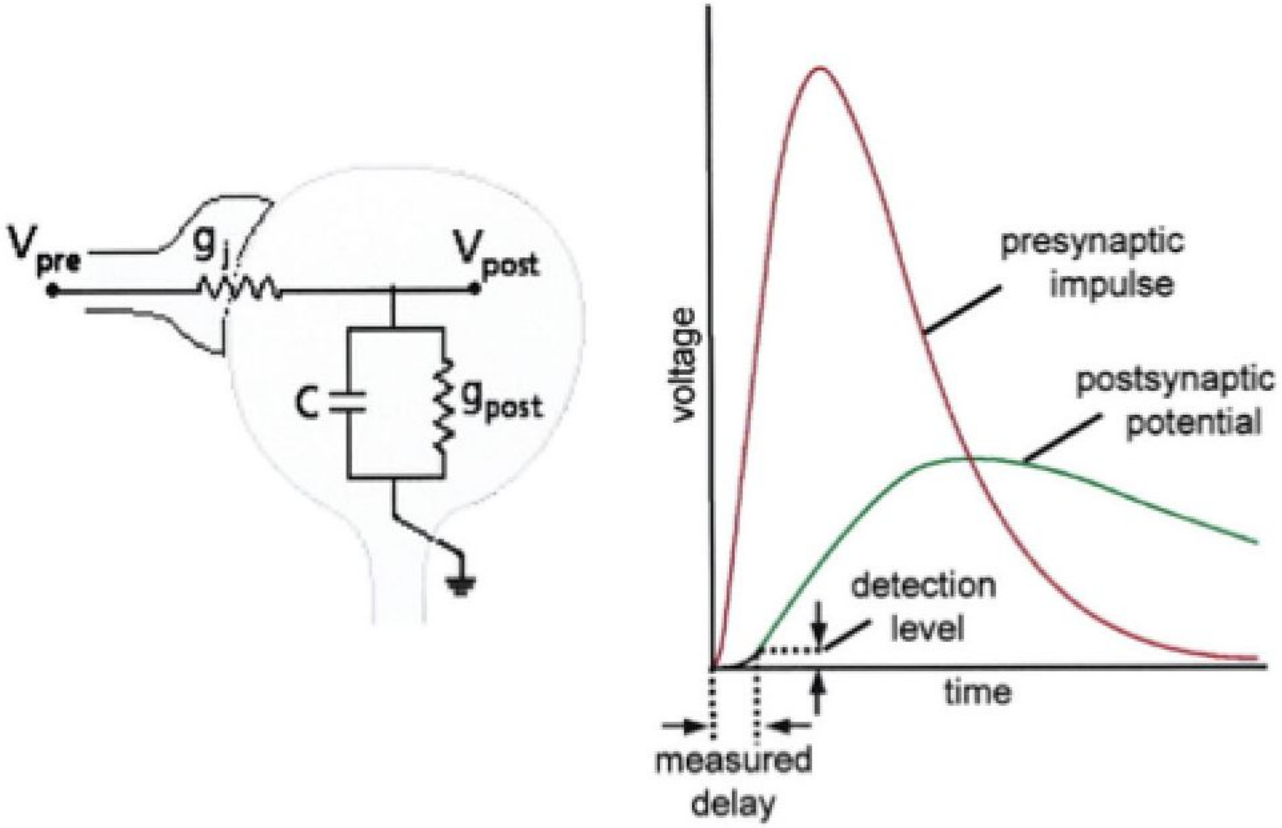

Figure 28. *Gap junctions act as low-pass filters. Left*, An equivalent circuit of a gap junction. *Right*, Electrical signals pass through gap junctions with a short delay, and high frequency presynaptic signal components are more highly attenuated upon passing to the postsynaptic cell. Taken from Bennett and Zukin (2004) (146).

to strike a balance, in low light levels, between detecting dim moving stimuli and accurately reporting the direction of movement **(Figure 34)** (111).

Motion anticipation

When light is flashed on the retina, it takes roughly 50 ms or more for a ganglion cell to fire a light-evoked action potential. Most of this delay is due to phototransduction in rods and cones, the relatively slow process whereby incoming photons are converted into an electro-chemical signal. This delay poses a problem, given that the same retinal circuity can process both static and moving stimuli. For static images, this delay does not pose a significant problem, as when a ganglion cell spikes the stimulus it is encoding is still in the appropriate position. In contrast, when a moving image activates photoreceptors in one location, the image will have moved to a different spatial location by the time the ganglion cells vertically connected to the photoreceptors at the earlier position begin to respond. The lag between where a ganglion cell reports an image is, compared to where the image actually is in space, increases as movement gets faster. One method that has been hypothesized for the retina to address this problem is for ganglion cells to dynamically shift the peak of their receptive field toward the leading edge of a moving stimulus (164, 165), which could theoretically be read out by downstream targets as anticipation if they decode position based on peak spike rate. Another method that has been proposed to compensate for the lag that arises when coding moving stimuli involves using gap junctions to allow upstream retinal ganglion cells to alert their downstream neighbors to the presence of an incoming image. This phenomenon, termed lag normalization, arises in homologously coupled retinal ganglion cells which exhibit a coupling-mediated subthreshold excitatory receptive field that surrounds their receptive field center **(Figure 35)** (113).

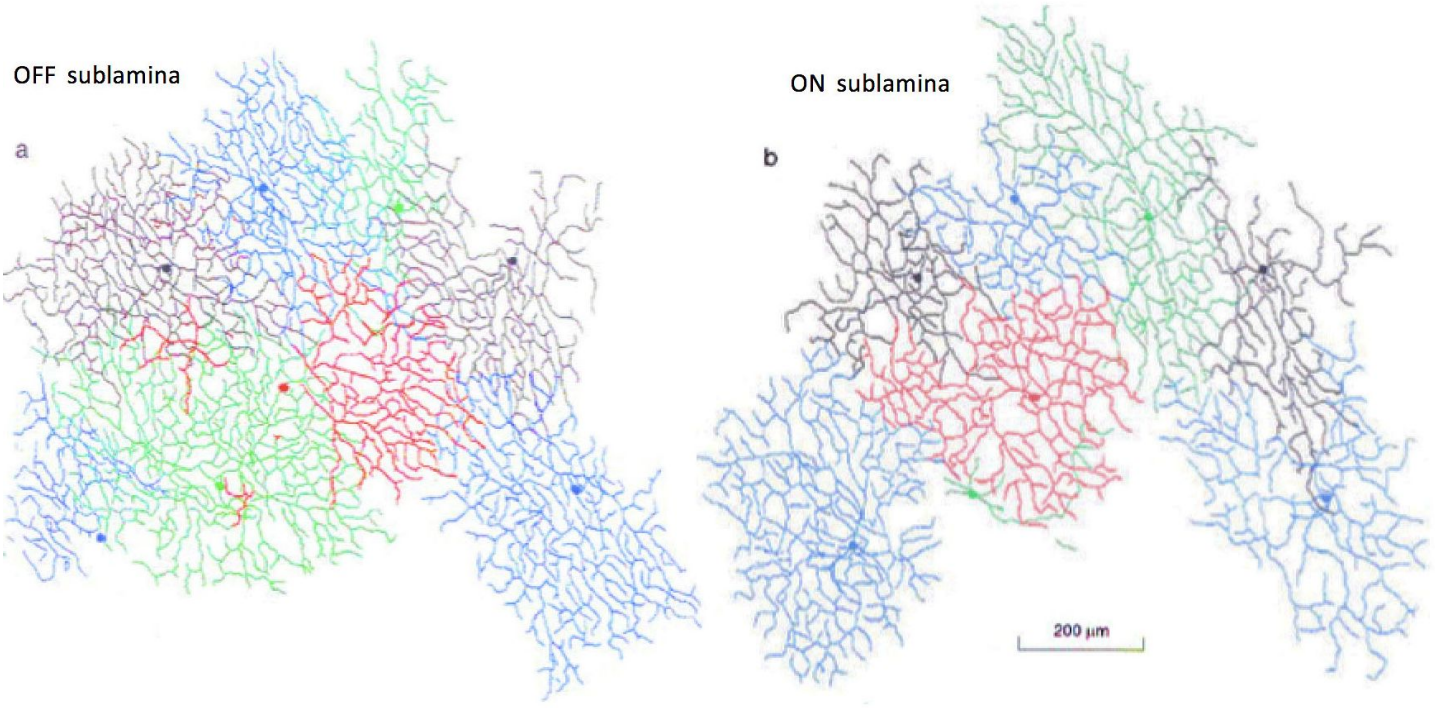

Figure 29. *Homologous coupling between directionally selective ganglion cells*. Neurobiotin injected into a single bistratified directionally selective ganglion in rabbit retina results in dye passing into neighbouring bistratified ganglion cells, with largely non-overlapping dendritic trees. **a**, OFF sublamina. **b**, ON sublamina. Taken from Vaney (1994) (105).

For moving images, the gap junction inputs spread laterally from one ganglion cell to another, and are able to combine with weak bipolar cell mediated chemical synaptic inputs to allow the ganglion cell to begin responding outside of the receptive area that drove spiking activity to static stimuli (166). Moreover, when these coupled ganglion cells are stimulated with images moving at various speeds, they can initiate their responses at nearly the same spatial location (i.e. they 'lag normalize'), in contrast to uncoupled ganglion cells which initiate their responses at positions further and further in space when presented with faster and faster speeds of moving images **(Figure 36)** (166).

Looming

Effective detection of looming visual stimuli, like an approaching predator, can be a matter of life or death. Accordingly, looming (or approaching) visual stimuli drive behavioral reflexes that are found across many species, including humans (167-171). In the retina, it appears that lateral gap junction connectivity – between AII amacrine cells and ON cone bipolar cells – plays a role in allowing a specific retinal ganglion cell to preferentially detect looming visual images. In mouse retina, the looming sensitive cell is an OFF ganglion cell, termed the PV-5 cell (124). When static decrements of light are presented over the receptive field of this cell, they evoke transient OFF excitation, followed by transient ON inhibition when the light level returns to baseline (124). As a large dark stimulus gets smaller over the receptive field of this cell, it exclusively drives ON inhibition and no excitatory OFF response, and thus does not result in spiking. On the other hand, if the same stimulus is now played backwards and the black area expands over the receptive field of the cell, it exclusively drives OFF excitation that drives robust spiking responses. Based on the described response properties, this cell should also respond reasonably well to moving stimuli that pass across the receptive field, which would drive a mix of OFF excitation and ON inhibition. However, the ON inhibitory input to the PV-5 cell is very fast and appears to arise via gap junction signals passed from ON cone bipolar cells to AII amacrine cells, which weaken the effect of concomitant excitatory OFF inputs. Indeed, when Cx36 was knocked out, PV-5 cells no longer responded

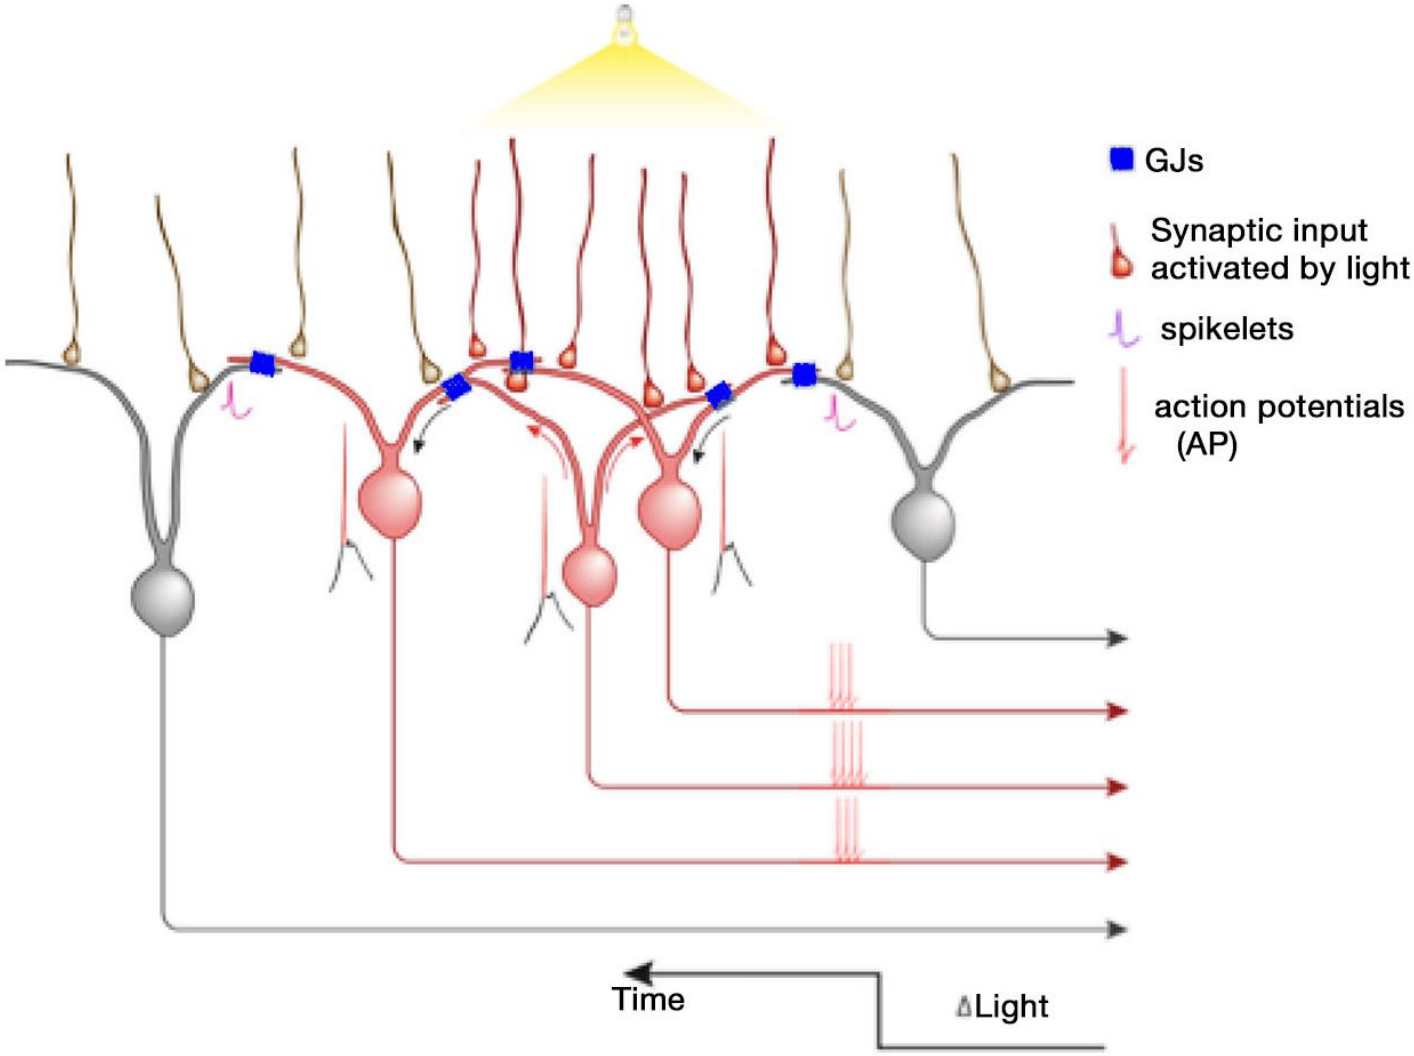

Figure 30. *Non-linear interactions between coupled spikelets and chemical synaptic inputs drive correlated spiking.* A flash of light drives an action potential (AP) in the central ganglion cell. The action potential back-propagates into the dendritic tree (red arrows), crosses gap junctions (GJs), which become coupled spikelets in the dendrites of coupled neighbors. Coupled spikelets integrate with light-evoked chemical synaptic inputs from bipolar cells to trigger dendritic spikes that in turn propagate to the soma (black arrows), where they generate a synchronized action potential. Taken from Lanore and Silver (2014) (202).

preferentially to looming stimuli over stimuli that simply moved across the receptive field (124). In mice, this retinal cell type is thought to underlie innate freezing/fleeing behavioral responses when dark looming stimuli are presented above the head of a mouse (172). Whether similar retinal circuitry underlies behavioral responses to looming visual stimuli in primates remains to be tested.

Gap junctions, retinal degeneration and spontaneous activity

While, as outlined above, gap junctions serve many functions in the healthy retina, they also promote aberrant neuronal activity following retinal degeneration (rd). In rodent rd models, following photoreceptor degeneration, instead of becoming silent many ganglion cells exhibit spontaneous oscillations with a frequency of around 10 Hz (**Figure 37**) (173-179). Understanding the source of this aberrant activity is important since it could underlie phosphenes experienced by patients suffering from vision loss (180, 181), and could impact the success of therapeutic strategies including electrical implants (182) and optogenetic vision therapy (183).

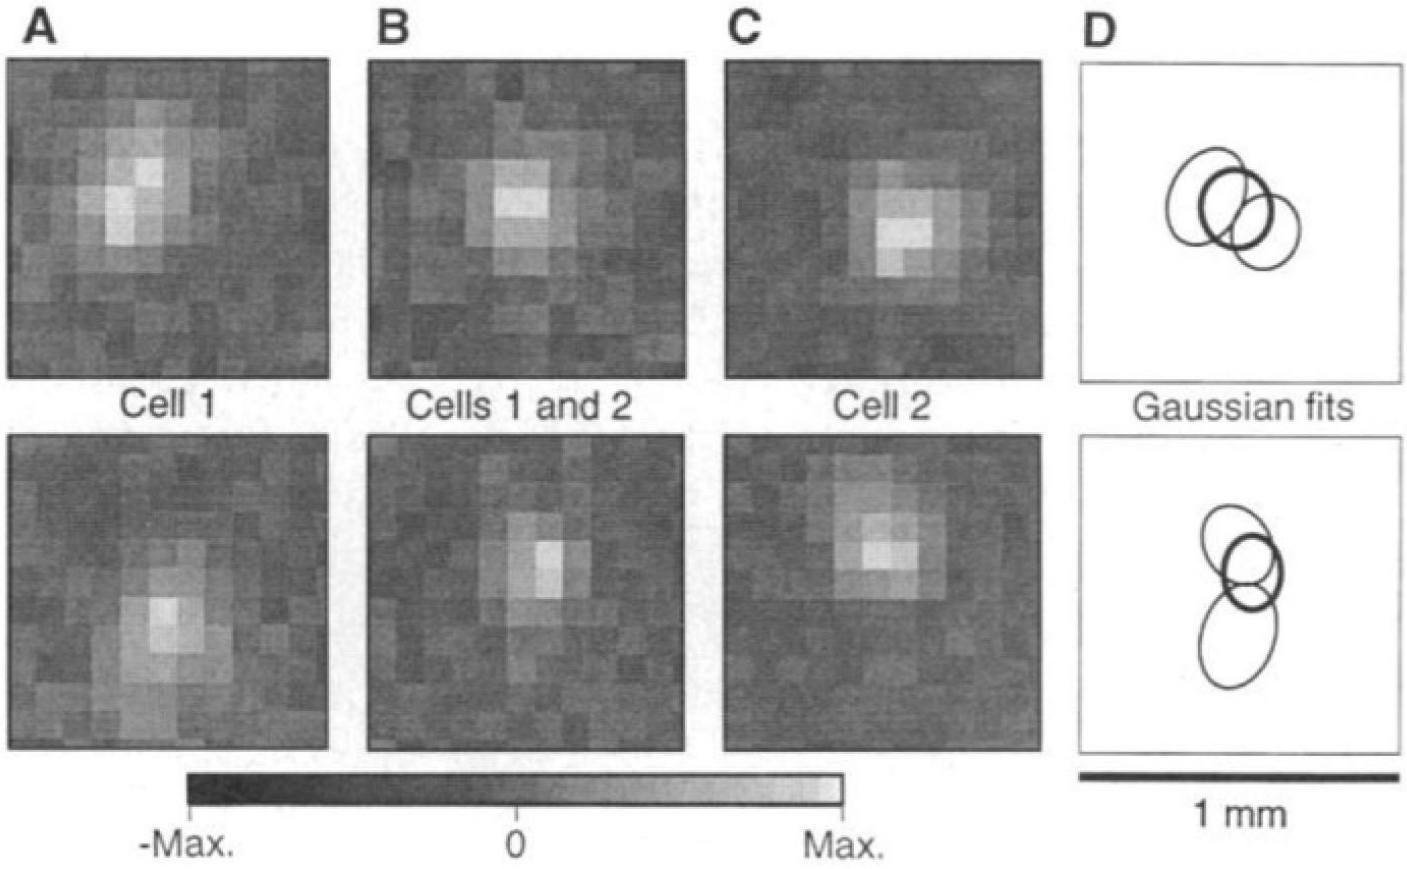

Figure 31. *Correlated spikes carry unique spatial information*. Receptive fields, generated with a flickering checkerboard stimulus, are plotted for two cells (**A**) and (**C**), and the 'receptive field' in which they exhibited correlated spiking is shown in the middle (**B**). **D**, Gaussian fit contours of the receptive fields from (A-C). Top and bottom rows are from different cell pairs. Taken from Meister et al (1995) (157).

In rd retina, ganglion cells oscillate as the result of receiving excitatory and inhibitory oscillatory inputs (174, 175, 179, 184). Application of chemical synaptic blockers inhibits ganglion cell oscillations, indicating that spontaneous oscillations do not arise in ganglion cells themselves (174, 176), but see also (185). In contrast, membrane oscillations in ON cone bipolar cells and AII amacrine cells, which also occur with a frequency of around 10 Hz, persist upon application of chemical synaptic blockers, indicating that spontaneous oscillations arise intrinsically within the coupled network of ON cone bipolar cells and AII amacrine cells (174). As evidence that gap junctions between bipolar cells and AII amacrine cells are important in this pathophysiology, pharmacologically blocking gap junctions inhibits oscillations in ganglion cells (176, 186), AII amacrine cells and ON cone bipolar cells **(Figure 38)** (186). Furthermore, spontaneous ganglion cell oscillations were greatly reduced in rd mice in which connexin 36 was knocked out (187).

Considering that there is extensive coupling between ON cone bipolar cells and AII amacrine cells in wild type retina, what occurs during retinal degeneration that promotes aberrant network activity? Experiments in wild type retina suggest that the main trigger for spontaneous activity relates to altered glutamate release from photoreceptors, as either pharmacologically blocking photoreceptor output in wild type retina or photobleaching the wild type retina with bright light (both of which would hyperpolarize the AII amacrine/ON cone bipolar cell network) can drive spontaneous activity similar to that found in the rd retina (186), though recent work also implicates retinoic acid in this hyperactivity (188). Consistent with the former idea, the resting membrane potential of AII amacrine cells in the degenerating retina appears to be hyperpolarized compared to those in the wild type retina (189). Such hyperpolarization could activate rhythmogenic conductances, such as

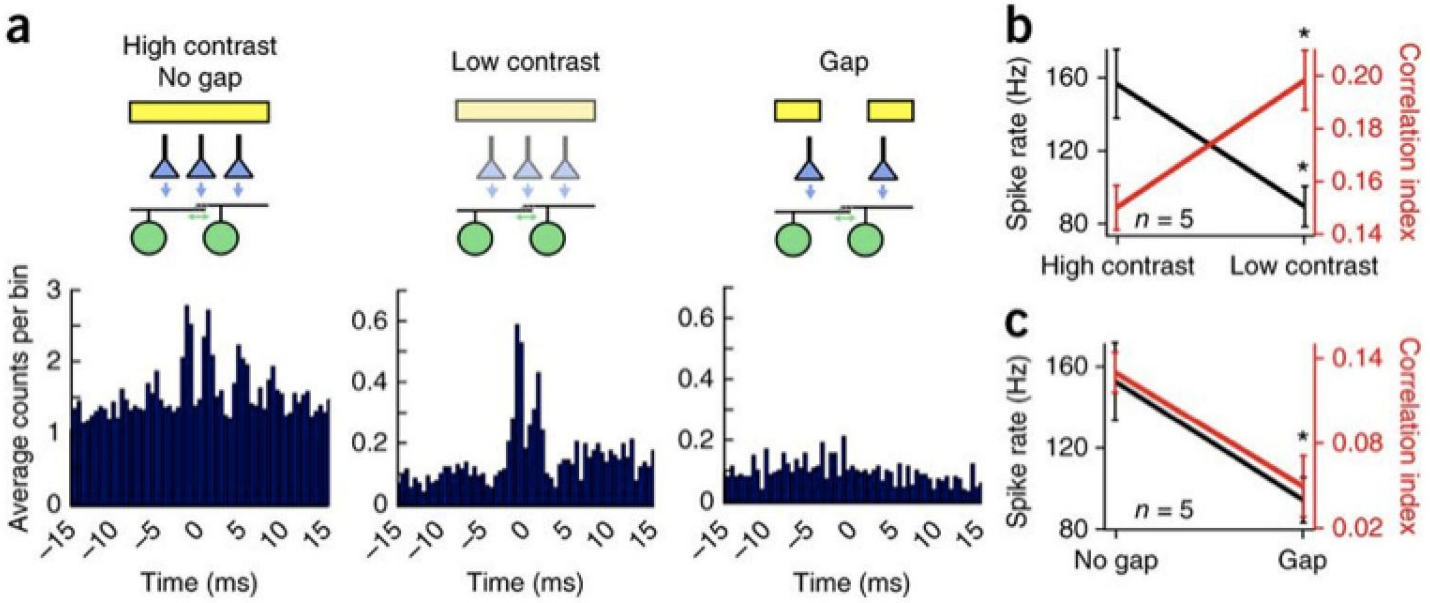

Figure 32. *Correlated spikes contain information that is independent from the spike rate*. **a** (*top*), Spikes are recorded from a pair of coupled ganglion cells when (*left*) a bright bar of light is flashed that covers both cells' receptive fields, (*middle*) the same bar of light is shown, but at low contrast, or (right) the same contrast of stimuli is shown as on the left, but is only presented to each cell in a portion of their receptive fields that is not shared between to the two cells, but that drives a similar amount of spiking as the middle stimulus. **a** (*bottom*), Cross-correlograms for the stimuli described above. **b**, Decreasing the contrast results in lower spike rates but higher spike correlations. **c**, Not stimulating the region of receptive field overlap between the pair of cells reduces spike rate but decreases correlation strength. Taken from Trenholm et al. (2014) (143).

I_h, which is present in some ON cone bipolar cells and has been shown to modulate oscillations in the rd retina (186). These oscillations have also been shown to be reliant on TTX-sensitive Na^+ channels in AII amacrine cells (186). Finally, it has been shown that gap junctional coupling of AII amacrine cells in the rd retina appears to be increased (as measured via an increase in phosphorylated Cx36), which could exacerbate aberrant activity following photoreceptor degeneration (190). As such, membrane conductances and gap junctions in the AII amacrine and ON bipolar cell network act in tandem following photoreceptor degeneration to elicit spontaneous membrane oscillations (**Figure 39**).

Conclusions

It is well established that the retina is extensively gap junction coupled, and that these connections endow retinal circuits with a plethora of functional properties. In the retina, gap junctions are associated with night vision, controlling receptive field size, signal correlation, spatial integration, and motion detection. Despite these findings, many unknowns remain. First, many critical experiments into the roles of gap junctions in the retina have employed either pharmacological agents or Cx36 KO to examine the roles of gap junctions in retinal circuits. However, simultaneously blocking gap junctions at all levels of the retina makes it difficult to assign roles for specific electrical synapses between given cell types. As such, future research will need to endeavor to modify gap junctions in specific cell types (111). Second, related to the first point, while it is clear that the retina splits incoming visual signals into over 30 distinct retinal channels (made up of distinct cell types, connected in distinct ways), unique roles for gap junctions in each of these channels is only beginning to be studied. Third, given that gap junctions are known to play important roles in retinal development (191), and may affect susceptibility to disease pathologies (192-195), it will be important to examine whether gap junctions play precise cell-type-specific roles in development (196) and disease. Finally, in addition to increasing our knowledge into the fine details of roles for gap junctions in microcircuits, it will be important to characterize

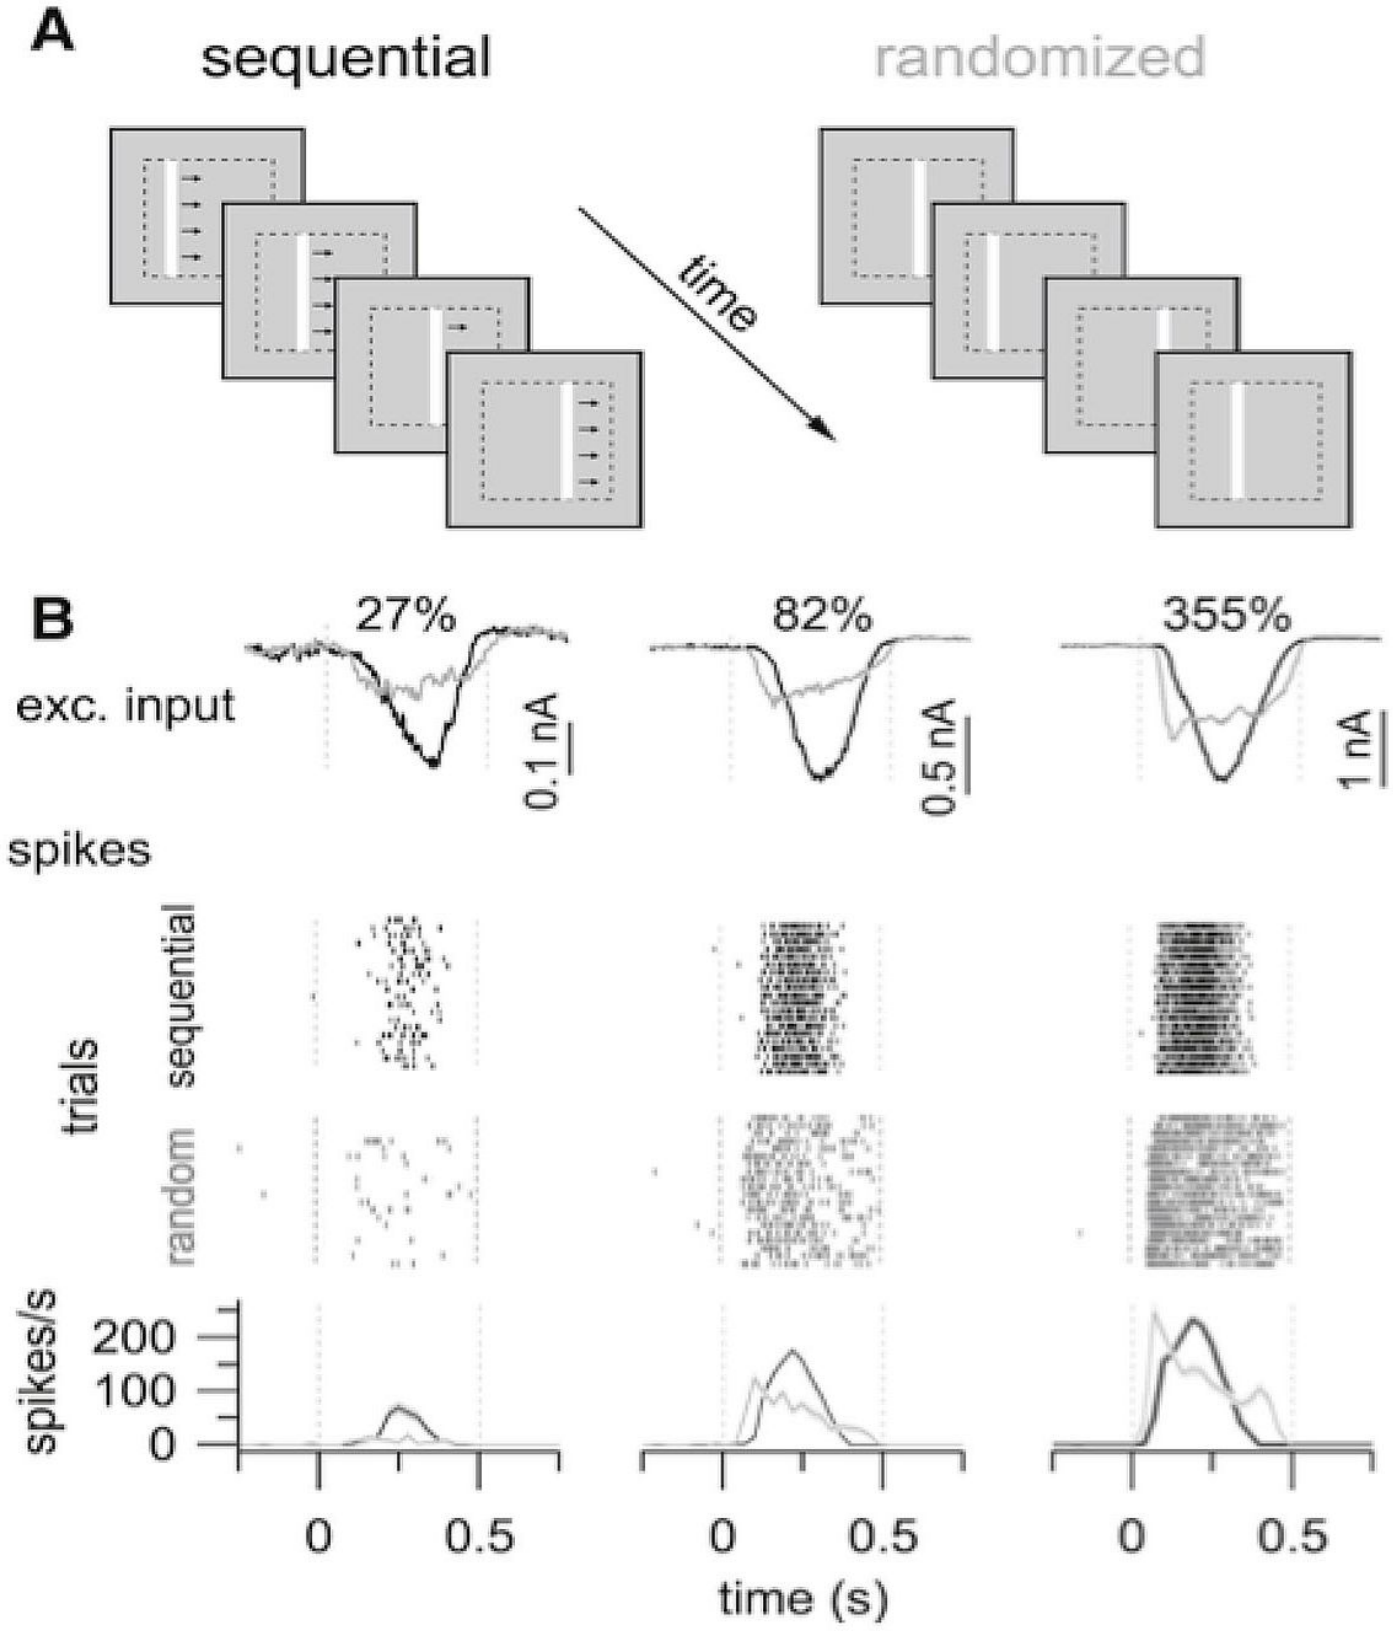

Figure 33. *Enhanced motion responses in retinal ganglion cells*. **A**, Two stimulus patterns, in which a bar of light is either flashed sequentially in space (left), mimicking coherent motion, or the same number of bars are presented in the same locations but in a random spatial order (right). **B**, The excitatory input and spiking responses of an ON sustained alpha ganglion cell in mouse retina is shown for the two stimulus paradigms described in (A). Spatio-temporally correlated stimuli drive stronger responses, and this is thought to arise from gap junction dependent spatial integration in presynaptic bipolar cells. Taken from Kuo et al. (2016) (84).

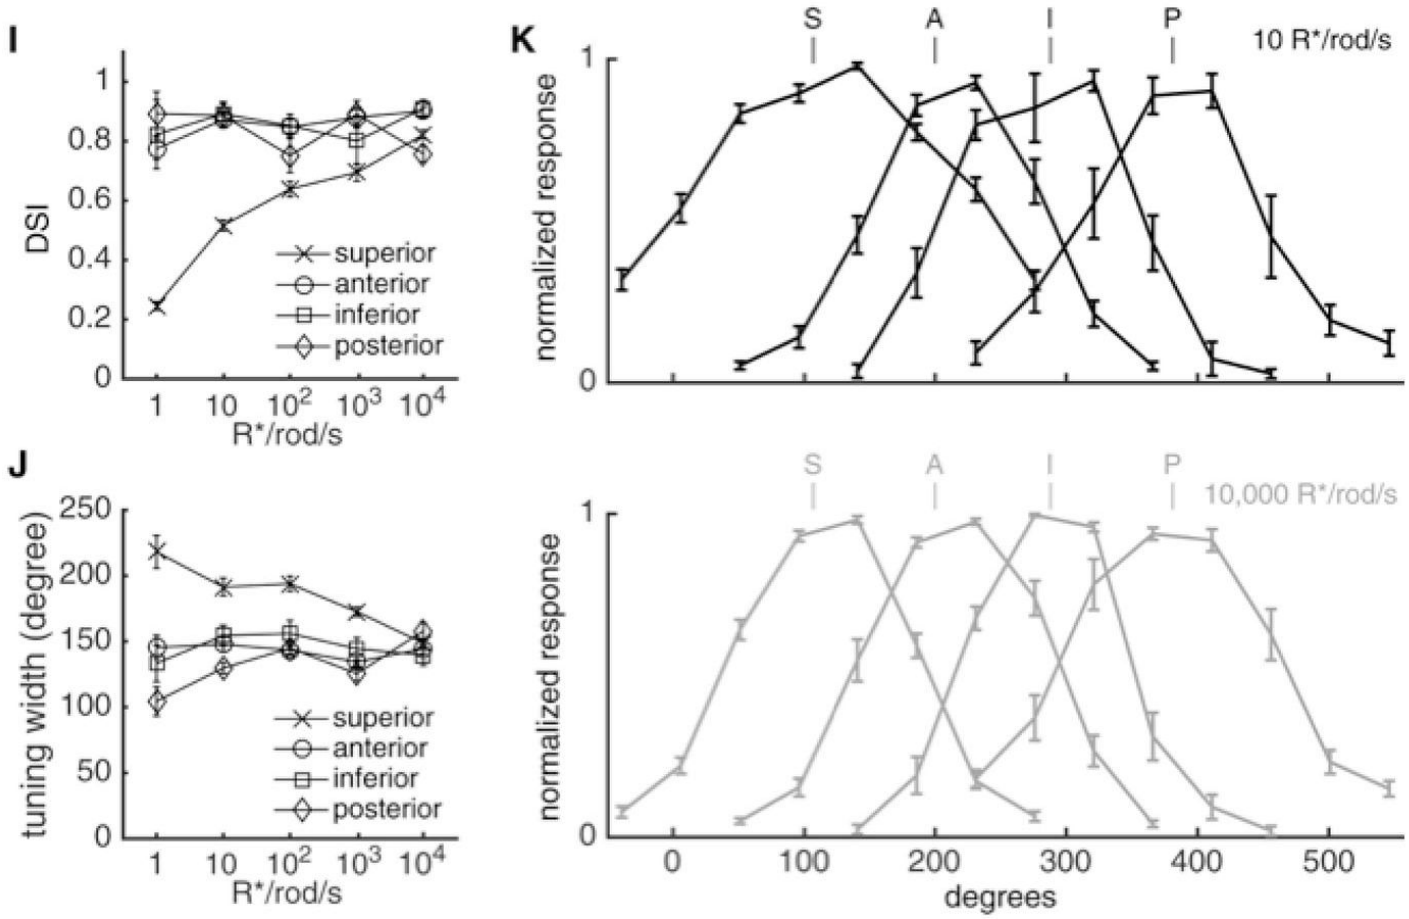

Figure 34. *The direction tuning of electrically coupled directionally selective ganglion cells changes at different light levels*. **I**, **J**, The direction selective index (DSI) and tuning width (high tuning width values mean a cell responds strongly to a wider angle of directions of motion) are plotted for direction selective ganglion cells coding the four cardinal directions (note that only superior coding direction selective cells are electrically coupled). **K**, Normalized tuning curves, to 8 directions of moving stimuli, are plotted for the four directions of ganglion cells, at dim (*top*) and bright (*bottom*) light levels. Taken from Yao et al. (2018) (111).

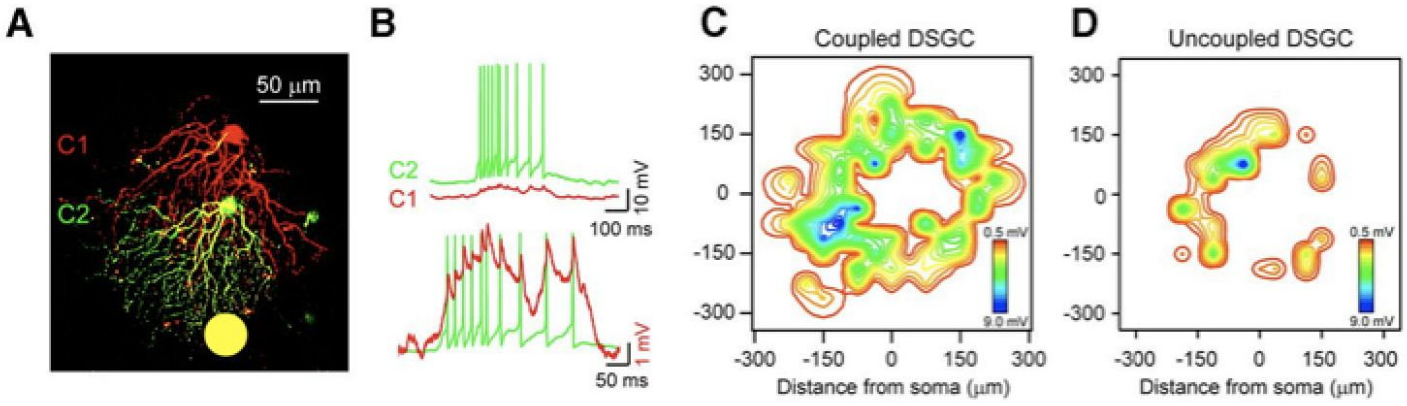

Figure 35. *Electrically coupled ganglion cells exhibit gap junction mediated excitatory subthreshold surround receptive fields*. **A**, An image of a pair of coupled ganglion cells in mouse retina, whose membrane responses to a flash of light (yellow spot) are shown in panel (B). **B**, A flash of light over the receptive field of cell 2 drives a strong spiking response in cell 2, which propagates via gap junctions into cell 1 as a subthreshold response including many coupled spikelets. **C**, **D**, The area surrounding coupled directionally selective ganglion cells (DSGC, (C)), and an uncoupled DSGC (D), where a small flash of light drives subthreshold depolarizations. Taken from Trenholm et al. (2013a) (113).

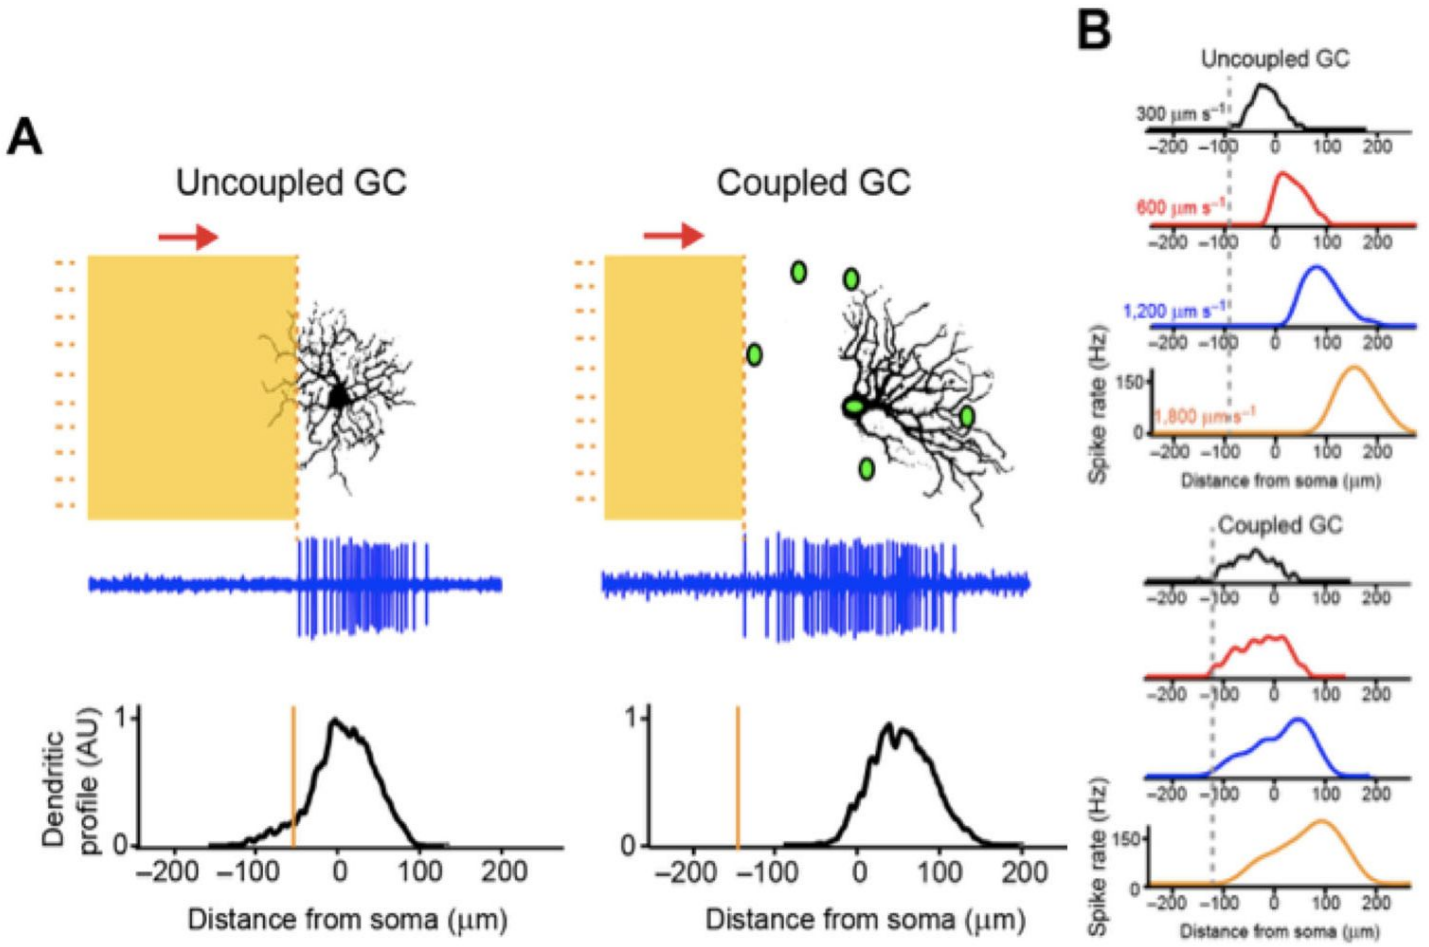

Figure 36. *Lag normalization in coupled ganglion cells*. **A**, A moving bar of light drives spiking responses in an uncoupled (left) and a coupled (right) ganglion cell (GC) in mouse retina. For the coupled cell, the locations of nearby coupled ganglion cells are plotted in green. The spike train elicited by the moving bar is shown in blue. The moving bar (yellow) is shown at the spatial location where it initiated responses. Below are average positions where spiking initiated (orange vertical line) compared to the average dendritic tree location (black lines) of uncoupled (left) and coupled (right) ganglion cells (n = 9 for each group). **B**, PSTHs of the spike rate of uncoupled (top) and coupled (bottom) ganglion cells to bars moving at 4 different speeds. On the X-axis, the spike rate is plotted with respect to where in space the leading edge of the moving stimulus was with respect to the soma (soma position is at 0 μm). Taken from Trenholm et al. (2013b) (166).

different manners in which gap junction connections are plastic, and thus allow circadian rhythm, light adaptation, or neuronal activity to gate their activity and modify circuit function.

About the authors

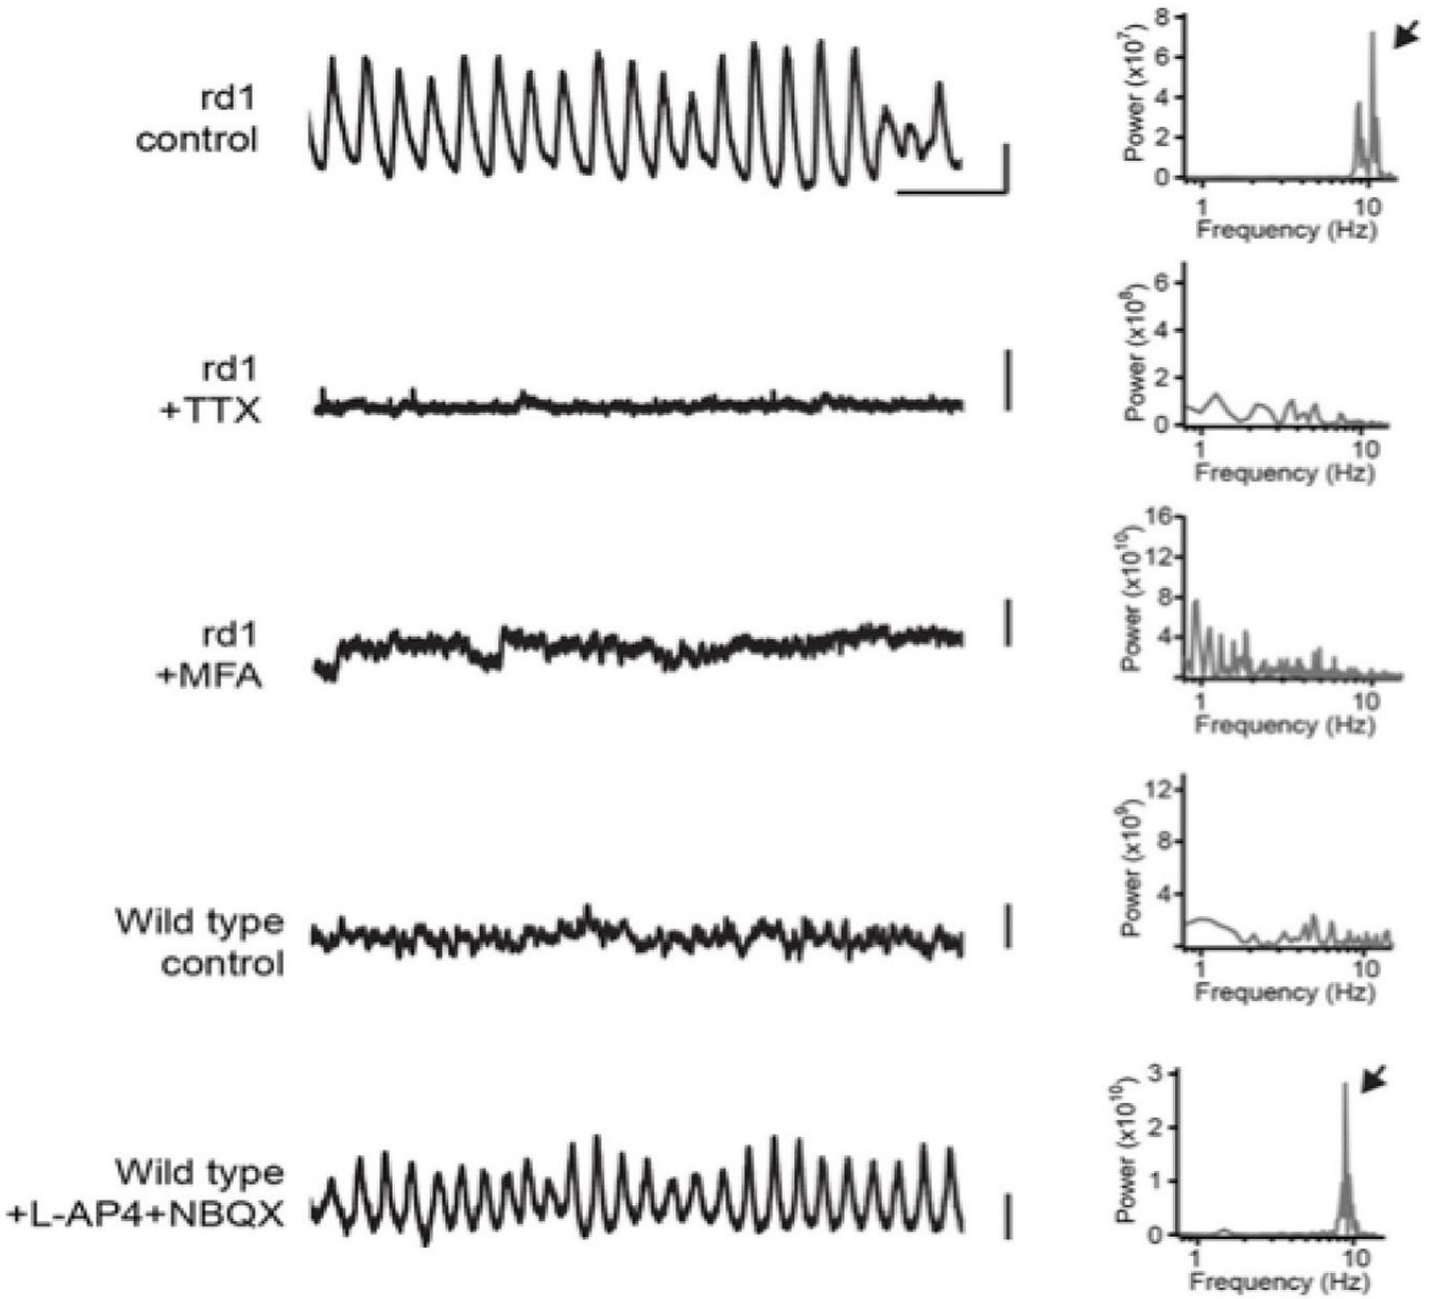

Figure 38. rd1 membrane oscillations are inhibited by TTX and gap junction blockers, and similar oscillations can be elicited in wild type retina. Left (top three traces), Current clamp recordings reveal membrane oscillations in an rd1 ON cone bipolar cell that are blocked by the voltage-gated Na^+-channel blocker tetrodotoxin (TTX) and the gap junction blocker meclofenamic acid (MFA). Left (bottom two traces), Current clamp recordings from a wild type ON cone bipolar cell in control (second trace from the bottom) and when glutamatergic input from photoreceptors was pharmacologically blocked (bottom trace). Right, Power spectra are shown for the traces on the left. Adapted from Trenholm and Awatramani (2015) (203).

Dr. Stuart Trenholm received his PhD in neuroscience from Dalhousie University, in Halifax Canada, in the lab of Dr. Gautam Awatramani. Subsequently he was a postdoctoral fellow in neuroscience in the lab of Dr. Botond Roska, at the Friedrich Miescher Institute for Biomedical Research in Basel, Switzerland. He is now an Assistant Professor at the Montreal Neurological Institute at McGill University, in Montreal, Canada. His lab examines the neuronal circuitry underlying visual perception and studies vision rehabilitation strategies.

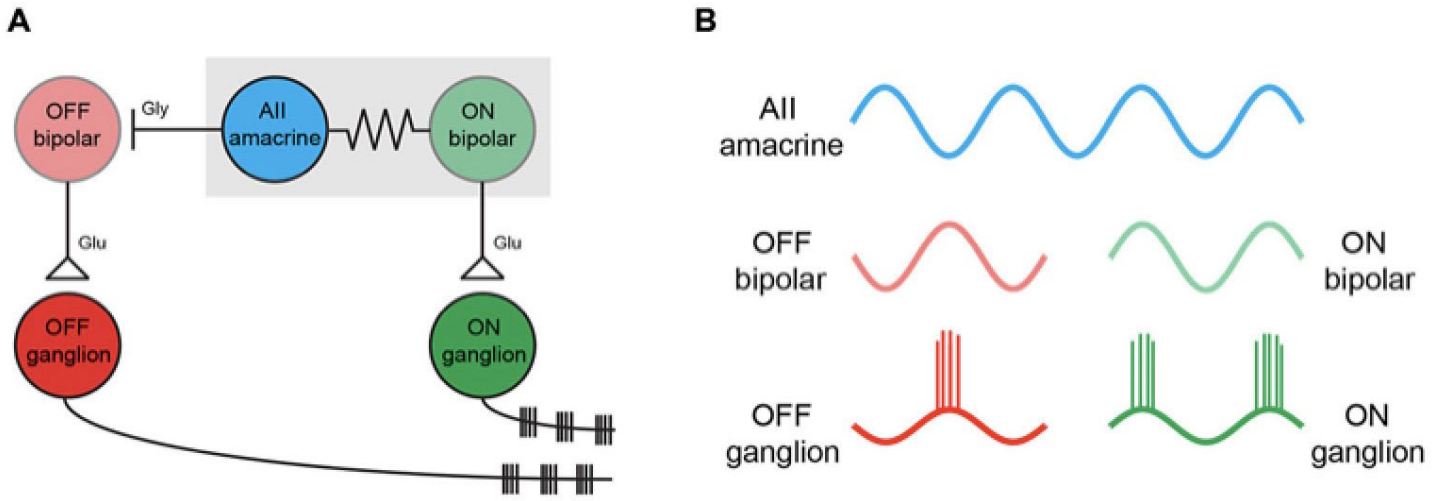

Figure 39. Model for spontaneous oscillations in rd retina. **A**, Upon losing normal glutamatergic input from photoreceptors following retinal degeneration, aberrant activity arises in the coupled AII amacrine cell-ON cone bipolar cell network, that then propagates through the rest of the retina (**B**). Taken from Trenholm and Awatramani (2015) (203).

Dr. Gautam Awatramani received his B.S. from the University of Rochester (1995) and then did his Ph.D. in Physiology and Biophysics under the supervision of Dr. Malcolm Slaughter at SUNY Buffalo. He was a postdoctoral fellow at the Vollum Institute (Portland, OR, 2000-2004) with Dr. Laurence Trussell, at the University of British Columbia (Vancouver, B.C, 2005-2007) with Dr. Tim Murphy and at the Friedrich Miescher Institute (Basel, CH, 2008) with Dr. Botond Roska. He then started his own lab at Dalhousie University (Halifax 2008-2011) and subsequently moved to the University of Victoria (Victoria, B.C.) where he is currently an Associate Professor/CRC chair in Physiology. His work currently focusses on understanding the synaptic mechanisms underlying the generation of direction selectivity in the retina.

Neuroactive Substances in the Retina

Neurotransmitters in the Retina

Helga Kolb

Created: May 1, 2005; Updated: June 1, 2009.

General Characteristics

Today's research on the retina focuses a great deal of attention on neurotransmission between the neurons of the retina. Various techniques using autoradiography, immunocytochemistry and molecular biology are being used to mark neurons for neurochemicals, their synthesizing enzymes, calcium binding proteins and receptors and transporters of these neurochemicals. Cells immunostained with antibodies to the various neurotransmitter candidates give particularly spectacular images by confocal microscopy because they become stained to their finest dendrites and so can be readily classified against their Golgi-stained equivalents. Furthermore, the whole population of neurotransmitter specific neurons are stained so one can understand their topographical organization into mosaics across the entire retina. Some immunocytochemistry for the common neurotransmitter candidates has been performed on the human retina (1, 2) but most have been done in the cat, rabbit and mouse retinas and so far the findings are the same in general. The consistency of cell types staining across species boundaries, in mammals at least, suggest that most, with a few exceptions, of the neurotransmitters, neuromodulators and neuropeptides discovered in nonhuman retinas are present in human retina too.

The Neurotransmitter of Neurons of the Vertical Pathways through the Retina is Glutamate

Glutamate is the neurotransmitter of the neurons of the vertical pathways through the retina. All photoreceptor types, rods and cones, use the excitatory amino acid glutamate to transmit signals to the next order neuron in the chain (see chapter on glutamate and Massey (3) for review). There was originally some evidence for the closely related amino acid, aspartate, being present in rods but the later sophisticated techniques of demonstrating amino acid signatures in retinal neurons cannot confirm aspartate as a retinal neurotransmitter at all (4). Uptake, release and action of glutamate and agonists upon second-order neurons in slice preparations or isolated cells in tissue culture have also all confirmed glutamate to be the neurotransmitter acting at the first synapse in the retina (see Lasater and Lam (5) for review). The action of the photoreceptor neurotransmitter upon the second-order neurons is through two different types of sensory channels though. The one type of postsynaptic receptor type is the metabotropic glutamate channel (mGluR6) that involves a second messenger cascade and cyclic GMP for activation of the channel (in the ON-center bipolar cell) whereas the other is an ionotropic channel via at least two types of AMPA receptors and Na ions (OFF-center bipolar and horizontal cells) (6-9). Photoreceptors in most vertebrates including human, havea content of D2 dopamine receptors somewhere upon there surface (10).

Glutamate is also considered to be the neurotransmitter of all bipolar cells and most ganglion cells in the vertebrate retina including the monkey retina (Kalloniatis and Marc, personal communication and Marc et. al. (4)). In an immunocytochemical study of the human retina a similar conclusion was drawn by us. All the ganglion cells appeared to label strongly with antibodies to glutamate (2) (see Fig. 1).

Bipolar cells have receptor channels that are either of the metabotropic type, mGluR6,(APB sensitive) or ionotropic type (AMPA) at their dendrites in the OPL, while their axonal ending in the IPL have channels and receptors for GABA (A, B and C types), D1 dopamine and glycine because, of course, all kinds of amacrine cells are presynaptic at these sites in the IPL neuropil. Ganglion cells are as diverse in receptor sensors as the bipolar cells with the addition of receptors to acetylcholine (11), and the first appearance in the retina of NMDA glutamate receptors that are typical in the brain (12, 13).

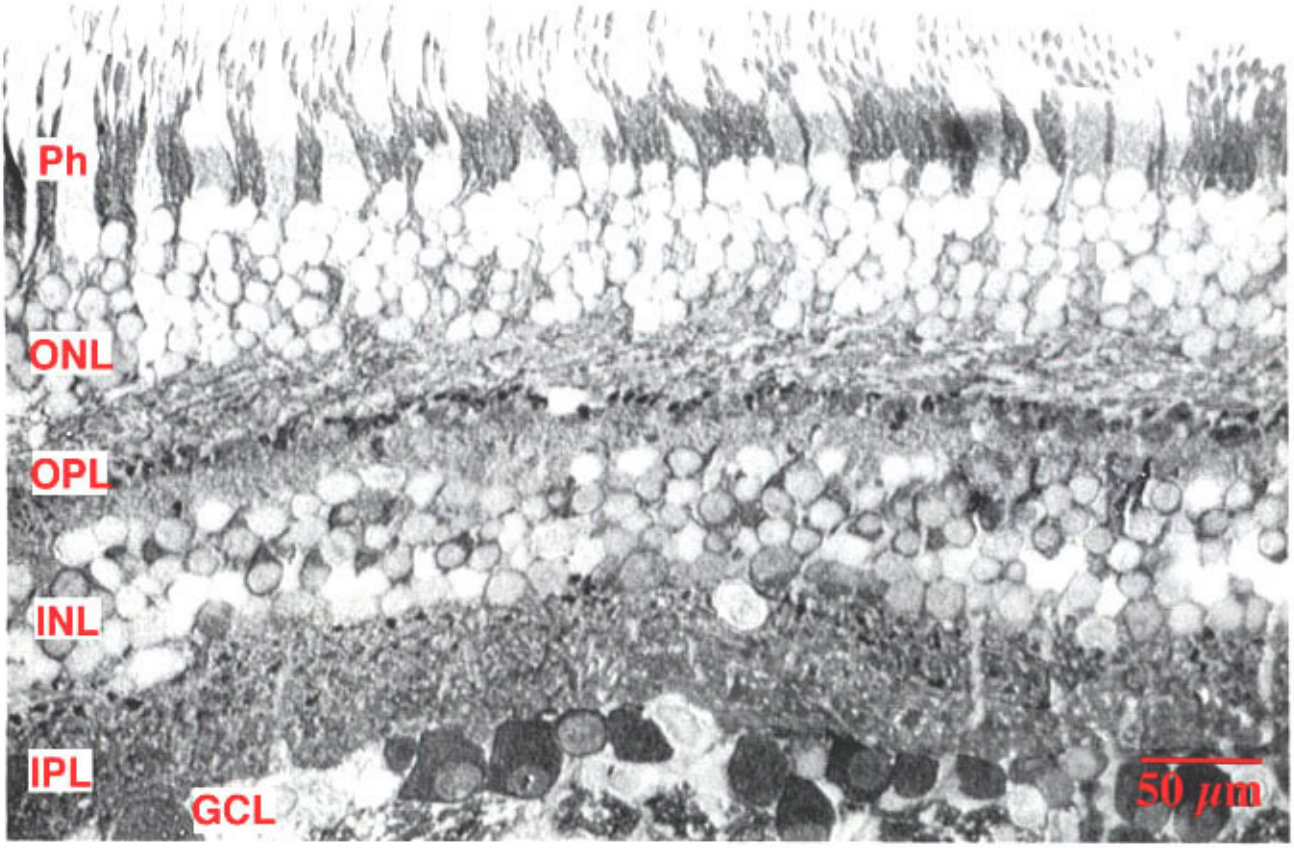

Figure 1. Distribution of Glutamate immunoreactivity in human retina.

Amacrine cells

Recently an amacrine cell type has also been shown to contain the glutamate transporter, vesicular glutamate transporter 3, shortened to VGLUT3 (14, 15). VGLUTs are used to concentrate cystolic glutamate into the synaptic vesicles. Typically in the retina the VGLUT1 isoform is expressed in photoreceptors and bipolar cells and the VGLUT2 in ganglion cells. The amacrine cell type that can be immunostained to the antibody to VGLUT3 is found to be a small-field amacrine cell with varicose processes that are restricted in branching to the OFF laminae (S1 and S2) of the IPL (Fig. 2A). It is also immunoreactive to the transmitter glycine as seen in Fig. 2, B and C, but not reactive for GABA, dopamine (Fig. 3, A-C) or acetylcholine. Fig. 3, A-C, shows that the dopamine cell and its dendrites run above the branches of the VGLUT3 cell and indeed appear to be able to make synaptic contact with the cell bodies of the latter cell type, in the way we know dopamine cell processes do (see below and amacrine cell chapter). The VGLUT3 amacrines appear to be in a good position to interact with OFF center ganglion cell, stained for MAP-1, dendrites as shown in Fig. 3, D-F.

Electron microscopy of VGLUT3 dendrites in the IPL, indicate that they are postsynaptic to OFF cone bipolar cell axons (Fig. 4B) and presynaptic to OFF ganglion cell dendrites (Fig. 4A).

Recent evidence from the metabolic mapping technique of Marc and Jones (16) indicates that a dopaminergic amacrine cell type also has a content of glutamate. However, from the above evidence on VGLUT3 immunostaining it is clear that the dopaminergic type 1 cell does not use that particular vesicular glutamate transporter.

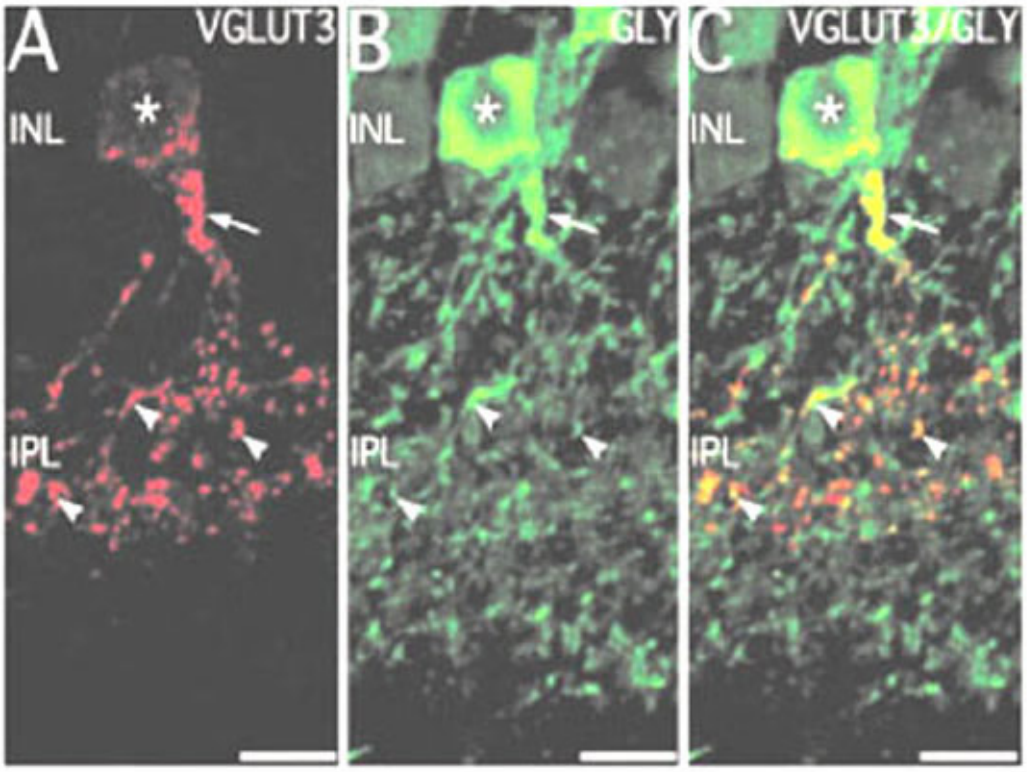

Figure 2. VGLUT3 immunostaining (A, red) shows a small-field amacrine cell. It also Immunostains for glycine (B,C).

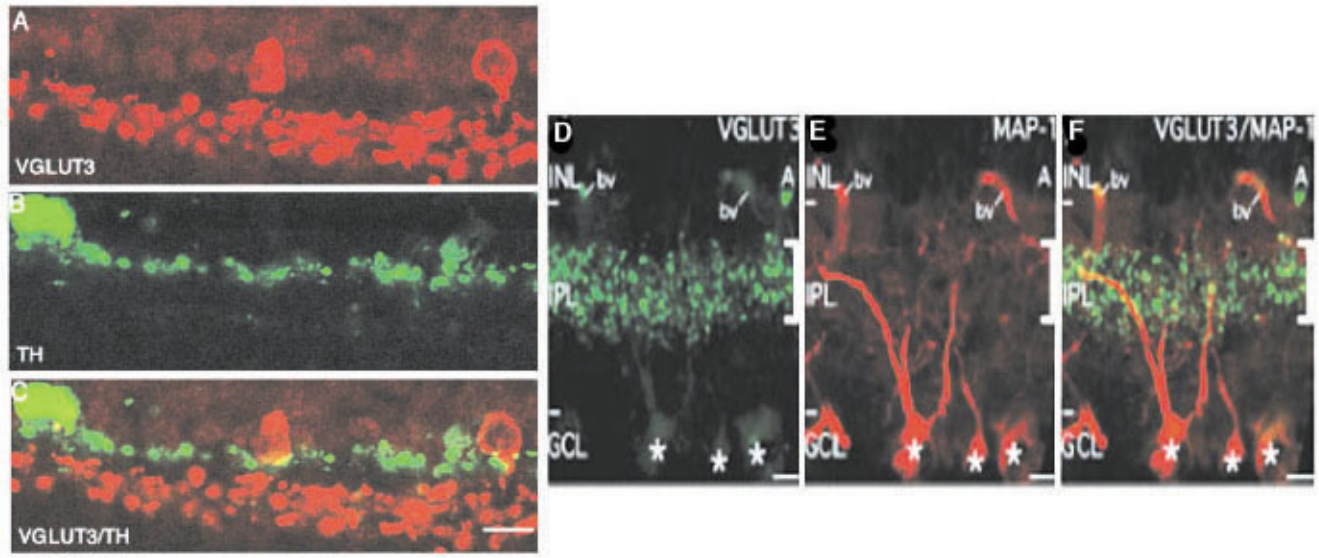

Figure 3. A-C, VGLUT3 cell has dendritic branching in S1 and S2. Dopamine cells branch above the main plexus of the VGLUT3 cell. D-F, The MAP-1 ganglion cells (red) branch in the same layers as the dendrites of the VGLUT3 cell.

Gamma Aminobutyric Acid

The classical inhibitory neurotransmitter gamma aminobutyric acid (GABA) occurs in many different varieties of amacrine cells, and in one or more classes of horizontal cell in most vertebrate retinas (4). There is still some controversy over whether GABA is contained within horizontal cells in monkey and human retina.

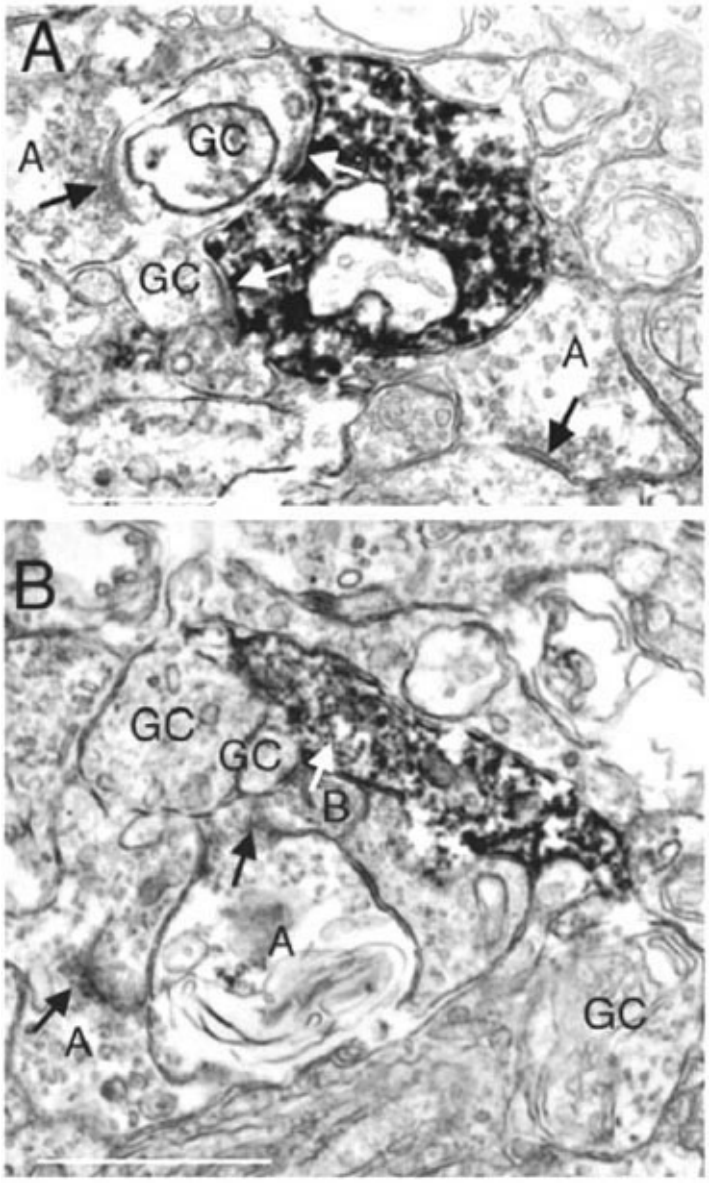

Figure 4. Electron microscopy of VGLUT3 immunostained processes in the IPL of the rat retina.

In this figure (Fig. 5a) taken from human peripheral retina, it can be seen that there is heavy staining with antibodies to GABA in the inner plexiform layer (three heavier bands can be discerned) and in about half of the amacrine cell bodies in the lower row of amacrine cells in the inner nuclear layer. Some displaced amacrines and interplexiform cells are also revealed with GABA immunocytochemistry (2). However, the horizontal cells are not stained at all in peripheral retina although they are in foveal retina apparently (Cuenca, personal communication).

A valuable identification of individual cell types that contain GABA has come from double staining techniques upon Golgi stained cell types (17). The amacrine cell that are contain GABA are all of the large-field types. Thus we know now that A10, A13, A17, A19, and the interplexiform cell accumulate GABA and probably use it as their primary neurotransmitter (Fig. 5b). Many large field amacrine cells also colocalize GABA with another neurotransmitter. Thus the GABAergic A17 colocalizes serotonin, the acetylcholine (starburst amacrine) colocalizes GABA and so does the dopamine A18 cell (18). Neuropetides (see later) are also commonly colocalized with GABA i.e. substance P in A22 is almost certainly the secondary transmitter to GABA as the primary. GABAergic amacrine cells and IPCs act upon bipolar, amacrine and ganglion cell processes or cell

bodies in the neuropils of the retina via all the three varieties of GABA receptors (a, b and c types). It appears clear that A17 type or the type that makes reciprocal synapse with the rod bipolar axon terminal uses a GABAc receptor (see chapter by Haohua Qian) (19). However, for most amacrine cells, what GABA receptors are associated with which morphological or physiological subtype of amacrine cell, still need more elucidation.

Glycine

The other classic inhibitory neurotransmitter glycine, accounts for most of the small-field types of amarine cell. All amacrine cells in the vertebrate retina can be accounted for by the two inhibitory neurotransmitters GABA and glycine (4). In addition one or more types of bipolar cell are also thought to contain glycine in mammalian retinas including monkey and human.

In Fig. 6 it can be seen that the immunostaining for glycine is just as strong in the inner plexiform layer as GABA staining. About the same number of amacrine cells are revealed. However there is an addition of some small bipolar cell bodies in the inner nuclear layer and the occasional large cell body of a ganglion cell type in the ganglion cell layer (2).

Pourcho and Goebel (20) showed quite clearly that tritiated glycine accumulated in Golgi stained AII, A4, and A8 cells in cat retina. More recently as many as 10 different morphological types of small field amacrine cells have been demonstrated by immunocytochemistry and GFP (green fluorescent protein) staining in mouse retina (21, 22). The A8 cell was the most strongly glycinergic of the small field amacrine cells according to Pourcho and Goebel, with the rod amacrine AII cell being also very clearly glycinergic. Fig. 7 shows the commonest glycinergic amacrine cells present in the mouse retina (22). These cells are presumably also so in the cat and primate retinas.

Glycine receptors are found on all the neurons that are postsynaptic to these glycinergic (all small-field) amacrine cells. Thus receptors are found on certain bipolar cell axons, and on many amacrine and ganglion cell dendrites. Again like for the GABA receptors, linking receptor type to morphological type of postsynaptic cell is still a hot topic for research in the retina (22, 23).

Dopamine Is Present in Amacrine Cells in the Mammalian Retina

The neuromodulator dopamine is found in one or more types of amacrine cell in the mammalian retina. The most robustly stained dopaminergic cell after immunocytochemistry to the rate limiting enzyme of dopamine synthesis, tyrosine hydroxylase (Toh), is recognized as an A18 cell of the Golgi descriptions (24, 25) (Fig. 8).

It is very characteristic in wholemount appearance, with a large cell body and a dense plexus of dendrites in stratum 1 of the inner plexiform layer. Holes or "rings" in the plexus of criss-crossing stained dendrites are sites of amacrine cell bodies or large amacrine dendrites (see chapter on amacrine cells) on which the processes of the Toh stained plexus synapse. The Type 1 dopamine cell (A18) is known to synapse upon the AII rod amacrine cell and possibly also upon A8 and A17 cells (26-29).

A second type of dopamine amacrine cell has also been described in the monkey and human retinas (2, 30). The Type 2 CA cell has dendrites stratifying in stratum 3 of the IPL and in vertical views of Toh processed human retinas these dendrites can be seen quite clearly below those of the Type 1 (A18) dendritic plexus in stratum 1 (orange arrows, Fig. 9).

Type 1 dopamine cells provide ascending processes to the outer plexiform layer (see above) which are known to synapse on the GABAergic interplexiform cell (see previous chapter on feed-back loops).GABA and dopamine colocalize to the A18 cell type (Type 1 CA cell) and serotonin has also been found to co-exist in in the same amacrine cells in cat retina (31).

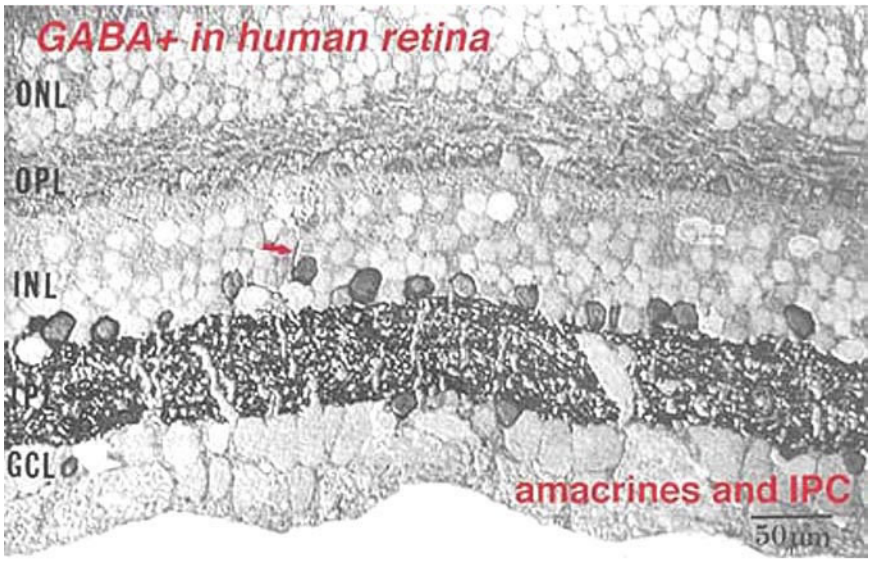

Figure 5a. Expression pattern of GABA immunoreactivity in human retina.

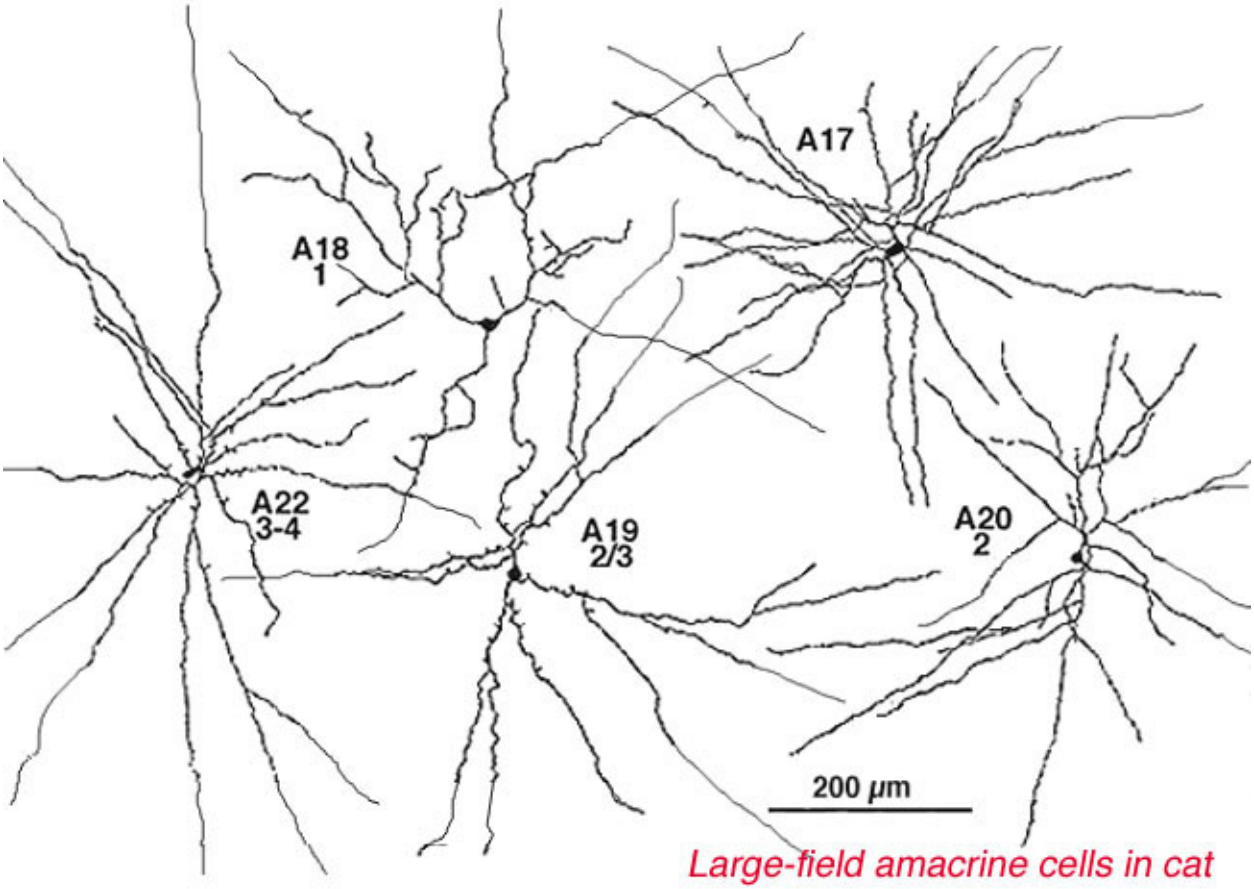

Figure 5b. Large-field amacrine cells in all retinas use gabaergic transmission. Illustration of large-field cell types in cat retina.

Both D1 and D2 receptor types have been found on neurons of the inner and outer retina in many vertebrates. It is thought that the D1 receptor is particularly associated with cells that are coupled by gap junctions, because of dopamine's known action in cyclic AMP regulation of gap junction channels (32). Thus D1 receptors have been

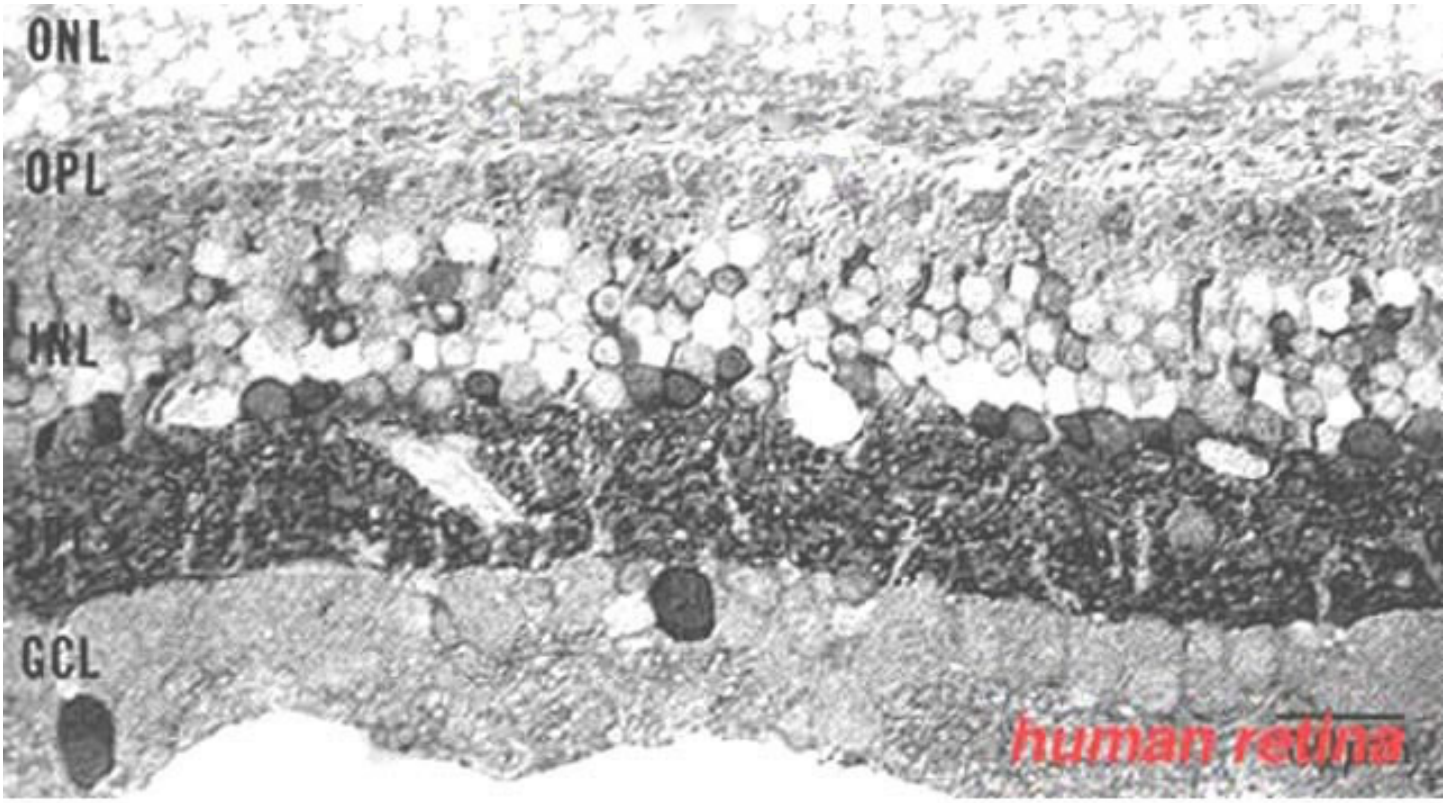

Figure 6. Expression pattern of glycine immunoreactivity in human retina.

demonstrated in association with horizontal cells of the OPL and some amacrine cells of the IPL. D1 receptors are robust on ganglion cell bodies as well (personal observations), despite the fact that the dopamine amacrine cell is not known to make direct synapses upon ganglion cells. D2 receptors are also found in the retina associated with photoreceptors in the outer nuclear layer, outer limiting membrane and retinal pigment epithelium even. Also they are present in the IPL but the target cells in this neuropil are not well understood yet.

Acetylcholine

The classic fast excitatory neurotransmitter of the peripheral nervous system, acetylcholine (ACh), is found in a mirror symmetric pair of amacrine cells in the vertebrate retina. In the rabbit such cells have been named starburst cell (33, 34). One of the mirror pair occurs in the amacrine cell layer with dendrites in sublamina **a** (OFF sublamina of the IPL). The other of the pair has its cell body displaced to the ganglion cell layer and its dendrites stratify in sublamina **b** (ON sublamina of the IPL).

These ACh containing amacrine cells are common to almost all vertebrate retinas and have been described morphologically in human retina too (25, 35) (see previous chapter on amacrine cells). Both muscarinic and nicotinic receptors have been demonstrated in the mammalian retina, particularly associated with transient phasic ganglion cells (Y cells) (36, 37) and effects of ACh and antagonists on ganglion cell responses are documented but not well understood (Fig. 10).

Serotonin

There are two types of serotonin-accumulating amacrine cell in the rabbit retina (38). One of these is almost certainly the A17 cell or the reciprocal amacrine cell of the rod system in the rabbit (see previous chapters) (Fig. 11). However, in cat retina, a completely different amacrine cell type stains with antibodies against serotonin.

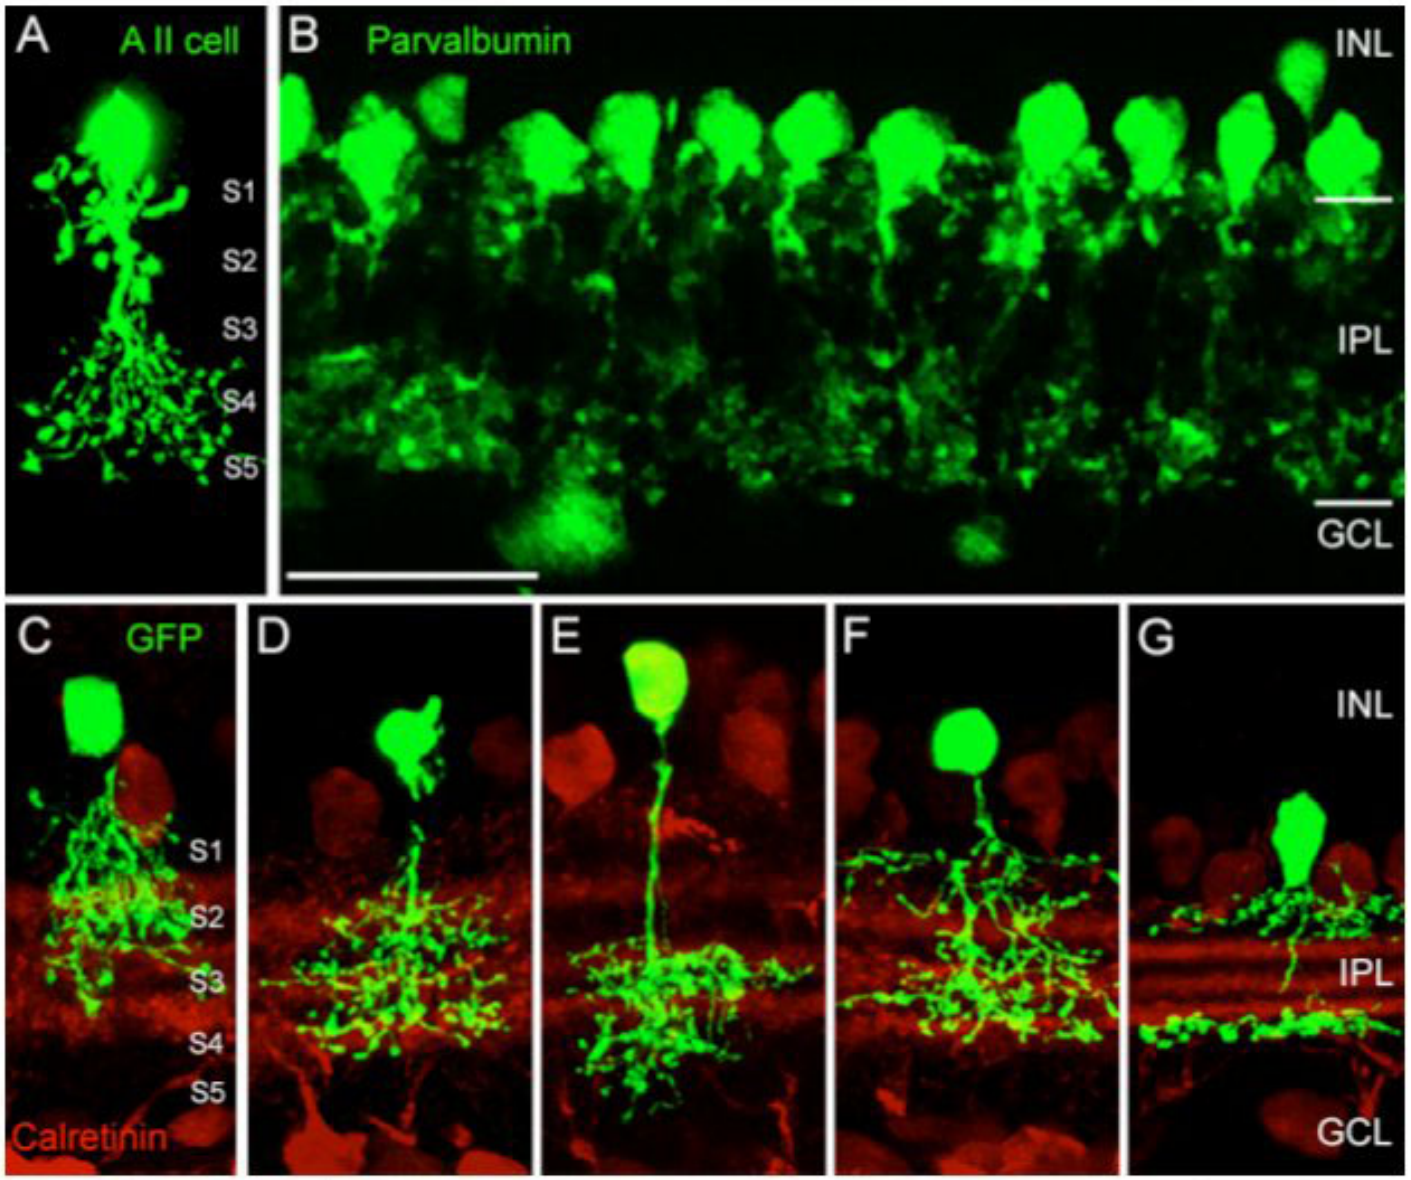

Figure 7. Expression of glycine immunoreactivity in small-field amacrine cells of mouse retina. A-B, aII amacrine cells; C, Type 2 cell (A2 cell); D, Type 3 cells (A4 cell); E, Type 4 cell (A6 cell); F, Type 7 cell (A9? cell): G, A8 cell (Kolb et al. (24)). (Adapted from Waessle et al. (22)).

One cell type in cat is similar to the wide-field cell A20, while the other may be the A18 or dopamine cell (31). Even where serotonin is strongly demonstrated in these amacrine cells in rabbit retina, it is not thought to be the neurotransmitter.

Serotonin co-exists with GABA, in the A17 cell and the latter is thought to be the releasable transmitter (18, 39). A few cold-blooded vertebrates have a bistratified amacrine cell and a bipolar cell type that immunostain for serotonin (40, 41).

Adenosine May Be a Retinal Neurotransmitter

The purine nucleotide, adenosine may be a neurotransmitter or neuromodulator in the mammalian retina. Autoradiography and immunocytochemistry for adenosine has revealed cell bodies in the amacrine and

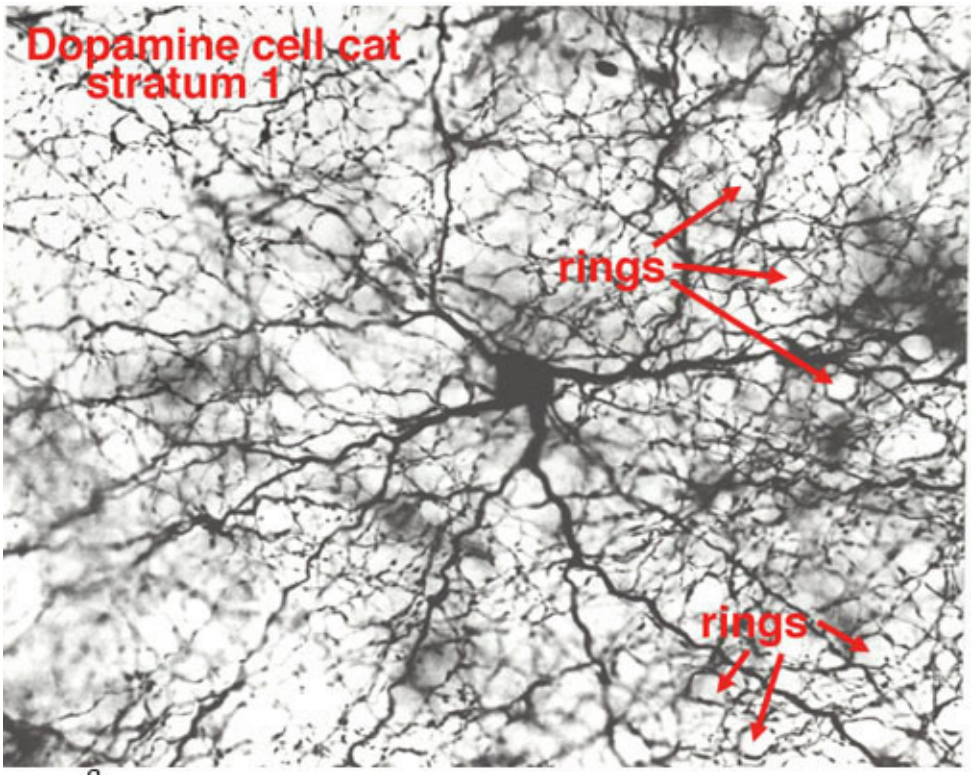

Figure 8. Immunostaining with antibodies to TOH. A18 amacrine cells stain and have overlapping dendrites that form into rings.

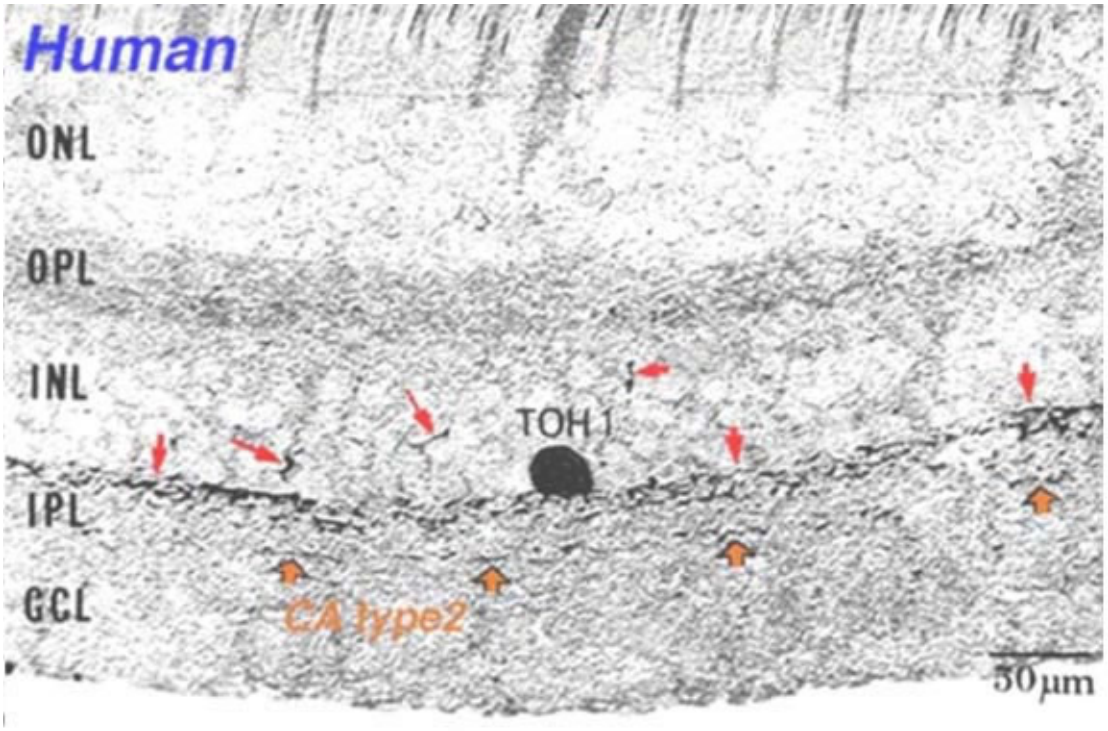

Figure 9. Vertical section of a type 1 TOH+ amacrine cell.

ganglion cell layers (42). Probably most of these cells are amacrine cells but some in the ganglion cell layer may be true ganglion cells. In human retina additional cells that could be bipolar or horizontal cell label too. K+ and light evoked release of adenosine can be measured in rabbit and chick retinas. And the vertical pathway

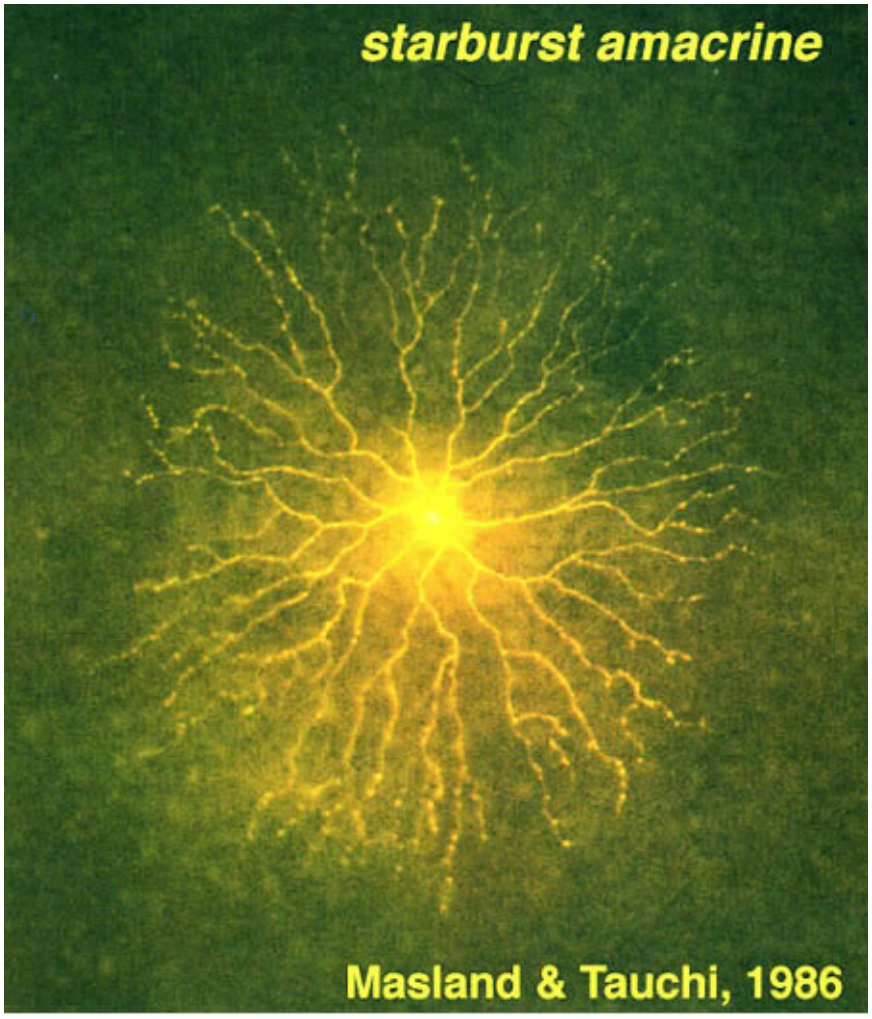

Figure 10. ACh containing amacrine cell stained with Lucifer yellow.

neurotransmitter glutamate can induce adenosine release from [^{3}H]-adenosine preloaded rabbit retina. Additionally some effects of adenosine on the ERG generated in the retina and on the activity of ganglion cell terminals in the superior colliculus have been recorded and the information points to the strong likelihood that adenosine does play a neurotransmitter role in the vertebrate retina (See review by Blazynski and Perez (42)). Adenosine colocalizes with GABA, acetylcholine and serotonin in various retinas. Much more research is needed in this area.

Substance P Occurs in an Amacrine Type and a Ganglion Cell Type

Substance P (SP) is a neuropeptide belonging to the tachykinin family that include neurokinin A, neuropeptide K and neurokinin B, as well. Substance P is thought to be a neurotransmitter or neuromodulator in the vertebrate retina (See Kolb et al. (43) for a review).

SP-IR amacrine cells appear to be of a single type in the human retina (Fig. 12). They are large-field cells with large cell bodies (16 um diameter) lying in normal or displaced positions on either side of the inner plexiform layer (IPL).

Their sturdy, spiny and appendage-bearing dendrites stratify in stratum 3 (S3) of the IPL, where many overlapping fine dendrites intermingle to form a plexus of stained processes. Either cell bodies or primary

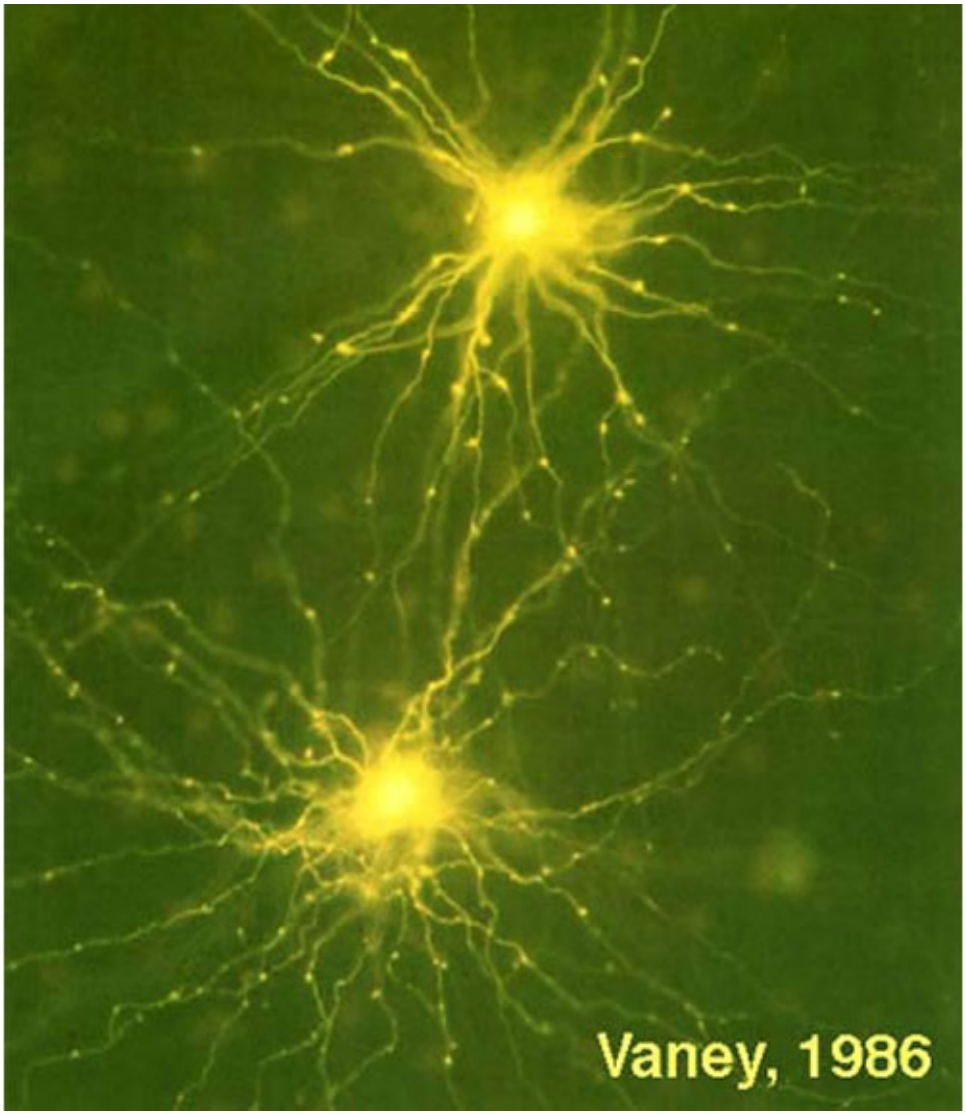

Figure 11. Serotonin accumulating amacrine cells in rabbit retina known as A17 GABAergic cells in cat and primate retinas.

dendrites emit "axon-like" process which divides typically into two long, fine processes that run in opposite directions for hundreds of microns in S5 and S3 before disappearing as distinct entities in the stained plexus in S3. Long fine dendrites also pass from the dendritic plexus to run in S5 and down to the nerve fibre layer to end as large varicosities at blood vessel walls. In addition fine processes are emitted from the dendritic plexus that run in S1, and some pass up to the outer plexiform layer (OPL) to run therein for short distances. The SP-IR amacrine cell has many similarities to thorny type 2 amacrine cells described in Golgi studies. SP amacrine cells co-localize GABA as a neurotransmitter (44).

In addition to the SP-IR amacrine cells, a ganglion cell type is immunostained with SP (Fig. 13). Its 20- 22 um cell body gives rise to a radiate, sparsely-branched, wide-spreading dendritic tree running in S3. Its dendrites and cell body become enveloped by the more intensely SP-IR processes and boutons from the SP-IR amacrine cell type (Fig. 13, fine arrows). The SP-IR ganglion cell type most resembles G21 of a Golgi study. A ganglion cell type in rabbit retina has definitely been proved to contain substance P. Such ganglion cells almost certainly colocalize a more standard neurotransmitter like glutamate too (45).

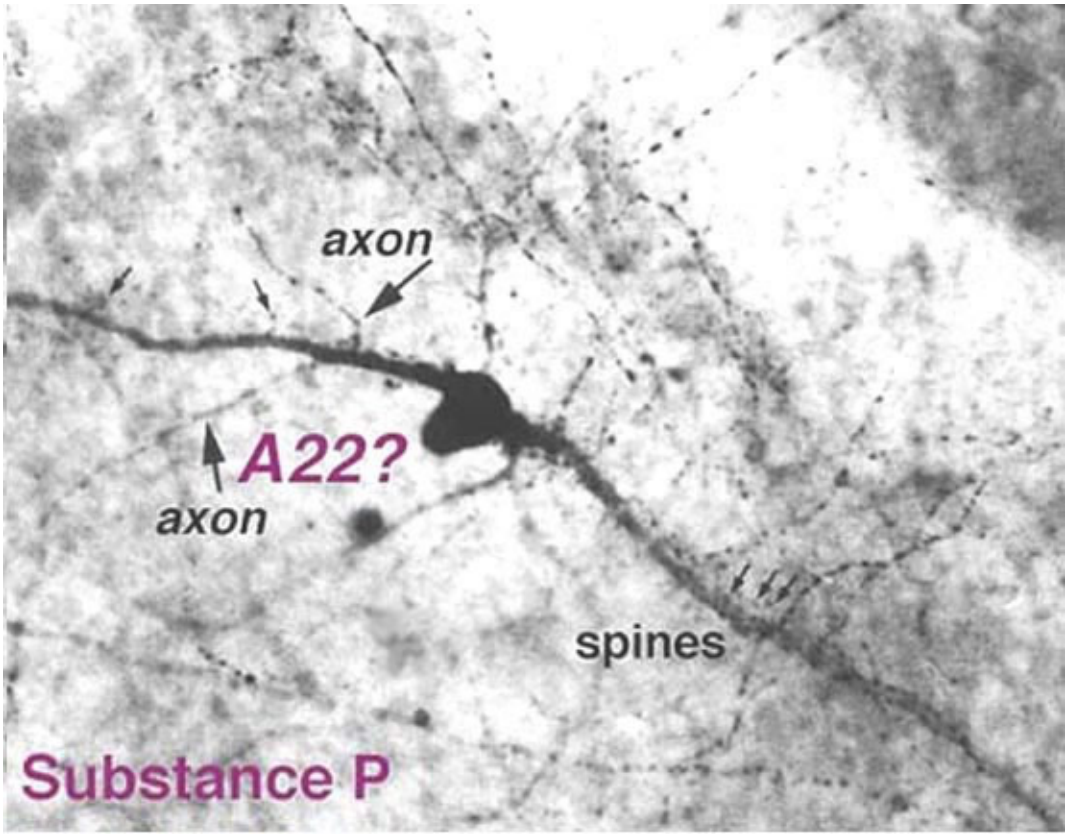

Figure 12. Substance P containing amacrine cell in human retina.

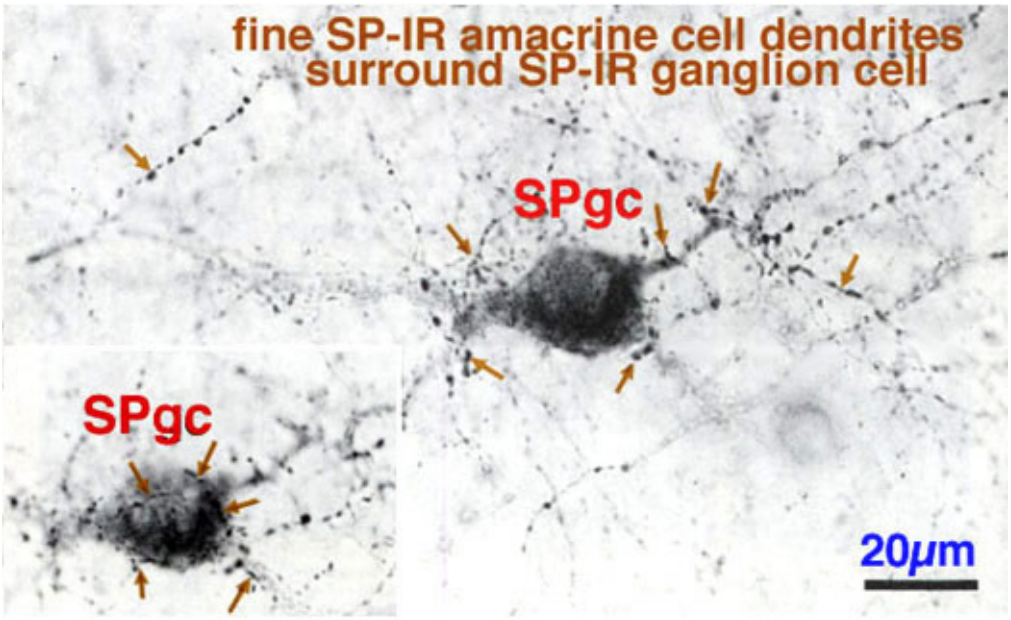

Figure 13. Substance P containing ganglion cell in human retina.

Other Neuropeptides

Immunostaining with antibodies against somatostatin has revealed a small population of neurons in the ganglion cell layer in the rabbit retina (46). They are distributed only in the inferior retina and in the far

peripheral circumference of the retina. However, in the monkey and human retinas these amacrines are more uniformly distributed. The somatostatin-IR amacrines have long fibers that distribute across the entire retina running in three plexuses in the middle and outer and inner strata of the inner plexiform layer (Fig. 14, from Marshak (47)). In the human and monkey most of the somatostatin-IR cells have their cell bodies in the ganglion cell layer (Fig. 14) and they emit fibers or axon-like processes that can be measured running 20 mm across the entire retina (48). Because these axon like processes stay within the retina, not passing to the optic nerve, the somatostatin-immunoreactive cells are likened to the associational neurons of Cajal (49).

Corticotropin releasing factor (CRF) is contained within a population of wide-field tristratified amacrines with long axon like processes, very similar in morphology to those containing somatostatin (Fig. 15) (47). Colocalization of the two peptides has not been attempted yet but it seems probably that they are one and the same cell type.

Vasoactive Intestinal peptide (VIP) immunostains a population of amacrine cells that can be normally place in the INL or displaced to the ganglion cell layer (Fig. 16). They appear to have a medium size dendritic field and dendrites that branch diffusely through the middle strata of the IPL. They may be equivalent to the A12 type of Mariani (50).

Amacrine cells that immunostain for neuropeptide Y are quite regularly stained in the primate and rodent retina. These amacrine cells have a characteristic sparsely branched wide-field dendritic tree with dendrites running in stratum 1 of the IPL (Fig. 17) (47). Recent research wherby NPY amacrine cells can be selectively ablated indicates that these cells have a role in low spatial frequency tuning of certain large ganglion cell types (51). Both ON and OFF center ganglion cell types are said to be equally affected by loss of NPY amacrine cells, which is a strange finding considering the OFF stratum branching of these particuar amacrine cells. Presumably another chain of amacrine cells is involved in spatial tuning of ganglion in addition to the NPY type.

Using antibodies to the glycine extended form of cholecystokinin, Marshak and colleagues were able to demonstrate the presence of two different morphological types of amacrine cell and a single morphological type of bipolar cell in the monkey retina (47, 52). The amacrines come as pairs that are either bistratified in the strata 2 and 4 and a larger bodied monstratified pair, again branching in either stratum 2 or 4 (Fig. 18). The blue cone specific bipolar cell is well characterized by CCK immunostaining and its distribution, contact with blue cones specfically and its probably ON center physiology is now well known (52, 53) (see chapter on S-cone pathways).

NADPH-Diaphorase Staining and the Possibility That There are Nitric Oxide Containing Neurons in the Retina

Nitric oxide is formed in many nerve cells of the peripheral and central nervous system. It is known to play a role in second messenger cascades by activating guanylyl cyclase and elevating cyclic GMP levels. Since many neurotransmitters and transduction events utilize cyclic GMP in the retina (notable phototransduction in the photoreceptors and activation of metabotropic glutamate receptors) the idea that nitric oxide might play a key role in retinal neurotransmission has been forwarded. Nitric oxide synthase the enzyme required for synthesis of nitric oxide requires NADPH as a cofactor in the cell. Thus the simple histochemical technique to reveal NADPH in a cell by the reduction of tetrazolium salts has proved to be a good marker of neurons that contain NADPH-diaphorase and hence possibly also nitric oxide synthase. An antibody has been made against the synthase but staining and identification of morphological cell types that contain this enzyme have been unsatisfactory to date for the retina. Thus the NADPH-diaphorase histochemical technique is still more reliable.

In monkey retina, three types of amacrine cell and one type of ganglion cell appear clearly stained with NADPH-diaphorase. The commonest type is the one shown above (Fig. 19 and Fig. 20) and occurs at a maximum density of 280 cell/mm2 at 1 mm from the fovea (Cuenca, personal communication). It has a large cell body that lies either in the amacrine cell layer or can be displaced to the ganglion cell layer. The dendrites radiate out from the

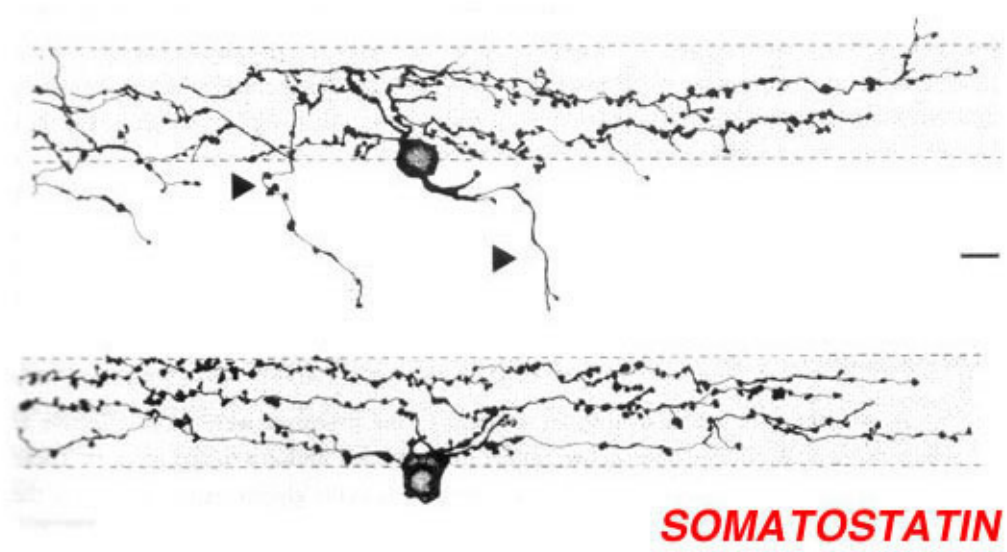

Figure 14. Somatostatin-IR amacrine cells of the monkey retina (47).

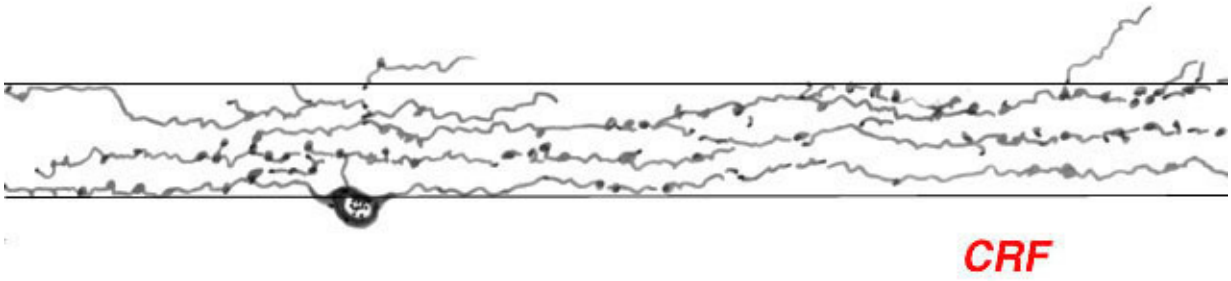

Figure 15. Vertical section of CRF-IR amacrine cells are probably the same type as those labelling with somatostatin (47).

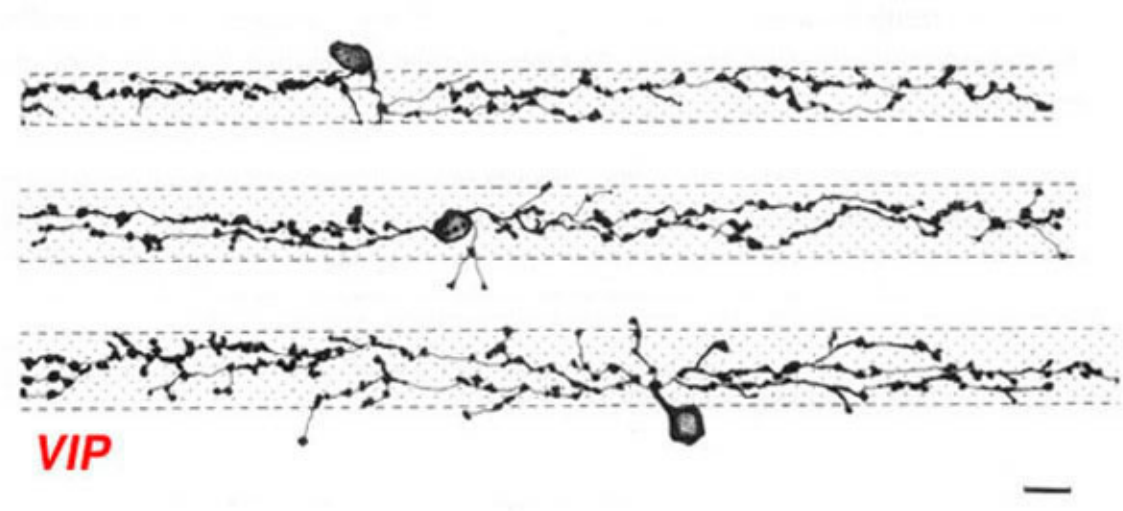

Figure 16. Vasoactive Intestinal peptide-IR amacrine cells of the monkey retina (47).

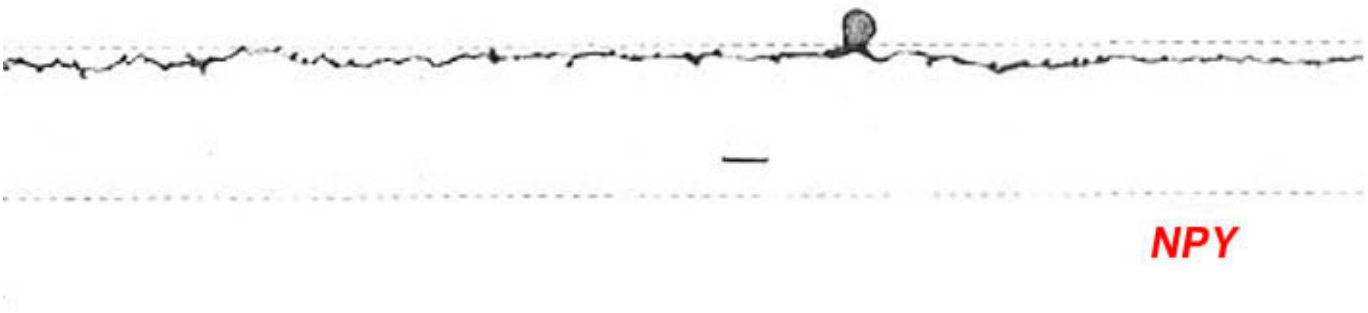

Figure 17. Vertical section of neuropeptide Y-IR amacrine cells are wide-field and unistratified in stratum 1 of the IPL (47).

cell body like the spokes of a wheel, contain, many fine spines, and lie on one plane in stratum 3 of the IPL. Fine axon like processes arise from the main dendritic tree that is about 300 um in diameter to run for mm in all directions. The cell is probably the equivalent of a spiny amacrine described by Mariani (50) and a cell type stained by Dacey as axon bearing (54).

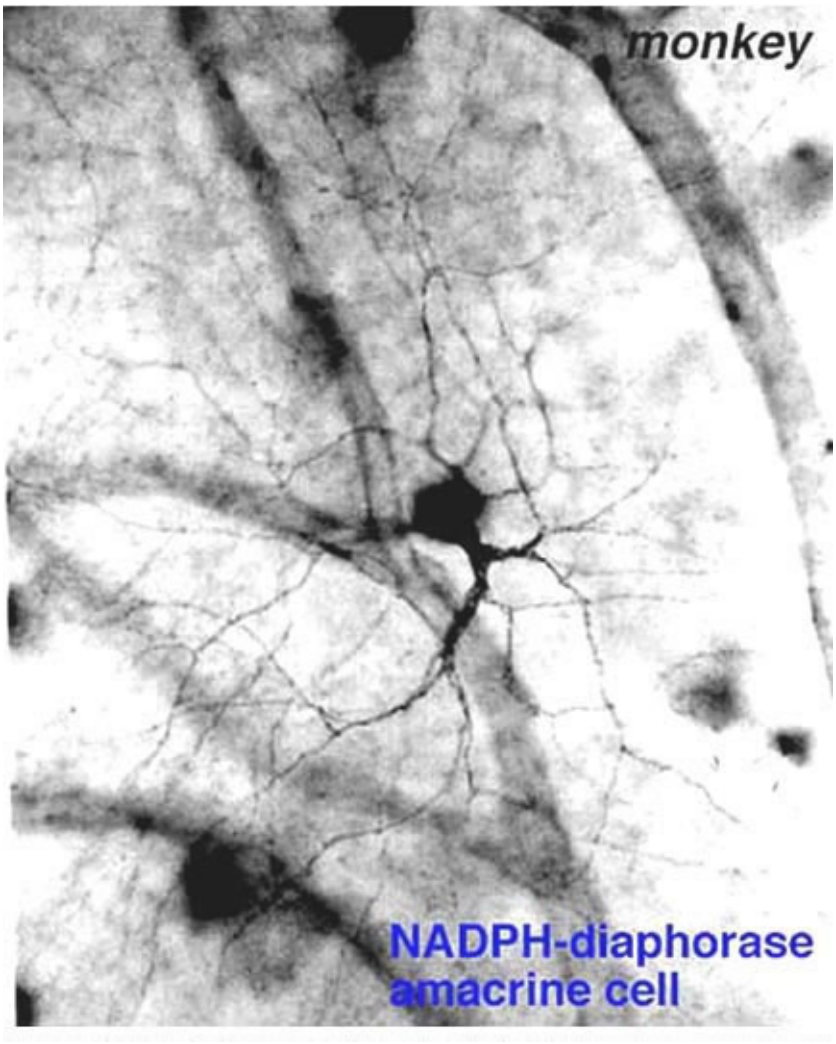

Figure 19. NADPH-diaphorase histochemical staining of an amacrine cell in monkey retina.

Amacrine Cell Populations and Mosaics Arrangements Are Revealed by Neurotransmitter Immunocytochemistry

Table 1 lists the amacrine cell types that have now become associated with particular neurotransmitter substances in the mammalian retina. The list is compiled primarily from data of cat and rabbit retinas. However, some clearly recognizable amacrine cell types of the monkey and human retina have been included. The list is as yet incomplete concerning an exact classification of each cell type by neurotransmitter signature because of the difficulty of agreeing on correspondence between different authors classification schemes and making cross species comparisons. The review article by Vaney (18) is the most comprehensive treatment on the subject of the differences between cat and rabbit retina in this regard.

Immunocytochemical staining of amacrine cells, when done on wholemounts of retina, can reveal every cell of the population that are immunoreactive to the antibody used. Thus we are increasingly acquiring population maps and distribution maps of all the different types of amacrine cells according to neurotransmitter content. Most amacrine types are arranged in regular mosaics and the individual cells have certain overlap characteristics that can be calculated from nearest neighbor statistics. The cat and monkey amacrine mosaics peak in cell density with closest packing of their smallest dendritic trees in the fovea or area centralis. Then from center to periphery the neurons distribute evenly in concentric rings of decreasing density and increasing dendritic field

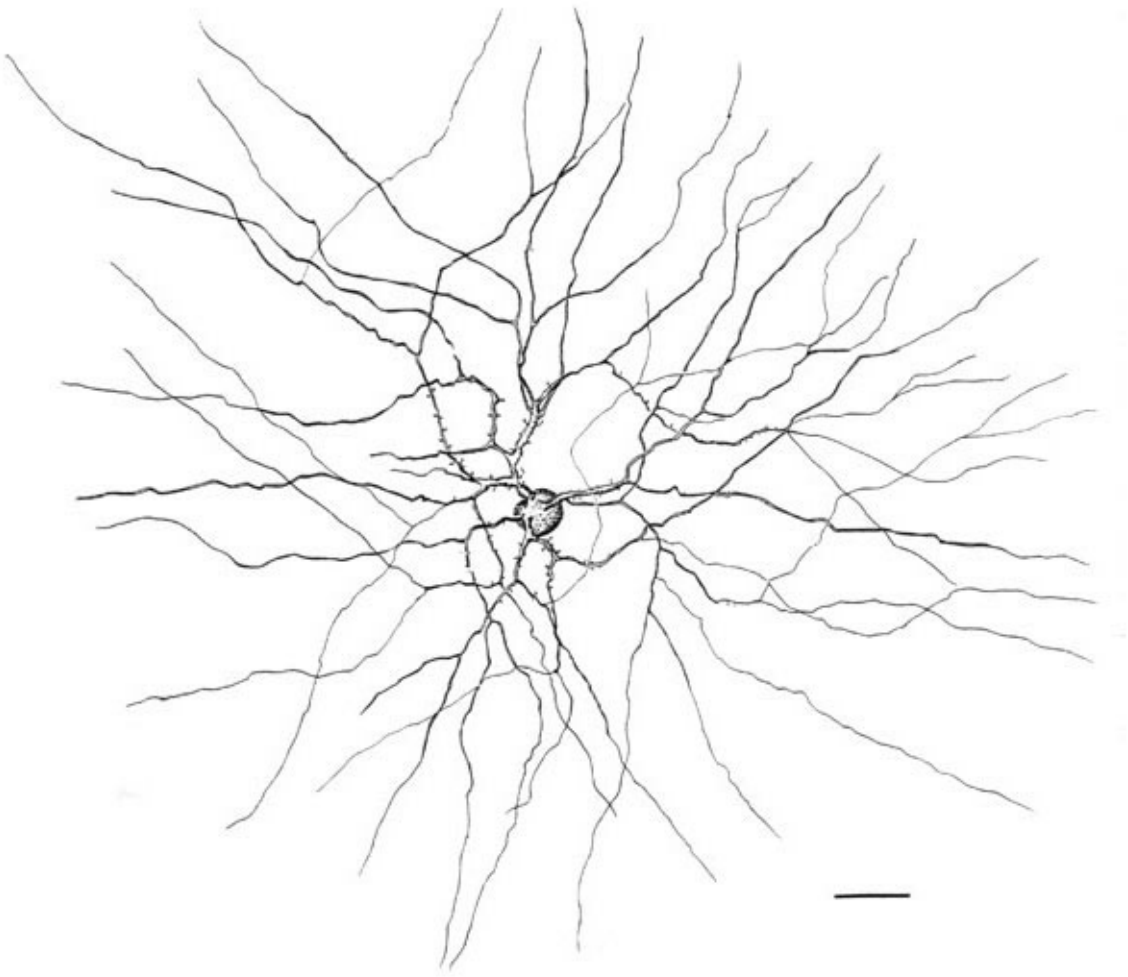

Figure 20. Drawing from wholemount retina stained with NADPH-diaphorase of the commonly stained amacrine cell.

sizes. The rabbit amacrine mosaics peak along the horizontally-organized visual streak and fall off therefrom linearly into superior and inferior retina (18). Some of the more sparsely distributed neurotransmitter types, have unique distributions. For example, the somatostatin-immunoreactive associational neurons in rabbit retina are located almost exclusively in inferior retina.

The commonest amacrine cell type of the cat and rabbit retina is the glycinergic AII amacrine (estimated 512,000 total in cat retina) followed by the serotonin-accumulating amacrines (between 170,000 and 230,000 cells in rabbit), cholinergic cells (approximately 130,000 in rabbit retina) and substance P-containing cell types (39,000 cells in cat retina). Dopaminergic amacrine cells are some of the lowest density populations of cells (3-5,000 in cat; 6-8,000 in rabbit). Somatostatin occurs in a small population of only 1000 cells in rabbit retina (Fig. 21).

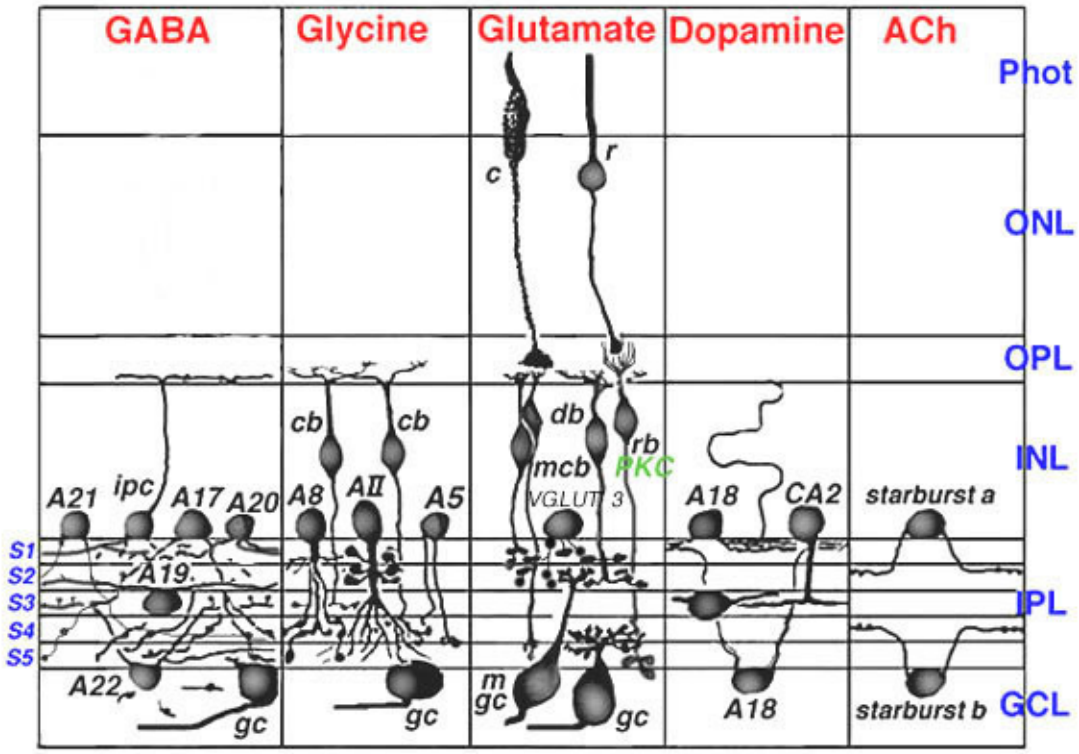

Figure 21. Summary diagram of the organization of neurotransmitters in the retina.

Table 1. Common neurotransmitter substances found in mammalian amacrine cells

Neurotransmitter		Amacrine cell type	
	rabbit	cat	primate
GABA		A2, A10, A13, A17, A19, A22, A20	same as cat
glycine	All DAPI-3	A3, A4 All A8	same as cat
acetylcholine	"starburst" Ca, Cb	"starburst" a-type, b-type	"starburst" a-type, b-type
dopamine	Toh-IR CA1, CA2, CA3	A18	CA-type1 CA-type2
serotonin	S1, S2	A20 and A22	A17
substance P	tri-stratified	A22	thomy 2
VIP	Tri-stratified		
somatostatin	association neuron long axon-like processes		
nitric oxide	NADPH-diaphorase cell		multiaxonal spiny

$GABA_C$ Receptors in the Vertebrate Retina

Haohua Qian

Created: May 1, 2005; Updated: June 1, 2007.

Properties of GABA Receptors

γ-Aminobutyric acid (GABA) is the main inhibitory neurotransmitter in the central nervous system. The inhibitory action of GABA is mediated by the receptors present on the cell membrane and results in a reduction of neuronal excitability. At least three types of GABA receptors have been characterized. Table 1 summarizes some of the general properties of these three types of GABA receptors. $GABA_A$ receptors are ligand-gated chloride channels. They mediate fast inhibition and have a wide distribution throughout the central nervous system. $GABA_A$ receptors have a diverse molecular composition. At least 16 subunits in six groups have been identified. Pharmacologically, these receptors are antagonized by bicuculline. $GABA_A$ receptors are also the targets of many therapeutic compounds (such as general anaesthetics, sedative drugs, and alcohols). These compounds allosterically modulate $GABA_A$ receptor channel activities. $GABA_B$ receptors belong to the G-protein-coupled receptor superfamily. The inhibition of $GABA_B$ receptors is mediated by indirect gating of either potassium or calcium channels. $GABA_B$ receptors are activated by baclofen and antagonized by phaclofen and saclofen. The subunits of $GABA_B$ receptors have recently been cloned. $GABA_C$ receptors are the newly identified member of the GABA receptor family. They are also linked to chloride channels, with distinct physiological and pharmacological properties. In contrast to the fast and transient responses elicited from $GABA_A$ receptors, $GABA_C$ receptors mediate slow and sustained responses. Pharmacologically, $GABA_C$ receptors are bicuculline- and baclofen-insensitive and are not modulated by many $GABA_A$ receptor modulators (such as benzodiazepines and barbiturates). GABA ρ subunits are thought to participate in forming $GABA_C$ receptors on the neuronal membrane, but the exact molecular composition of these receptors is yet to be determined. $GABA_C$ receptors are expressed in many brain regions, with prominent distributions on retinal neurons, suggesting that these receptors play important roles in retinal signal processing.

Table 1. Characteristics of GABA receptors.

	$GABA_A$ receptor	$GABA_B$ receptor	$GABA_C$ receptor
Category	Ligand-gated channel	G-protein-coupled receptor	Ligand-gated channel
Subunits	α, β, γ, δ, ε, π	GBR1, GBR2	ρ
Agonists	Muscimol, THIP	Baclofen	
Antagonists	Bicuculline, picrotoxin	Phaclofen	TPMPA, picrotoxin
Desensitization	Yes	No	No
Modulator	Benzodiazepine barbiturates		Zinc

$GABA_C$ Responses on Retinal Neurons

The term "$GABA_C$ receptor" was first used by Johnston to describe a novel GABA binding site on neuronal membranes (1, 2). Although recent studies indicate a wide distribution of $GABA_C$ receptors in many parts of the central nervous system (3-7), these receptors are most prominently expressed in the vertebrate retina. In the fish white perch retina, rod-driven (H4) horizontal cells were the first retinal neurons where $GABA_C$ receptors were characterized (8). Subsquently, $GABA_C$ receptor-mediated responses have been detected in many types of retinal neurons, including bipolar cells (9-15), cone-driven horizontal cells in catfish (16, 17), cone photoreceptors (18), and ganglion cells (19). Among all these retinal neurons, the rod-driven horizontal cells of white perch are the only cells where GABA responses are mediated solely by $GABA_C$ receptors. The GABA responses elicited from

other cells are usually a mixture of GABA receptors and/or GABA transporters. The unique properties of the white perch rod-driven horizontal cell provided an excellent model to characterize the physiological and pharmacological properties of $GABA_C$ receptors on retinal neurons (8, 20).

An example of a solitary rod-driven horizontal cell isolated from white perch retina is shown in Fig. 1, together with a typical GABA-elicited response from such a cell. These horizontal cells receive input from rod photoreceptors in the retina; and when isolated, they keep their typical morphology in culture. Rod-driven horizontal cells have a flat cell body with diameter of 50-100 μm. There are several thick primary dendrites from which many fine processes extend. As shown in Fig. 1, GABA elicits a slow and sustained response from these cells. The GABA-induced membrane currents are mediated by chloride ions and, therefore, exhibit inhibitory actions on these neurons. The responses showed no sign of desensitization, i.e., the responses are maintained at a steady level as long as GABA is present. Furthermore, the GABA responses elicited from these horizontal cells exhibit slow kinetics, which could best be observed in the offset response. After the termination of GABA application, the membrane current returns to the baseline very slowly, with a time constant of ~15 seconds. Such slow and sustained response properties are typical of $GABA_C$ receptors.

It is interesting to note that the neurons in distal retina (i.e., photoreceptors, horizontal cells, and bipolar cells) do not produce action potentials at all. They only generate slow graded responses to light stimuli. It has always been thought that retinal neurons must have special ways to process and analyze such slow signals compared with fast transient neurons of the brain. The kinetics of $GABA_C$ receptor-mediated responses are thus particularly suited for the generatation of signals in distal retinal neurons.

Pharmacology of $GABA_C$ Receptors

$GABA_C$ receptors exhibit a distinct pharmacology that differs from classical $GABA_A$ or $GABA_B$ receptors. $GABA_C$ receptors were first described by Johnston for bicuculline- and baclofen-insensitive GABA binding sites on neuronal membranes (1, 2). More detailed studies indicated that $GABA_C$ receptors on retinal neurons are not sensitive to the competitive antagonists of either $GABA_A$ receptors (such as SR95531 and hydrastine) or $GABA_B$ receptors (such as phaclofen and saclofen). Because the competitive antagonists are thought to interact with the GABA binding sites on the receptors, these results indicate that a different conformation of GABA molecule is preferred for binding to the $GABA_C$ receptor. In agreement with such a notion, the specific agonists of $GABA_A$ and $GABA_B$ receptors exhibit quite different activity on $GABA_C$ receptors. They either have no effect (isonipecotic acid, baclofen), act as partial agonists (isoguvacine, muscimol), or as antagonists (THIP, P4S, 3-APA, and 3-APMPA) (20, 21). I4AA, a partial agonist of $GABA_A$ receptors, behaves as a potent antagonist on $GABA_C$ responses of retinal neurons and as a partial agonist on expressed $GABA_C$ receptors in *Xenopus* oocytes (20, 22).

$GABA_C$ receptors also differ from classical $GABA_A$ receptors in terms of their responses to various modulators. Two groups of compounds, benzodiazepine and barbiturates, are well-known to modulate $GABA_A$ activity. On the other hand, none of these compounds have any significant influence on responses mediated by $GABA_C$ receptors (23). For example, the GABA-elicited response on white perch rod-driven horizontal cells are virtually identical in the presence or absence of either diazepam or pentobarbital (8). Another class of $GABA_A$ receptor modulators, known as neuroactive steroids, has different effects on the expressed $GABA_C$ receptor in *Xenopus* oocytes. Whereas some of them modulate GABA responses on these receptors, others do not (24, 25). The effect of these neuroactive steroids on $GABA_C$ receptors on neurons has yet to be determined.

Although both $GABA_A$ and $GABA_C$ receptors are linked to chloride channels, the channel properties of these two receptors are quite different. Unlike $GABA_A$ receptors, picrotoxin inhibition on $GABA_C$ receptors in white perch horizontal cells exhibits both competitive and non-competitive mechanisms (20). In mammalian retina (rat), on the other hand, $GABA_C$ receptors are insensitive to picrotoxin blockage (9, 13). The unusual features of $GABA_C$ receptors in rat retina are attributed to a single amino acid substitution in the receptor subunit (26).

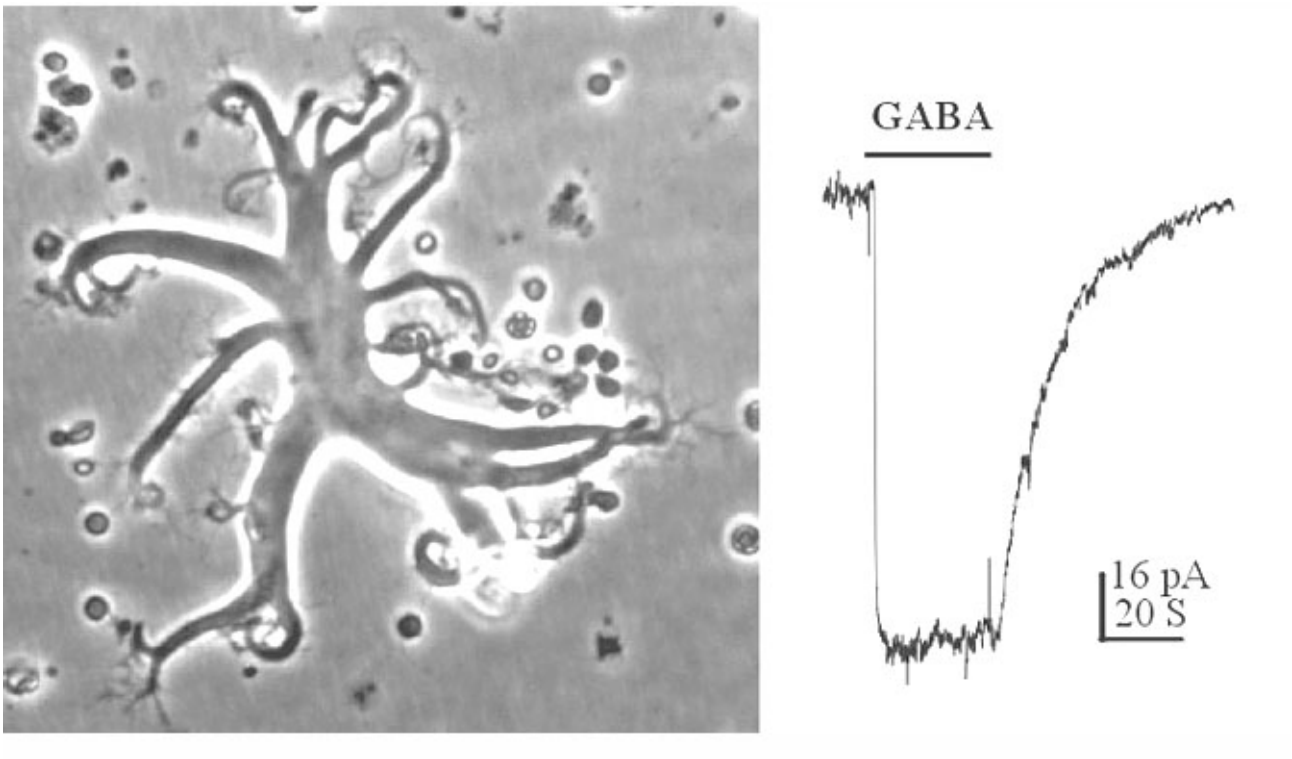

Figure 1. An example of a rod-driven (H4) horizontal cell (left) isolated from white perch retina. GABA elicits a sustained and slow response (right) from these cells mediated by GABA$_C$ receptors. Thus far, this is the only preparation in which the GABA response is mediated solely by GABA$_C$ receptors.

Furthermore, TBPS (like picrotoxin, another chloride channel blocker on GABA$_A$ receptors) does not block the responses mediated by GABA$_C$ receptors (20, 27). In addition, GABA$_C$ receptor-gated chloride channels exhibit a very small single channel conductance (14, 28).

GABA$_C$ receptor activities are modulated by divalent cations (17, 29-31). In particular, GABA$_C$ receptor-mediated responses are inhibited by low concentrations of zinc ions. The high sensitivity of GABA$_C$ receptors to zinc inhibition is attributed to a histidine residue on the extracellular domain of the subunits (32).

Recently, a new GABA$_C$ receptor antagonist, TPMPA, has become available commercially. This compound is thought to be a specific inhibitor of the GABA$_C$ receptor (33). The availability of such a drug will greatly facilitate further studies of this receptor.

Molecular Biology of GABA$_C$ Receptors

The GABA$_C$ receptor is a member of the ligand-gated channel superfamily. By analogy to the well-studied nicotinic acytocholine receptors, GABA$_C$ receptors are thought to exhibit the structure shown schematically in Fig. 2. These receptors are pentamers, i.e., five subunits constitute the functional channel (34). The receptors have a long extracellular domain containing ligand binding sites and several modulatory sites. In the middle of the receptor, GABA gates an ionic channel. Binding of GABA to the receptor induces a conformational change in receptor structure, which leads to the opening of the channel.

For each subunit forming the receptor, the structure is thought to be that shown in Fig. 3. The subunit contains a long extracellular N-terminal domain that has ligand binding sites, four transmembrane domains, and a large intracellular loop that connects the third and the fourth transmembrane domains. The ionic channel is formed by the second transmembrane domain of each subunit. For the large intracellular loop, there are several putative

phosphorylation sites, indicated as colored circles with letter "P" in the figure. Phosphorylation of these residues is implicated for modulation of receptor activities. For example, it has been reported that dopamine modulates $GABA_C$ receptor activity in both catfish cone-driven horizontal cells and tiger salamander bipolar cell terminals (35, 36). On rat bipolar cells, the $GABA_C$ receptor activities are modulated by protein kinase C (37). The modulation of receptor activities by intracellular second messenger systems is also observed at $GABA_C$ receptors expressed on *Xenopus* oocytes (38). However, the mechanisms for modulation by intracellular second messager systems are yet to be determined. Recently, Filippova and coauthors (39) provided evidence for $GABA_C$ receptor internalization upon phosphorylation of the subunits. In addition, there is evidence that the large intracellular loop of $GABA_C$ receptor subunits is involved in the interaction of receptor protein with other intracellular proteins, which may play an important role in the clustering of the receptors on neuronal membranes (40).

There is much evidence to indicate that $GABA_C$ receptors are composed of GABA ρ subunits. These were first cloned from a human retinal cDNA library (41, 42). When expressed in *Xenopus* oocytes, GABA ρ subunits formed functional homo-oligomeric receptors with properties similar to those of $GABA_C$ receptors in retinal neurons (43). Furthermore, the expression of GABA ρ subunits has been detected on retinal neurons where $GABA_C$ receptor-mediated responses have been recorded (44-46). In white perch retina, we have now cloned five forms of GABA ρ subunits (22, 46). Fig. 4 shows a comparison of white perch GABA ρ subunits and those cloned from mammalian retinas. The distances between the various connecting elements represent the degree of divergence among subunits. Unlike the mammalian retina, where only one form of ρ1 and ρ2 subunits has been identified, in white perch there are two forms of the subunit for each ρ1 and ρ2 family. In accordance with their deduced amino acid sequences and the properties of the receptors they formed on *Xenopus* oocytes, each ρ1 and ρ2 family was subdivided into A and B forms. All white perch GABA ρ1 and ρ2 subunits are able to form functional homo-oligomeric receptors when expressed in *Xenopus* oocytes. GABA-elicited responses in these expressed receptors are sustained, bicuculline insensitive, and are not modulated by either benzodiazepines or barbiturates, features typical of $GABA_C$ receptors. Similar to $GABA_C$ receptors on retinal neurons, GABA ρ receptors also gate chloride channels. However, the receptors expressed by each of the GABA ρ subunits display unique response properties that distinguish one from the other. For example, the sensitivity of GABA activation and picrotoxin inhibition varies among subunits. In addition, I4AA acts as an antagonist on A-type ρ receptors, whereas it is a partial agonist on B-type ρ receptors (22).

The waveform of receptor-mediated responses plays an important role in shaping the neuronal signal. Interestingly, the kinetics of the GABA response are also different for the receptors formed by each individual subunits. Current-trace responses to application of 10 μM GABA are illustrated in Fig. 5. These recordings indicate that there are significant differences in the kinetics of the GABA responses from *Xenopus* oocytes, depending on which white perch GABA ρ subunitis are expressed. To quantitate the kinetics of the GABA response, the offset GABA responses (current traces after GABA application is terminated) were replotted on a semi-logarithmic scale, with the amplitudes normalized to their initial values (Fig. 6). In each case, the data were fit by a straight line, indicating that offset responses can be described by a single exponential function. The slope of the line represents the time constant of the decay and shows that the receptors formed by the various ρ subunits exhibit significant differences in their response kinetics. The average time constants of offset responses elicited from receptors formed by various white perch GABA ρ subunits are shown in the bar graph in Fig. 6C. There are consistent differences between the response kinetics of the two receptor families and between their subgroups. For example, the responses from ρ1 receptors were significantly slower than those of ρ2 receptors. Such difference in the response kinetics among ρ1 and ρ2 receptors are determined, in large part, by a single residue at the second transmembrane domain of the subunits (47). This dichotomy among ρ1 and ρ2 subunits is well conserved in all species where GABA ρ subunits have been cloned. ρ1 subunits, which have a proline at the residue site, combine to make a receptor with slower kinetics, whereas ρ2 subunits, which contain a serine at the residue site, form receptors with faster response rate. Thus, receptors made of human ρ1 subunits exhibit slower response kinetics than receptors made of ρ2 subunits (5). The kinetic differences among the receptors formed by

various GABA ρ subunits could provide building blocks for the nevous system to construct different types of signal filters and different types of neuronal signaling in the nervous system.

Function of GABA$_C$ Receptors in the Retina

Although rod-driven horizontal cells provide an excellent model in which to characterize GABA$_C$ receptors in the retina, recent studies indicate that GABA$_C$ receptors are present on various other types of retinal neurons. GABA$_C$ receptor-mediated responses have been recorded from cone-driven horizontal cells in catfish (16, 17), cone photoreceptors (18), and some types of ganglion cells (19). GABA$_C$ responses are particularly prominent in bipolar cells of every species examined thus far (9-12, 14, 15), and both immunocytochemistry and *in situ* hybridization studies indicate that GABA$_C$ receptors are present on bipolar cells (15, 44, 45, 48). It appears that these receptors play an important role in shaping signal transmission from bipolar cells to third-order neurons in the retina.

Fig. 7 illustrates some examples of bipolar cells isolated from white perch retina. These bipolar cells keep their morphology when isolated in culture. They usually have a pear-shaped cell body from which several dendrites and one axon extend. The GABA responses of bipolar cells in white perch retina have both transient and sustained components, indicating both GABA$_A$ and GABA$_C$ receptors are present, as shown in Fig. 8. The transient component can be selectively blocked by the co-application of bicuculline, leaving a more sustained response. Thus, the electrophysiological and pharmacological properties of GABA$_C$ receptors on bipolar cells are very similar to those of GABA$_C$ receptors on rod-driven horizontal cells (11, 14, 37, 49).

Different kinetic properties of GABA$_A$ and GABAc receptors suggest that they play different roles in mediating inhibition on bipolar cell terminals (15, 46, 50). Furthermore, various subtypes of bipolar cells exhibit different proportions of GABA$_A$ and GABA$_C$ receptors. For example, in the rat retina, there is a clear difference in the contribution of GABA$_A$ and GABA$_C$ receptors to rod and cone bipolar cells (51). In white perch, too, different morphological types of bipolar cells exhibit different proportions of GABA$_C$ receptor-mediated components (14). These results strongly suggest that different subtypes of bipolar cell use various mixtures of GABA$_A$ and GABA$_C$ receptors to perform different activities and help create the variety of functional pathways through the retina.

Because of the presence of multiple GABA receptors on retinal neurons, it is sometimes difficult to isolate the contributions of each receptor. Recent studies on ganglion cell responses reveal some interesting features of GABA$_C$ receptors in retinal information processing. For example, activation of GABA$_C$ receptors leads to more transient light responses in ganglion cells (52) and the delayed inhibition mediated by GABA$_C$ receptors is thought to play a major role in shaping edge-enhancement of ganglion cell receptive fields (53). The bipolar cell to ganglion cell synapse is probably heavily influenced by inhibitory amacrine feed-forward or feedback synapses, and these appear to be via primarily GABA$_C$ receptors.

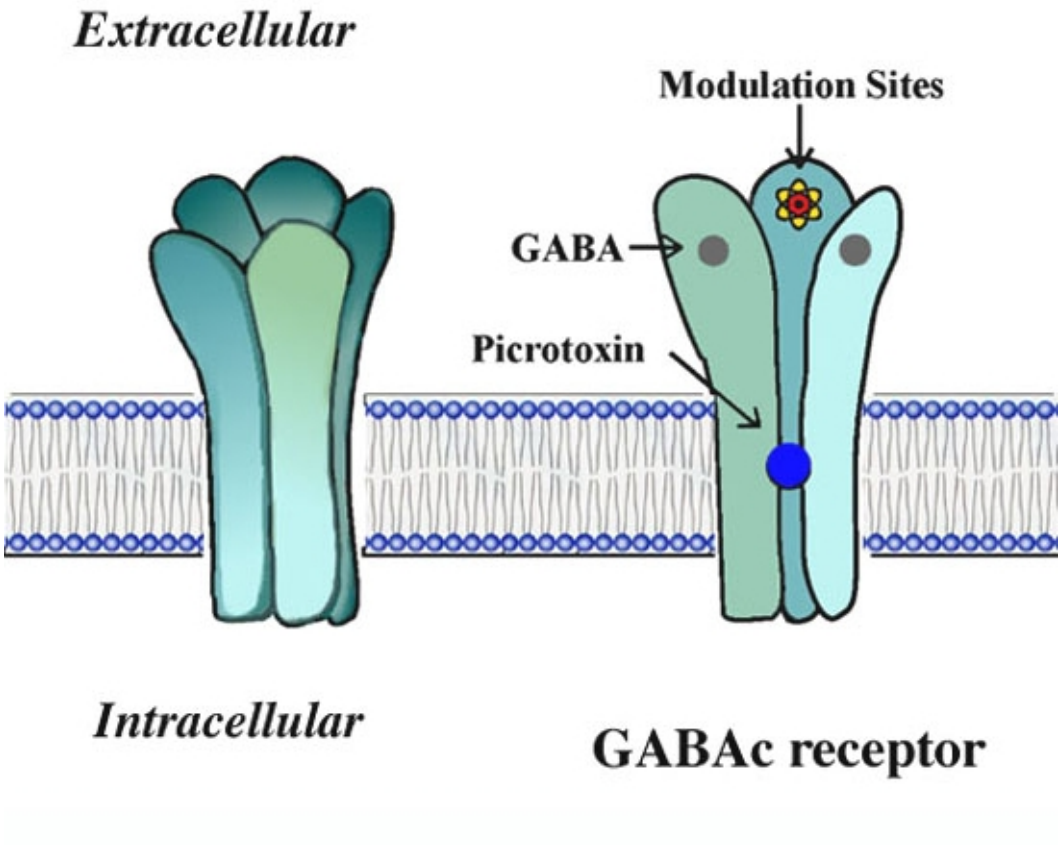

Figure 2. Schematic diagram of $GABA_C$ receptors. These receptors are formed by five subunits with an ionic channel in the middle of the receptor. On the extracellular side, the receptor contains the binding site for GABA and several modulatory sites.

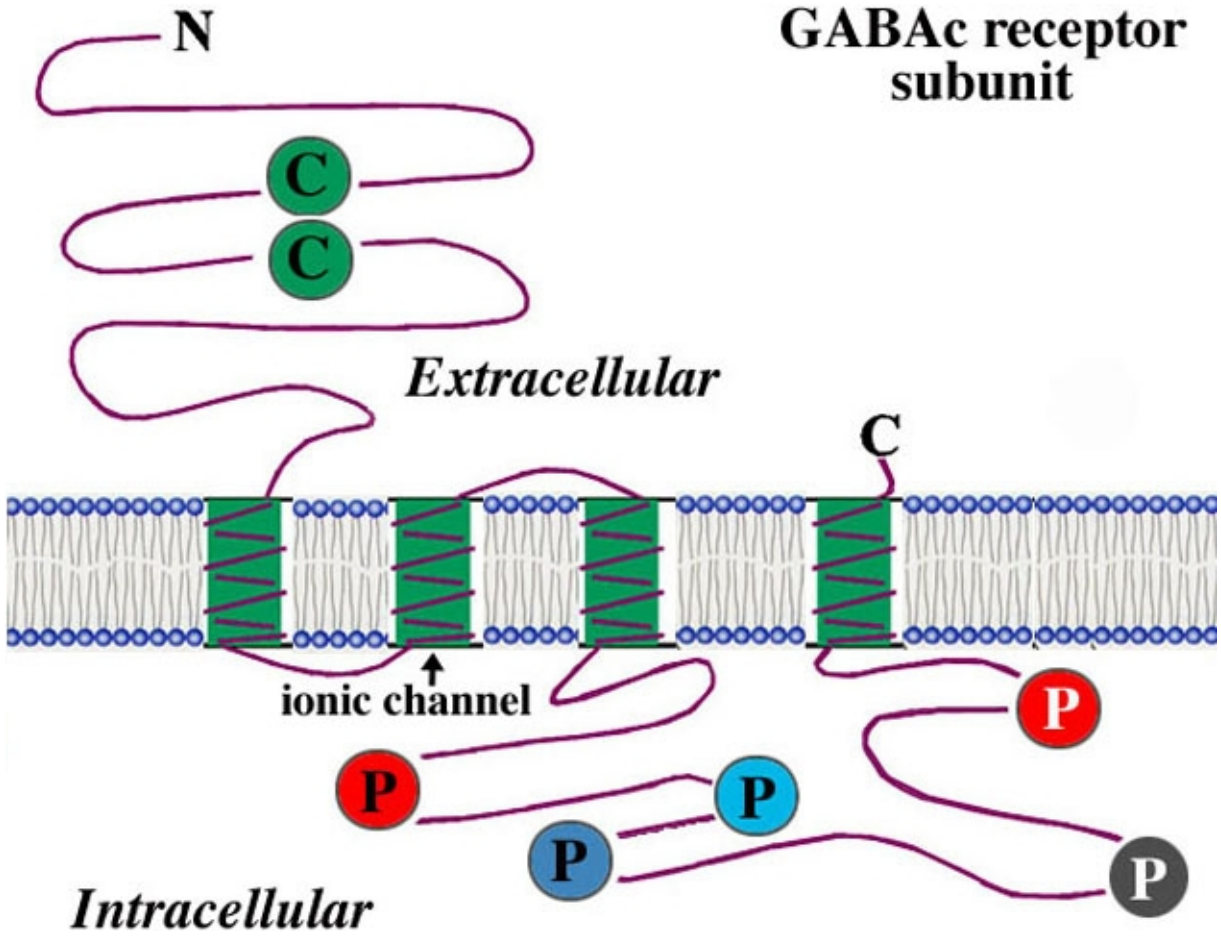

Figure 3. Schematic digram of the GABA$_C$ receptor subunits. Each subunit contains a long extracellular N-terminal region that contains two cystine residues thought to form disulfide bonds. The extracellular domain forms the GABA binding sites and other modulatory sites. The subunit crosses the cell membrane four times with a short C-terminal region on the outside of the cell. The second transmembrane domain forms the ionic channel of the receptor. There are several putative phosphorylation sites on the large intracellular loop between the third and the fourth transmembrane domains (colored circles with letter "P").

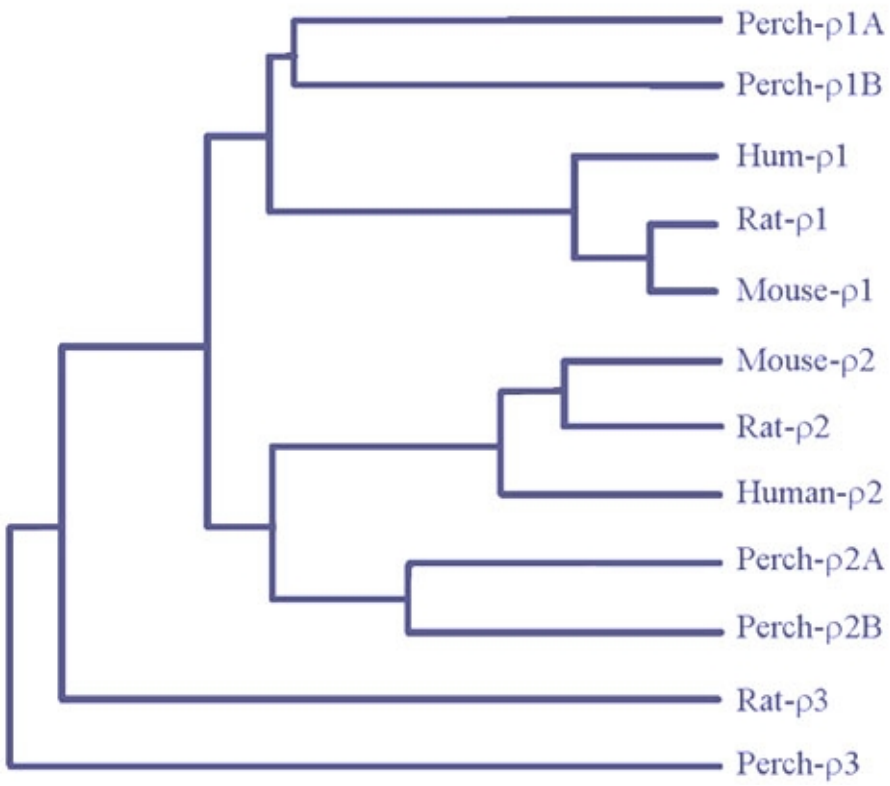

Figure 4. Dendrogram showing the relation of the GABA ρ subunits cloned from white perch retina to those cloned from mammalian retinas. Analysis was performed on the deduced amino acid sequence of each subunit.

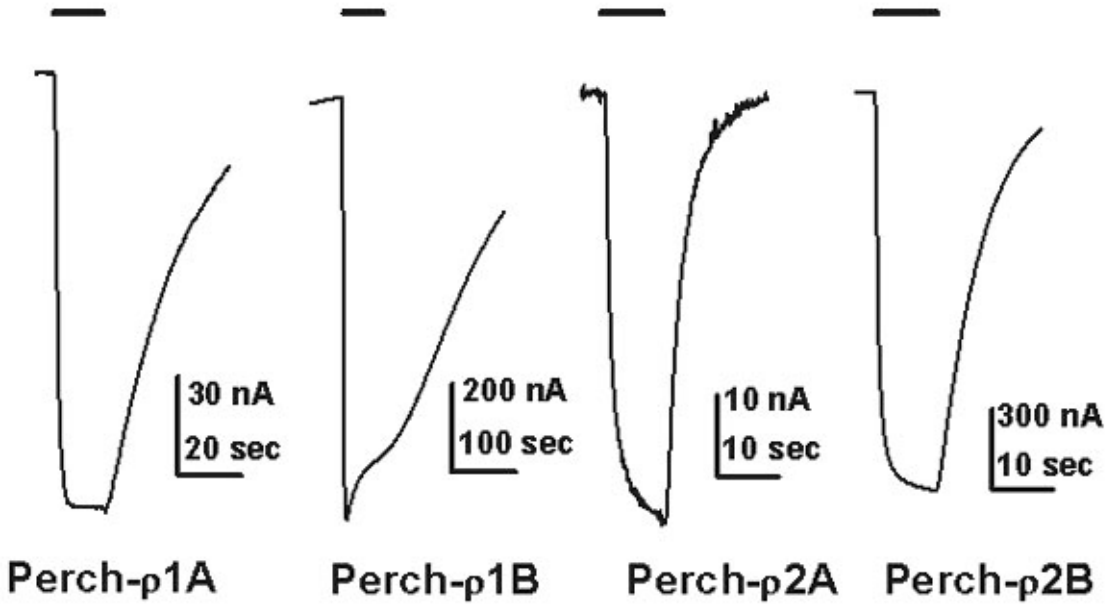

Figure 5. GABA (10 μM) induced responses from white perch GABA ρ subunits expressed in *Xenopus* oocytes. The duration of GABA application is shown by the bar above each trace. Variations in response amplitude often result from the different level of receptor expression in individual oocytes; response kinetics are a relatively stable feature, independent of amplitude.

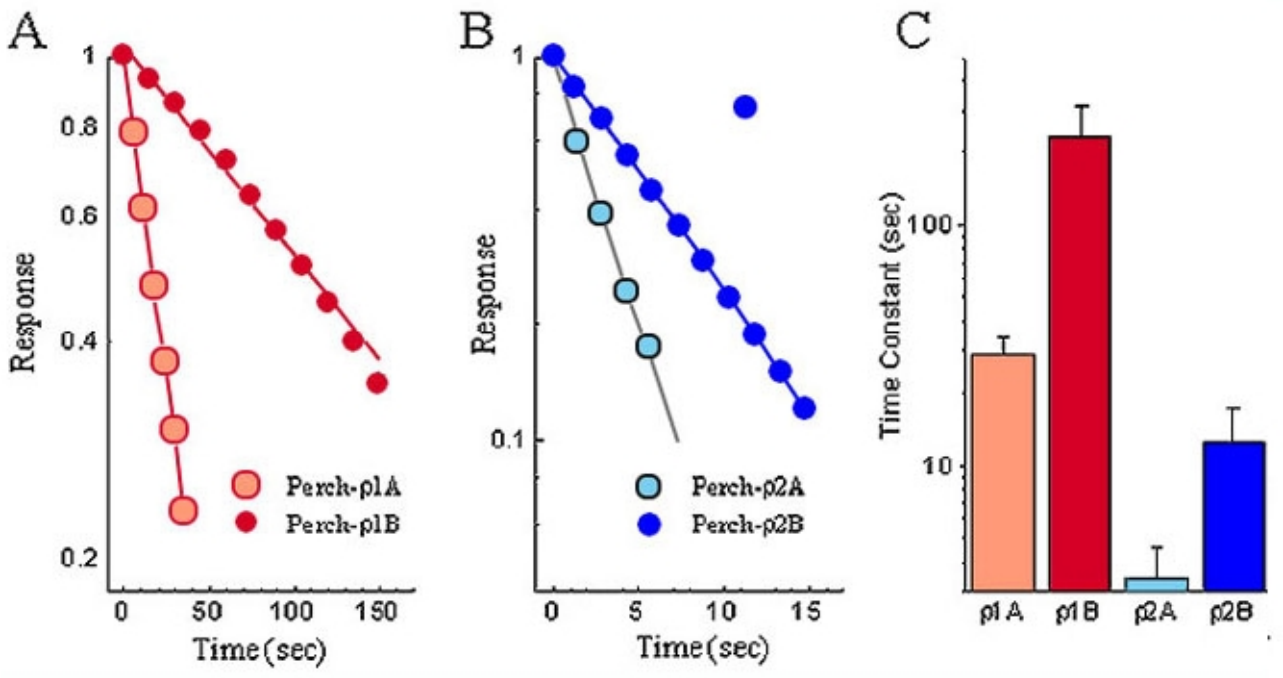

Figure 6. Kinetics of the GABA responses obtained from the white perch GABA ρ receptors expressed in *Xenopus* oocytes. A. Semi-logarithmic plot of GABA responses measured at various times following the offset of drug application (10 μM GABA); the responses were normalized to their initial amplitude at the time of offset. The responses are well fit by straight lines, indicating that the relationship can be described by a single exponential function. B. A similar analysis applied to the offset GABA responses obtained from perch ρ2 receptors. Note different time scales in A and B. C. Comparison of the time constants calculated from GABA offset responses elicited from various GABA ρ receptors.

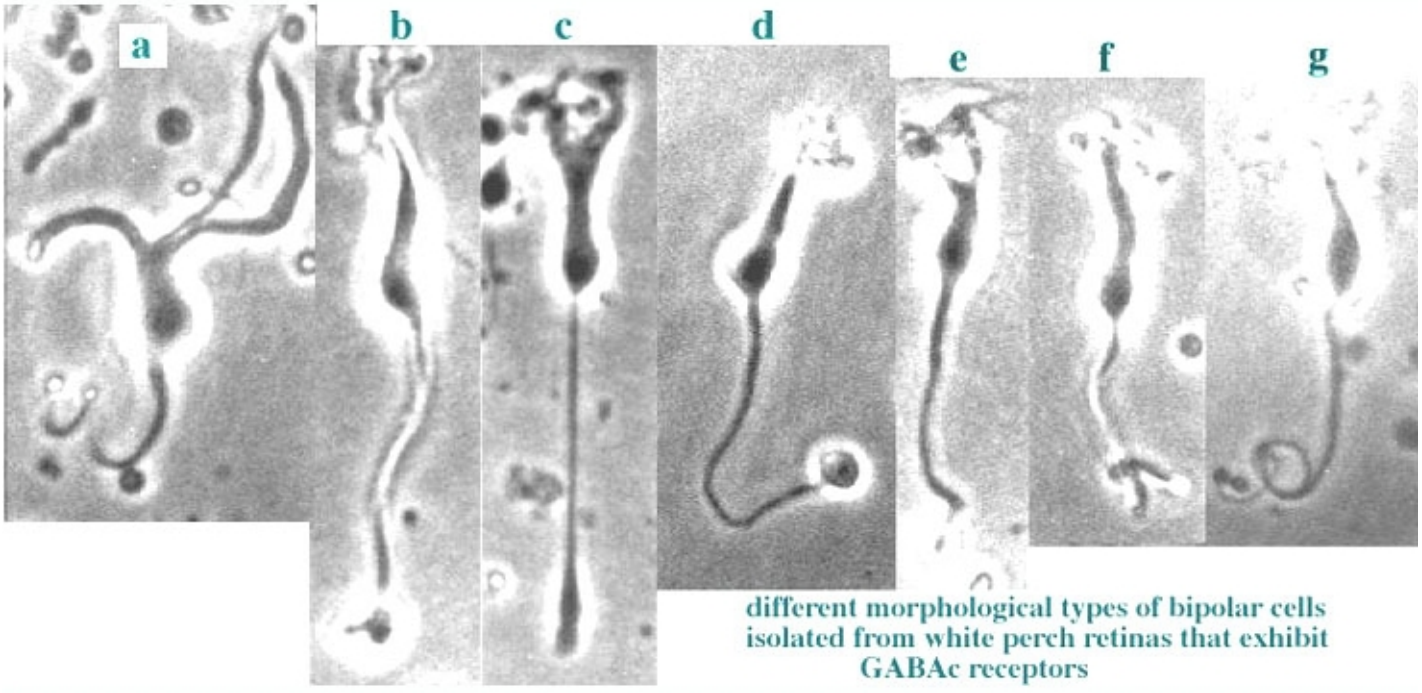

Figure 7. Examples of solitary white perch bipolar cells in culture.

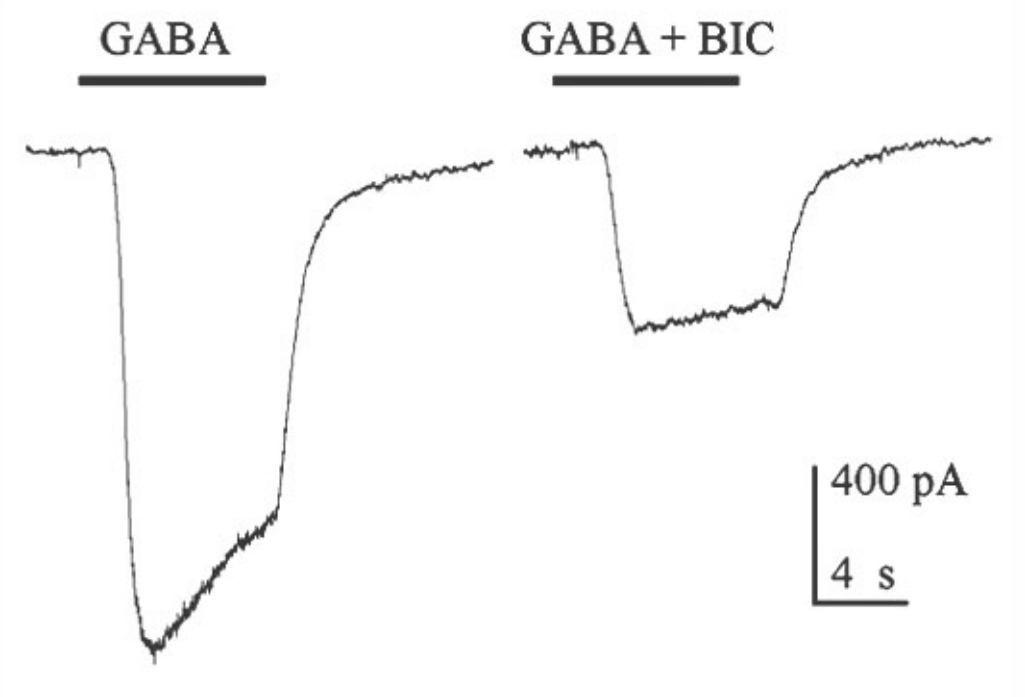

Figure 8. GABA-elicited responses from isolated white perch bipolar cells. The membrane currents elicited by GABA application (left) contain both transient and sustained components, indicating both $GABA_A$ and $GABA_C$ receptors are present. In the pesence of bicuculline, $GABA_A$ receptor activity is inhibited, revealing sustained GABA responses mediated by $GABA_C$ receptors (right).

About the Author

Dr. Haohua Qian was born in Jiangsu, China. He received his B.A. in Biology from Nanjing University (1982), M.S. in Neurobiology from Shanghai Institute of Physiology (1985), and Ph.D. in Anatomy and Cell Biology from University of Illinois at Chicago (1991). He is currently an Assistant Professor of Neurosciences in the Department of Ophthalmology and Visual Sciences at the University of Illinois at Chicago. During his postdoctoral studies with Dr. John E. Dowling at Harvard University, he characterized a new type of GABA receptor, the $GABA_C$ ρ receptor, on retinal neurons. He is currently continuing these studies on the molecular structure and physiological functions of $GABA_C$ receptors in the vertebrate retina.

Glycine Receptor Diversity in the Mammalian Retina

Silke Haverkamp, PhD[1]

Created: March 27, 2012.

1 Introduction

Glycine is a major inhibitory neurotransmitter in the mammalian central nervous system (CNS). Its receptors, the inhibitory glycine receptors (GlyRs), are ligand-gated chloride channels composed of ligand-binding α and β subunits (1, 2). In mature neurons, the activation of GlyRs allows for an influx of chloride ions into the cytoplasm, which hyperpolarizes the postsynaptic membrane and, thereby, reduces neuronal firing. Inversely, the blockade of GlyRs by the competitive antagonist strychnine causes overexcitation resulting in pain, muscle cramps and exaggerated startle responses (3). Apart from its major transmitter function in spinal cord and brainstem, glycine also mediates substantial inhibitory neurotransmission via glycinergic amacrine cells in the mammalian retina. Thus, the abundant and highly complex expression patterns of different GlyR subtypes in the inner plexiform layer create an appealing field of retinal research.

2 Structure of glycine receptors

The GlyR was the first neurotransmitter receptor protein to be isolated from the mammalian CNS. Purification of the GlyR from rat spinal cord by strychnine affinity chromatography revealed three distinct polypeptides of molecular mass 48, 58 and 98 kDa (4). The 48 and 58 kDa peptides were shown to correspond to the α1 and β subunits, respectively. The 98 kDa peptide was later identified as the cytoplasmic protein, gephyrin, which is essential for clustering GlyRs at postsynaptic densities via direct interactions between the GlyR β subunit and intracellular microtubules (5).

GlyRs are pentameric ligand-gated ion channel receptors of the Cys-loop family, which also include $GABA_{A/C}$ receptors, muscle and neuronal nicotinic acetylcholine receptors, and serotonin type 3 receptors. Members of this superfamily share a common proposed structure (Fig. 1). Each subunit consists of a large N-terminal extracellular domain, four transmembrane segments (TM1–TM4), a long intracellular loop connecting TM3 and TM4, and a short extracellular C-terminus. The second transmembrane segment, TM2, lines the inner ion pore which, in GlyRs and $GABA_{A/C}$ receptors, displays strict anion selectivity.

Molecular cloning has revealed four genes encoding the α subunits (α1, α2, α3, α4) and only one gene encoding the β subunit (6, 7). In the adult organism, two copies of the α subunit and three copies of the β subunit form the pentameric receptor protein (8).

3. Developmental expression

Glycine is excitatory during embryonic development and around birth. The neonatal form of the GlyR is thought to be a homopentamer of α2 subunits that are mainly found extrasynaptically in vivo, whereas adult synaptic GlyRs are heteromeric αβ receptors. It seems that homomeric α2 GlyRs mediate a depolarizing glycine-gated chloride flux that in turn stimulates the calcium influx necessary for the development of numerous neuronal specializations, including glycinergic synapses (2, 9). Surprisingly, however, knockout of the α2 subunit has no obvious effect on neuronal development (10), whereas an α1 knockout (*Glra1*$^{spd\text{-}ot}$*"oscillator")* has severe

consequences: mice appear normal until the 2nd postnatal week whereupon they show prolonged periods of rapid tremor, producing extreme rigor and stiffness, and die within 10 days (11, 12).

4. Glycinergic amacrine cells

In the retina, approximately half of the amacrine cells release glycine at their synapses with bipolar, other amacrine, and ganglion cells. Glycinergic amacrine cells can be immunolabeled with antibodies against glycine or against the glycine transporter GlyT1 (13-15). Figure 2 shows a vertical section through a mouse retina that was double immunolabeled for glycine and for GlyT1 (16). Strong glycine immunoreactivity can be observed in amacrine cell bodies and their dendrites descending into the inner plexiform layer (IPL) or in dendrites from interplexiform amacrine cells ascending into the outer plexiform layer (OPL). Weak glycine expression is also found in putative ON-cone bipolar cells in the outer half of the inner nuclear layer (INL). The section was also immunolabeled for GlyT1 which labels all glycinergic amacrine cells but not bipolar cells. Bipolar cells do not express GlyT1 but they receive glycine by diffusion through electrical synapses (gap junctions) from glycinergic amacrine cells (17). In other parts of the CNS, GlyT1 has been localized to glial cells, while GlyT2 is now known to represent the presynaptic neuronal glycine transporter. Surprisingly, GlyT2 does not appear to be expressed in the mammalian retina (18).

5. Morphological types of glycinergic amacrine cells

Glycinergic amacrine cells are small-field amacrine cells with principally vertically oriented dendrites, and they comprise more than 10 different morphological types (13, 19). Most of them have small, diffuse dendritic trees and perform local circuit operations between the different sublayers of the IPL.

The most prominent and also most numerous glycinergic amacrine cell is the AII amacrine cell which transfers the light signal from rod bipolar cells into the cone pathway (20). In the inner IPL, AII cells receive direct glutamatergic input from rod bipolar cells, but they are also engaged with ON-cone bipolar cell axon terminals via electrical synapses (gap junctions). In the outer IPL. AII cell lobular dendrites provide glycinergic, chemical output synapses onto OFF-cone bipolar cell axon terminals and dendrites of OFF ganglion cells. Further glycinergic, small-field amacrine cells were identified in the cat retina by combined Golgi-staining and glycine

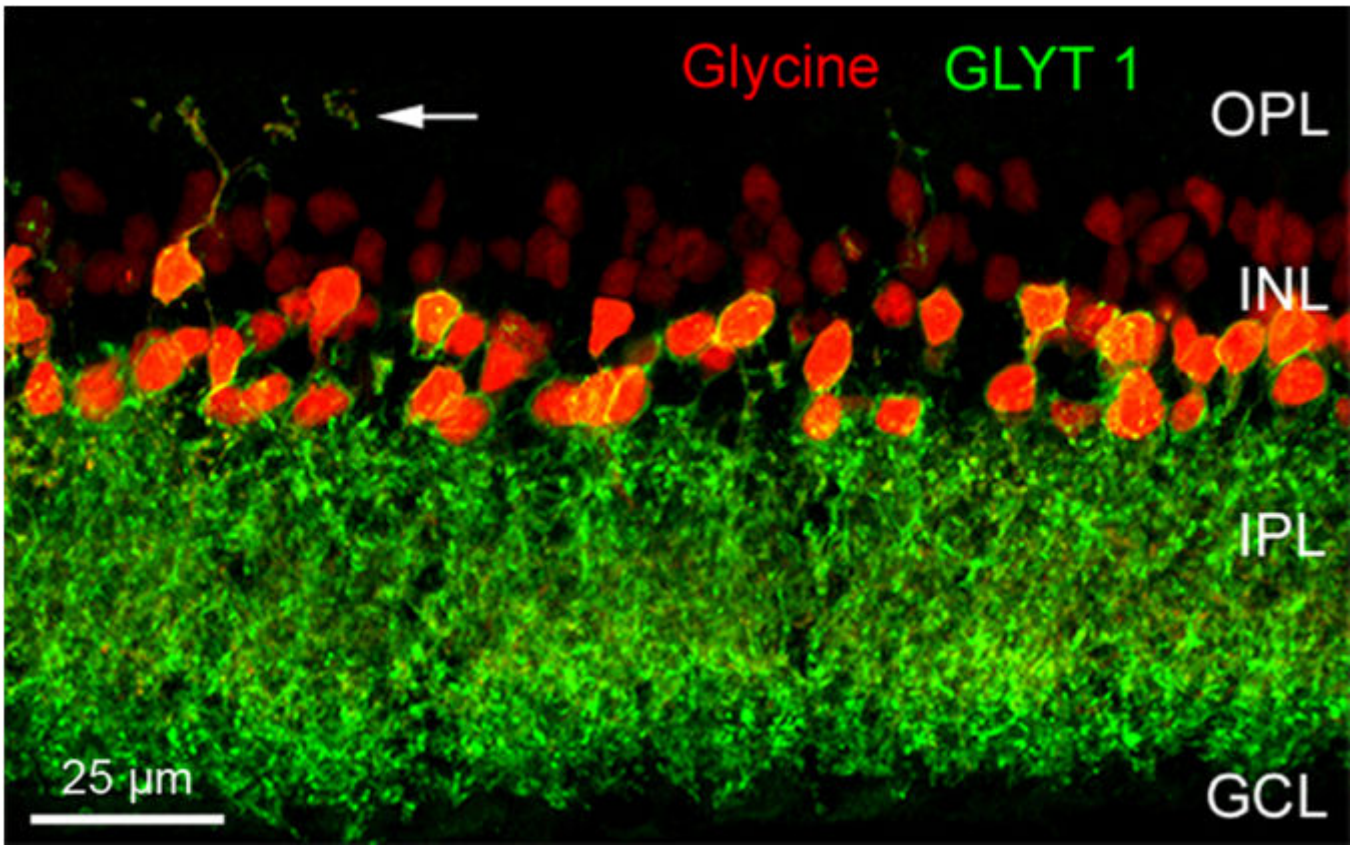

Figure 2. Glycinergic amacrine cells of the mouse retina. A vertical section was double immunolabeled for glycine (red) and the glycine transporter GlyT1 (green). The arrows indicate an interplexiform process ascending to the OPL (OPL: outer plexiform layer; INL: inner nuclear layer; IPL: inner plexiform layer; GCL; ganglion cell layer). From Haverkamp and Wässle, 2000 (16).

uptake (21), and Menger et al. (13) identified at least 8 different glycinergic amacrine cells in the rat retina (Fig. 3).

Recently it became possible to study glycinergic amacrine cells in the retina of transgenic mice which express green fluorescent protein (GFP) under the control of the Thy1 promotor (Thy1-GFP-O) (22, 23). Three such cells are illustrated in figure 4, with double labeling for calcium binding protein 5 (CaBP5) in order to reveal the different sublaminas of the IPL and possible bipolar cell candidates as synaptic partners. The cells in figures 4A and B have small, diffuse dendritic trees; the cell in figure 4C has a bistratified appearance and has been identified as A8 cell in cats and human retinas (24-26) (see also chapter on 'Roles of Amacrine Cells', Webvision).

6. GlyR diversity in the mouse retina

The diversity of types of glycinergic amacrine cells is paralleled by the striking heterogeneity of glycine receptors. All four α subunits of the GlyR have been localized to specific synapses within the mammalian retina (23, 27-30). When subunit selective antibodies were applied to lightly fixed tissue, they each produced a distinct punctate immunofluorescence pattern (Figure 5).

The GlyRα1 subunit is expressed in a sparse population of puncta in the OPL, which represent synapses between glycinergic interplexiform cells and bipolar cell dendrites (Fig. 5A). In the outer IPL (stratum S1 and S2) GlyR α1 immunoreactivity is found in large puncta, which occur at high density. They represent synapses between AII amacrine cells and OFF-cone bipolar cells (30). In the inner IPL (stratum S3-S5) smaller GlyRα1 immunoreactive puncta can be observed representing synapses onto ganglion cell dendrites and rod bipolar cell axons (31, 32). The GlyRα2 subunit is more uniformly distributed across all strata (Fig. 5B), and GlyRα2

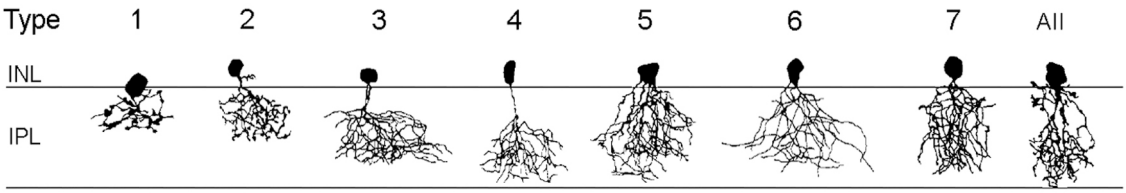

Figure 3. Glycinergic amacrine cells of the rat retina. From Menger, Pow and Wässle, 1998 (13).

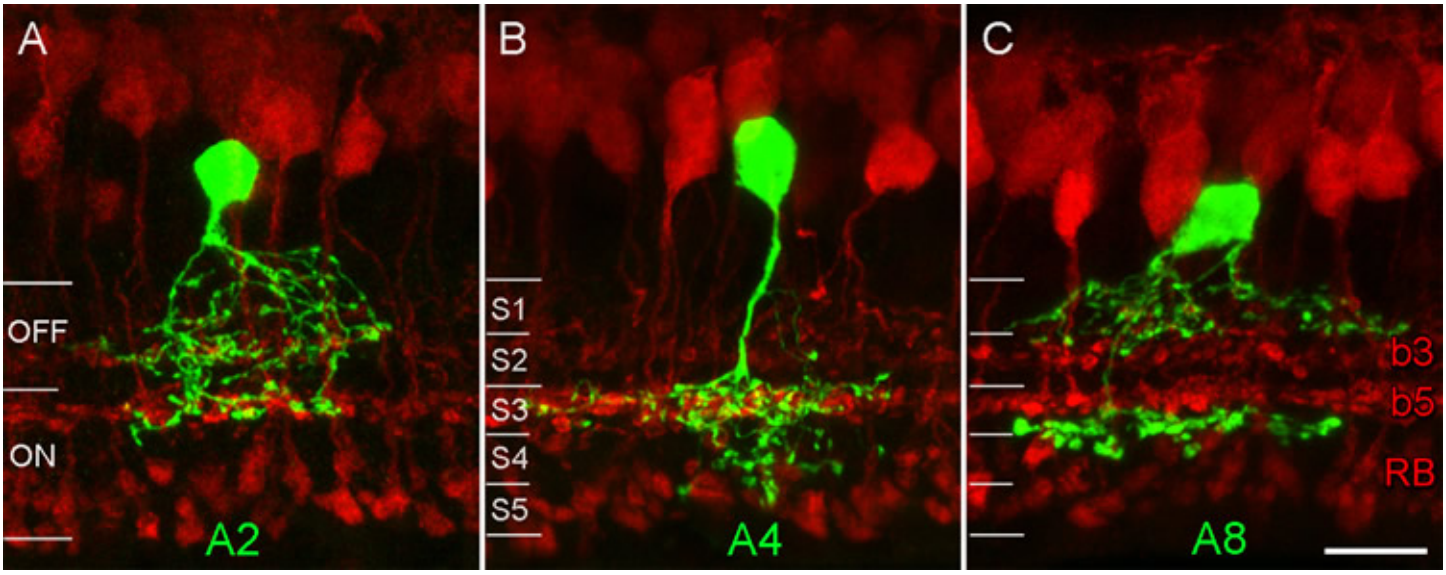

Figure 4. Glycinergic amacrine cells expressing GFP in the Thy1-GFP-O mouse. Sections are double labeled for bipolar cell marker CaBP5 (red). CaBP5 is expressed in rod bipolar cells (RB), in type 5 ON-cone bipolar cells (b5), and in type 3 OFF-cone bipolar cells (b3) (55). A2 and A4 amacrine cells are classified according to the scheme of Menger et al., 1998 (13); A8 according to Kolb et al., 1981 (26). Scale bar: 25 µm. Unpublished data.

immunoreactive puncta occur at the highest density amongst the four α subunits (28). The GlyRα3 subunit (Fig. 5C) shows four bands whose density of puncta successively declines towards the ON sublamina (27). Lastly, the GlyRα4 subunit (Fig. 5D) shows a band of high density of puncta at the border between stratum 3 and 4 and further small and sparsely distributed puncta throughout the remaining strata (23). Taken together, the characteristic distribution of subunits across the IPL suggests that the GlyR subtypes are expressed at different synapses and are involved with different neuronal circuits.

Electron microscopy confirms the notion that the immunofluorescent puncta represent clusters of GlyRs at postsynaptic sites. Antibodies against the α1 subunit recognize extracellular epitopes of the receptor. Thus, staining from preembedding immunoelectron-microscopic experiments appears in the synaptic cleft of the synapse (Fig. 6A). Accordingly, postembedding immunoelectron microscopy showed that the α3 subunit was localized at the postsynaptic membrane (Fig. 6B).

7. Co-localization of GlyR subunits at postsynaptic sites

Since synaptic GlyRs are composed of 2α and 3β subunits (8) there is the possibility that two different α subunits co-exist in a single heteromeric GlyR. In addition, it is possible that two different GlyR subtypes, such as α2β and α3β GlyRs co-distribute at the same postsynaptic sites. In both cases, the immunoreactive hot spots should coincide. However, when retinal sections were double labeled for the GlyRα1 subunit and the other three GlyRα subunits, no statistically significant coincidence rate of immunoreactive puncta was observed. When retinal

The GlyR subunit is localized at the postsynaptic membrane of an amacrine cell synapse (provided by Christian Puller, unpublished data).

sections were double labeled for the GlyRα2 and α3 subunits a coincidence rate of 26.7% was found (28). In retinal sections double labeled for the GlyRα3 and α4 subunits no significant coincidence rate was found (23). In sections double labeled for the GlyRα4 and α2 subunits, 31.5% of the α4 immunoreactive clusters also contained the α2 subunit (Fig. 7). The results indicate that postsynaptic GlyR clusters usually contain only one type of α subunit. The exception is approximately one third of synapses immunoreactive for GlyR α2 which can also contain the α3 or the α4 subunits.

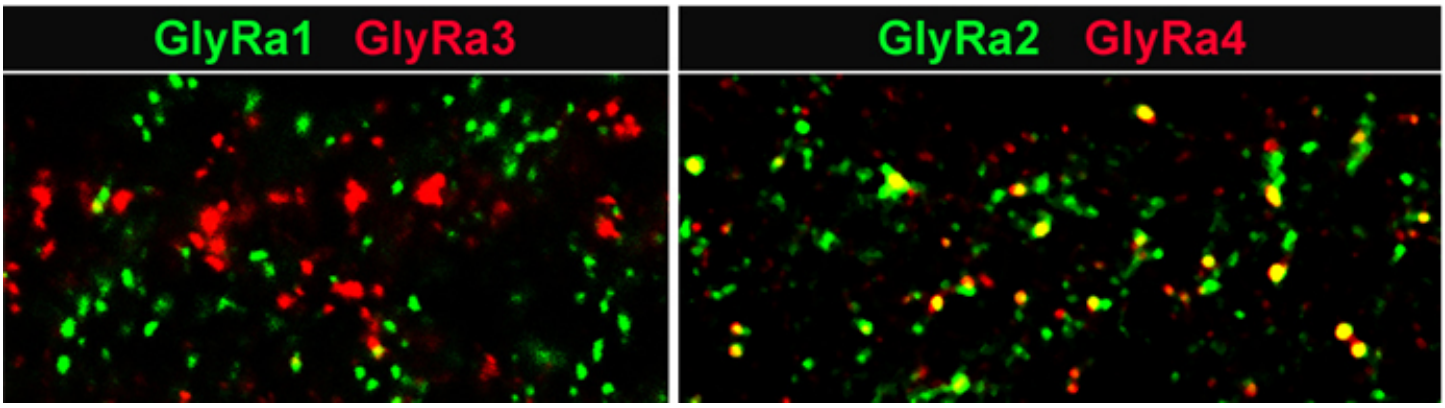

Figure 7. Colocalization of GlyR subunits at postsynaptic sites. GlyRα3 and GlyRα1 immunoreactive puncta are not colocalized whereas GlyRα2 and GlyRα4 immunoreactive puncta sometimes colocalize. From Haverkamp et al., 2003 (27); Heinze et al., 2007 (23).

8. Expression of GlyRs by identified neurons

In order to reveal the involvement of selected GlyR subtypes with different retinal circuits, identified neurons were immunostained for the different GlyR α subunits. Figure 8 shows a GFP labeled A-type ganglion cell in a whole mount of Thy1-GFP-O mouse retina (32). The retina was immunolabeled for the GlyRα1 subunit demonstrating that many GlyRα1 immunoreactive puncta decorate the dendrites of this A-type ON ganglion cell. A coincidence of puncta and dendrites was also obvious for A-type OFF ganglion cells, which suggests that both ON and OFF A-type ganglion cells receive glycinergic input through α1 subunit expressing synapses. A-type ganglion cells were also double labeled for the other α subunits but quantification showed that the predominant input is through GlyRα1 containing synapses (32).

Figure 9 shows a vertical view of a Type 3 glycinergic amacrine cell in the Thy1-GFP-O mouse retina (33). Many GlyRα2 immunoreactive puncta (red) coincide with dendritic varicosities of the Type 3 cell (green) (Fig. 9D-F). Since this cell is a glycinergic amacrine cell, the puncta may represent input synapses the cell receives from other glycinergic amacrine cells or output synapses the cell makes onto other, non-labeled neurons. The fact that the red GlyRα2 immunoreactive puncta are always slightly displaced from the green varicosities (Fig. 9F) indicates that these synaptic GlyRα2 clusters are expressed by unknown neurons that are postsynaptic to this Type 3 cell.

The two examples of cells presented in figure 8 and figure 9 suggest a correlation between the morphological type of a given neuron and the molecular signature of the glycinergic synapse it receives or forms onto postsynaptic neurons. In this context one interesting question is whether the presynaptic neuron instructs the postsynaptic cell to express certain GlyR subunits or whether a given postsynaptic neuron expresses an exclusive GlyR subtype. To address this question a detailed physiological characterization of selected synaptic GlyRs on individual cells is essential.

To date, selective agonists or antagonists that distinguish different isoforms of synaptic GlyRs have not been identified (1, 34). However, mutant mice are available that have dysfunction of specific GlyR subunits and thus it became possible to study details of the glycinergic synaptic transmission in the mammalian retina (31, 32, 35, 36). The kinetic properties of GlyRs were measured by recording spontaneous inhibitory postsynaptic currents (sIPSCs) from identified retinal neurons in wild-type mice and mice lacking GlyR α subunit (*Glra1*$^{spd\text{-}ot}$, *Glra2* and *Glra3*. From the observed differences of sIPSCs in wild-type and mutant mice, the cell-type specific subunit composition of GlyRs can be defined.

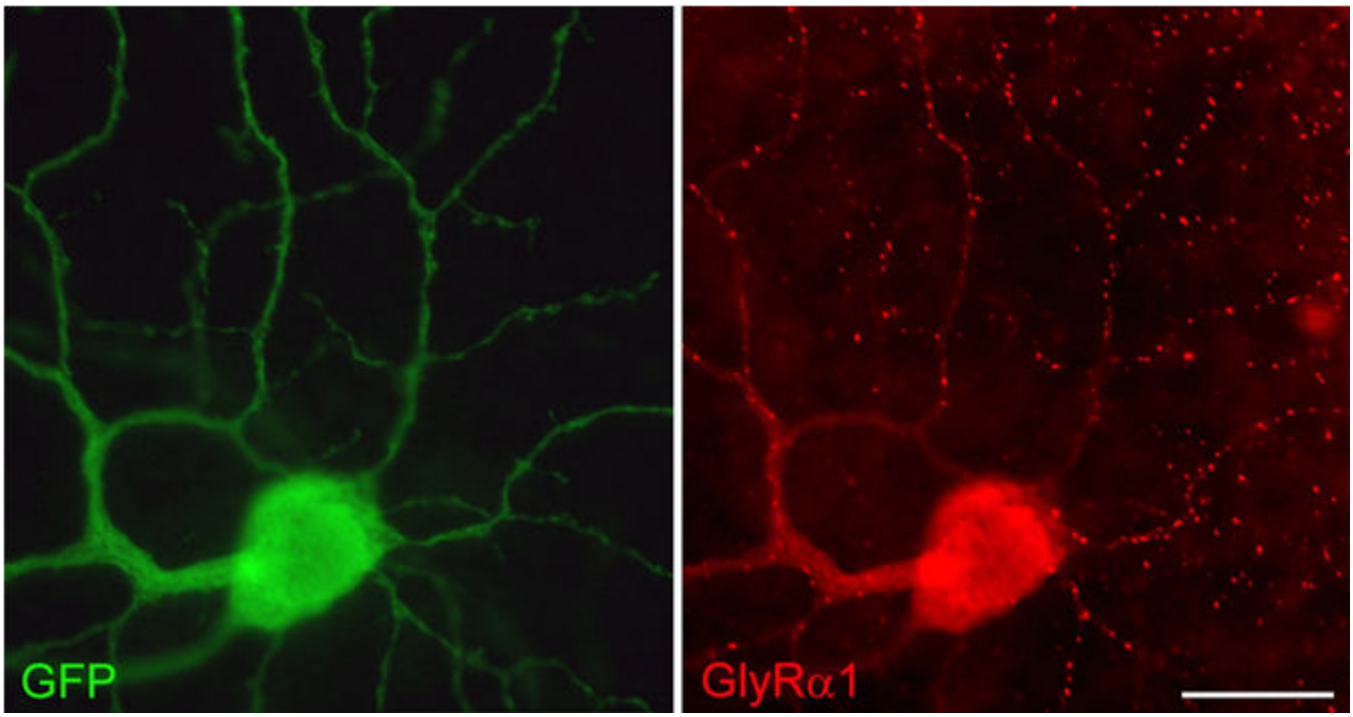

Figure 8. Colocalization of GlyRα1 with the dendrites of an A-type ganglion cell. The image on the left shows an A2-ON ganglion cell in the Thy1-GFP-O mouse (22). The whole mount was also immunostained for GlyRα1 and many immunoreactive puncta decorate the dendrites of this ganglion cell. Scale bar: 20 μm. From Majumdar et al., 2007 (32).

The boxed area is shown at higher magnification in E and F. Scale bar: 17 μm in C & D, 10 μm in E & F. From Wässle et al., 2009 (33).

Glycine receptors expressed by bipolar cells

Patch-clamp recordings performed from identified bipolar cells in slices of the mouse retina (31) enabled the study of GlyRs by the application of exogenous glycine and by recording glycinergic spontaneous inhibitory postsynaptic currents (sIPSCs). Glycine application elicited large-amplitude currents in all OFF-cone and rod bipolar cells while ON-cone bipolar cells exhibited only very small, if any, glycinergic currents (Fig. 10 (31, 37),). By comparing sIPSCs of bipolar cells in wild-type and *Glra3*$^{-/-}$ mice, no statistically significant differences were found; whereas glycine-induced currents and sIPSCs were absent from all bipolar cells of *Glra1*$^{spd\text{-}ot}$ mice. Thus, OFF-cone and rod bipolar cells receive kinetically fast glycinergic inputs, preferentially mediated by GlyRs composed of α1 and β subunits (decay time constant τ ~ 5 ms). Slow sIPSCs, the characteristic of GlyRs containing the α2 subunit, were not observed in bipolar cells.

Glycine receptors on AII and narrow-field amacrine cells

Amacrine cells are known to express strychnine-sensitive glycine receptors. The GlyRs expressed by AII amacrine cells and by the narrow-field (NF) amacrine cells (Fig. 11A) were studied by patch-clamp recordings in mouse retinal slices (36). Glycinergic sIPSCs of AII cells displayed medium fast kinetics (τ ~ 11 ms, Fig. 11B), which were completely absent in the *Glra3*$^{-/-}$ mouse, indicating that synaptic GlyRs of AII cells mainly contain the α3 subunit. Glycinergic sIPSCs of NF cells had slow kinetics (τ ~ 27 ms, Figs. 11B and 12C) that were significantly prolonged in *Glra2*$^{-/-}$ mice (τ ~ 69 ms, Fig. 12F). These data show that morphologically distinct amacrine cells express different sets of glycine receptors.

Glycine receptors expressed by wide-field amacrine cells

Glycine induced currents and sIPSCs were also recorded from displaced wide-field, putative GABAergic amacrine cells. These GlyRs had slow kinetics (τ ~ 25 ms) (35, 38) comparable to NF amacrine cells. ON-starburst (cholinergic amacrine cells) had sIPSCs with extremely long decay time constants (τ ~ 50 - 70 ms), which did not differ between wild-type and the three mutant mice (35). Since GlyR α4 immunoreactive puncta (Fig. 5D) occur at higher density along the dendrites of ON-starburst amacrine cells, it is possible that GlyRs of ON-starburst cells are dominated by the α4 subunit. This would in turn suggest that GlyRs containing the α4 subunit have slow kinetics.

Glycine receptors expressed by ganglion cells

There are more than ten different types of ganglion cells in any mammalian retina. The GlyRs expressed by A-type ganglion cells (alpha-cell homologues) of the mouse retina were also investigated both in wild-type and mutant mice (32). In the wild-type retina, glycinergic sIPSCs of A-type ganglion cells have fast kinetics (mean τ = 3.9 ± 2.5 ms). Glycinergic sIPSCs recorded from *Glra2*$^{-/-}$ and *Glra3*$^{-/-}$ mice did not differ from those of wild-type mice. However, the number of glycinergic sIPSCs was significantly reduced in *Glra1*$^{spd\text{-}ot}$ mice and the remaining sIPSCs had slower kinetics. These results show that A-type ganglion cells receive preferentially kinetically fast glycinergic inputs, mediated by GlyRs containing the α1 subunit.

B-type cells (beta-cell homologues) are probably involved with sustained neurotransmission. They are also believed to perform complex tasks like local edge detection. However, the specific roles of different B-type cells in the mouse retina are not yet clearly understood. There are four classes of small-field B-type ganglion cells (39), and there seems to be a substantial heterogeneity with respect to GlyR expression in these cell types. GlyRs of B1 cells are dominated by the α1 subunit, while in B4 cells the α3 subunit plays an important role. B2 and B3 cells express a more balanced mixture of fast (α1) and slow (α2, α3, α4) GlyR subunits (40).

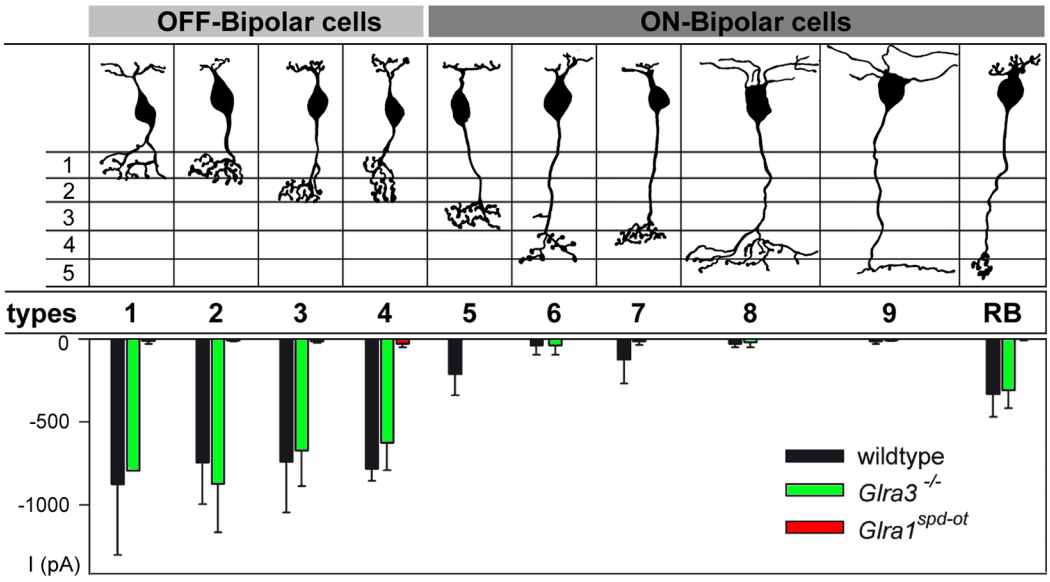

Figure 10. Glycine-induced currents from mouse bipolar cells. OFF- and ON-bipolar cells of the mouse retina as described by Ghosh et al., 2004 (55) and summary diagram of the peak amplitudes of inward currents elicited by the application of glycine (1–2 mM) in the nine cone bipolar cell types and rod bipolar (RB) cells of wild-type, Glra3$^{-/-}$ and Glra1$^{spd\text{-}ot}$ mice. From Ivanova et al., 2006 (31).

9. Summary and conclusion

All four GlyR α subunits are clustered in synaptic hot spots (Fig. 5) that show characteristic distributions across the IPL of the mouse retina (23). Gephyrin is responsible for clustering GlyRs to postsynaptic sites by linking the GlyR β subunit to the cytoskeleton (5, 41). No GlyR clusters could be detected in gephyrin deficient mouse retinas (42), which suggests that synaptic GlyRs in the retina are always heteromeric. In the adult, two copies of the α subunit and three copies of the β subunit form the pentameric receptor protein (8).

Bipolar cells and A-type ganglion cells represent the fast transfer channel of the mammalian retina and, therefore, express α1β GlyRs with fast kinetics. AII amacrine cells relay rod light signals with lower temporal resolution and express α3β GlyRs with medium-fast kinetics. NF amacrine cells are modulatory interneurons, where temporal precision seems less important and they express the α2β and α4β GlyRs with slow kinetics.

Both GABA and glycine inhibition are used to modulate different aspects of ganglion cell responses and receptive field (RF) organization (43-45). GABAergic amacrine cells often provide feedforward inhibition and target both $GABA_A$Rs and $GABA_C$Rs in reciprocal inhibitory circuits to modulate the RF center excitation (46), and they target $GABA_A$Rs to amplify and refine the RF surround (47). Glycinergic inhibition on the other hand modulates less spatial than temporal properties and may increase the gain of the ganglion cell response. Glycinergic amacrine cells often use (crossover) inhibition to modulate ganglion cell excitatory inputs within their RF center (48-52).

About the Authors

Silke Haverkamp received her PhD from the Carl von Ossietzky Universität Oldenburg, Germany, in Visual Neuroscience under the mentorship of Josef Ammermüller. She was a postdoctoral researcher at the Boston University with Bill Eldred and then at the Moran Eye Center in Salt Lake City with Helga Kolb. Afterwards, Silke moved back to Germany to join the Department of Neuroanatomy headed by Heinz Wässle at the Max Planck Institute of Brain Research in Frankfurt. She has now her own research group at the Institute and focuses on the structure and function of neurons and synaptic circuits within the mammalian retina, using neuroanatomical and electrophysiological methods.

Role of Dopamine in Retinal Function

Elka Popova, Ph.D.[1,*]

Created: May 28, 2020.

Abstract

Dopamine (DA) is the major catecholamine in all vertebrate retinas including man. All vertebrates have dopaminergic neurons identified as amacrine cells (ACs) and interplexiform cells (IPCs), with great variations among different species. DA neurons are comparatively rare with density about 10-100 per mm^2, which means that they are less than 1% of all amacrine cells. In retinal circuitry DA serves principally as a neuromodulator, which reaches distant target cells by diffusion, and thus exerts a "volume transmission" mode of communication. Dopamine release appears to be circadian, with high release levels during the day in many species, and is a counterpart to the circadian rhythm in melatonin, which is released at night. Dopamine regulates voltage-gated ion channels and alters chemical and electrical synaptic transmission through five D_1-like and D_2-like G-protein-coupled receptors. DA is particularly associated with retinal circuitry reconfigurations with nighttime and daytime vision. DA actions are highly cell type, species and context dependent. DA acts through multiple intracellular pathways, in particular G-protein activated Adenylate Cyclase (AC) and Phospholipase C (PLC) pathways.

Introduction

In 1970 Julius Axelrod received the Nobel prize for Neuropharmacological studies of brain neurotransmitter pathways, among them biogenic amines such as dopamine (DA). His work was key in developing a treatment for Parkinsonism, a DA deficiency disorder (1). The discovery of enzymatic pathways of DA synthesis, an early histochemical DA marker involving formaldehyde-induced fluorescence for biogenic amines (2), and association with a prominent neurological disease gave incentive to study actions of DA circuitry in retina. DA is the major catecholamine in all vertebrate retinas including man. All vertebrates have dopaminergic neurons identified as amacrine cells (ACs) and interplexiform cells (IPCs) with great variations in neural types represented among different species. DA neurons are comparatively rare with density about 10-100 per mm^2, which means that they are less than 1% of cells in the amacrine cell layer of the retinal inner nuclear layer. In retinal circuitry dopamine serves principally as a neuromodulator, which reaches distant target cells by diffusion and thus exerts a "volume" transmission mode of communication. DA regulates voltage-gated ion channels and alters chemical and electrical synaptic transmission through five D_1-like and D_2-like G-protein-coupled receptors. It is particularly associated with retinal circuitry reconfigurations undergone with nighttime and daytime vision. DA acts through multiple intracellular pathways, in particular, G-protein activated Adenylate Cyclase (AC) and Phospholipase C (PLC) pathways. Dopamine receptors also directly modulate voltage-gated membrane channels through protein-protein interactions as well as G-proteins. DA actions are highly cell type, species and context dependent. This article reviews five decades of DA research of actions on and within neurons of the retina.

Morphology and circuitry of Dopaminergic neurons in the retina

The distribution of DA among retinal cell types varies with species. Some species (*amphibians*) have both dopamine cell types (ACs and IPCs), while others (*elasmobranch fishes, reptiles, birds ,cats, rabbits, monkeys,*

* About the authors

human) have only DA **amacrine** cells that spread over a wide field in stratum 1 of the inner plexiform layer (IPL) (**Figure 1 a, b**). *Teleost fish* have only DA IPCs (**Figure 1 c, d**) (3, 4). IPCs are wide field amacrine-like cells that have dendrites running through both the IPL and outer plexiform layer (OPL). *Turtles* appear to have DA cells with tristratified IPL dendritic trees but no dendrites to the OPL (5). In *human, cat,* and *ground squirrel* retinas dopaminergic ACs have some rare processes projecting towards and into the OPL (6-8) but their major dendritic plexus is in stratum 1 of the IPL (**Figure 1 a, b; Figure 2 a, b**). In *cat* the OPL-running DA dendrites make synaptic contacts upon a different IPC, which is GABAergic, and possibly upon B-type horizontal cells (7) (**Figure 2 a**, **b**). In primates, mouse, and rabbit retinas a second type of catecholamine amacrine (CA) is seen, called Type 2 CA (9-12) (see also Webvision chapter on Neurotransmitters in the Retina).

The primary Type 1 DA cell in mammals is very characteristic with a large cell body and a dense plexus of dendrites in stratum S1 of the inner plexiform layer (**Figure 2 a**, **c**). Holes or "rings" in the plexus of criss-crossing stained dendrites are sites of amacrine cell bodies or large amacrine dendrites (**Figure 2 b**), on which the processes of the DA cell plexus synapse. In this respect the processes of DA cells appear to be axon-like (**Figure 2 a**, **b**, **c**).

Electron microscopy of a cat Type 1 DA cell, in tyrosine hydroxylase (Toh) immunostained retinas (7), shows that Toh amacrine dendritic rings synapse upon the glycinergic AII rod amacrine cells (**Figure 3 b**), A8 glycinergic amacrine cells (**Figure 3 a**), and upon GABAergic A17 amacrine cells (not shown) (7, 13, 14). The type 1 DA cell is postsynaptic to OFF-bipolar cells in stratum 1 (**Figure 4 a**) and to occasional ectopic synapses from an ON-bipolar axon passing through the OFF layer (not shown) (15). The main DA plexus in S1 sends a few processes to the S3 level of the IPL (7, 11, 16) (**Figure 2 d**) where they are postsynaptic to ON-bipolar cells (**Figure 4 b**) (16). Glycinergic and GABAergic amacrine cells (**Figure 4 c-f**), melanopsin M1 ganglion cells (17-19) and histaminergic centrifugal fibers (20) make synapses upon the Type 1 DA cell as well (see chapters on Roles of Amacrine Cells and Melanopsin-expressing, Intrinsically Photosensitive Retinal Ganglion Cells (ipRGCs) in Webvision).

In cat the OPL-running DA dendrites make synaptic contacts upon a non-dopaminergic IPC, which is GABAergic, and possibly upon B-type horizontal cells (7) (**Figure 3 c and d**). These contacts are, however, probably not signs of synaptic vesicle release of transmitter because no synaptic vesicle proteins have been found at these attachment points. They are possibly sites of dopamine release and action through "volume transmission".

The DA Type 1 cell exhibits glutamate, GABA and histamine H1 receptors (7, 19, 20). Glutamate (21), GABA and dopamine colocalize to the Type 1 DA cell (22, 23), and serotonin has also been found to co-exist in these same amacrine cells in cat retina (23). Thus, the dopamine amacrine cells of the vertebrate retina are a complex cell type, differing in branching patterns in different species, making different synaptic connections dependent on species, and synthesizing multiple neurotransmitters. A general summary diagram of the DA cell in *mammalian* retinas with the synaptic inputs and outputs is shown in **Figure 5** (explanations are in the figure legend).

Physiology of Dopaminergic amacrine cells

DA amacrine cells fire spontaneously at a modest rate (< 10 spikes/s) and the action potentials trigger dopamine release by exocytosis (22, 24). In the dark, the spontaneous spike activity differs markedly among DA cells. The characteristics of their spike activity falls into four categories in intact *mouse* retina: quiet cells that generated spikes infrequently at random intervals (**Figure 6**, **A1**), rhythmic cells that fire spikes at a maintained rate, and cells that generate bursts that are either mixed with single spikes (**Figure 6 B1**) or occur in discrete bursts at regular intervals (**Figure 6**, **C1**, **D**) (25). The bursting, but not the overall firing rate, increases during blockade of the GABAergic and glycinergic retinal synapses, indicating that an inhibitory synaptic input from amacrine cells in the dark modulates the bursting aspect of DA cell spontaneous activity (12). On the other hand, blockade of

(b) Double immunostaining for Toh-labeled DACs (green) and Calretinin-labeled AII amacrine cells (red) in wholemount *monkey* retina. Many of the Toh-labeled dendritic rings are occupied by AII amacrine cell bodies. (a, b) courtesy of Nicolas Cuenca. (c) Toh-immunostained DA cell processes in stratum 1 (S1) of the mouse IPL form a dense monolayered plexus. (d) A few processes descend from the S1 plexus to ramify loosely in S3 of the IPL. (c, d) from Contini et al. (16).

AMPA/kainate-type or NMDA-type glutamate receptors affects neither the firing rate nor the firing pattern of DA cells, indicating a lack of direct excitatory glutamate synaptic input from bipolar cells in the dark.

In contrast to spontaneous firing, the light-evoked activity of DA cells in *mammalian retina* is modulated by the excitatory glutamatergic input from the ON cone bipolar cells (CBCs) (16) and melanopsin-expressing intrinsically photosensitive retinal ganglion cells (ipRGCs) (19) (**Figure 7**) (for relationship between DA and

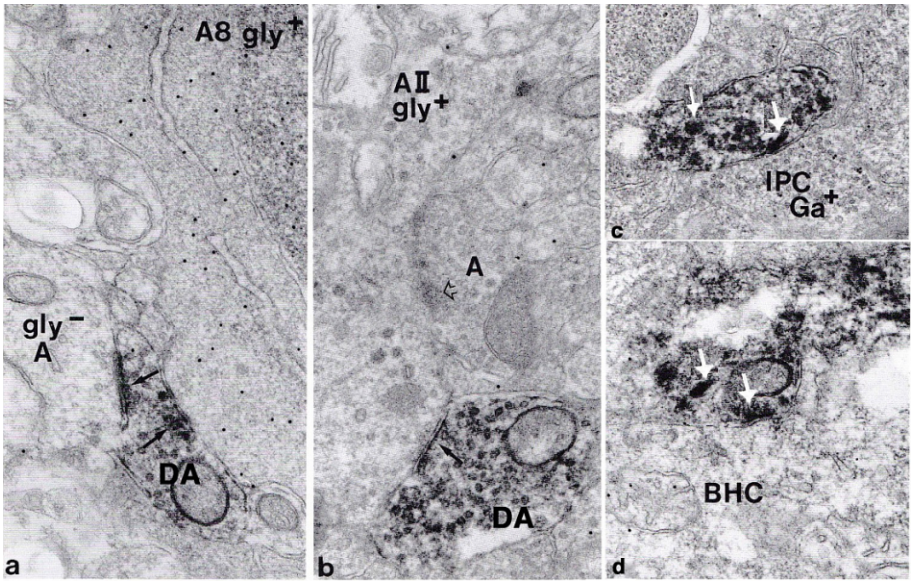

Figure 3. EM of dopamine amacrine processes (**DA**) immunostained with Toh in *cat* retina. These processes are synaptic upon (a) **A8** amacrine cell bodies and (b) **AII** amacrine cell bodies. The A8 amacrine cell is heavily counterstained by colloidal gold techniques for glycine (small black spots), whereas the AII cell is only lightly stained. The AII amacrine cell body receives a glycine-negative synapse on its cell body (open arrow, b). The DA process in (a) synapse nearby to a glycine negative cell body. (c) Toh-stained processes in the OPL are closely opposed to an interplexiform cell (**IPC**) that is GABAergic (black spots of **Ga$^+$** immunogold). (d) In the OPL, the same Toh-stained profile as (c) is attached to a B-type horizontal cell (**BHC**). The attachment points (c, d) are characterized by dense-cored vesicles in the Toh-stained profiles (white arrows). From Kolb et al. (7).

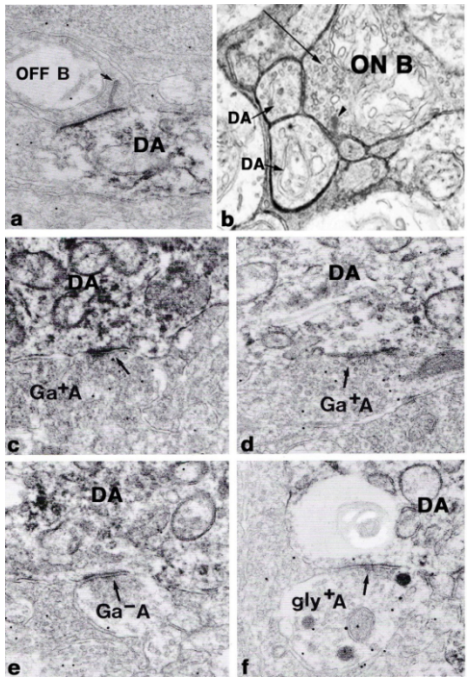

Figure 4. EM of synaptic input to **DA** cells in *cat* retina. (a) An OFF cone bipolar cell in stratum 1 of the IPL (**OFF B**) makes a ribbon synapses (arrow) upon a DA process immunostained for Toh. (b) An ON cone bipolar in stratum 3 of the IPL (**ON B**) makes a ribbon synapse (arrowhead) upon two postsynaptic dopaminergic amacrine cell processes (short arrows, DA) in a transgenic mouse immunolabeled with human placental alkaline phosphatase (PLAP). A precipitate of lead phosphate labels DA processes on the external plasma membrane as a black precipitate. From Contini et al., 2010 (16). (c-f) Toh-immunolabelled DA amacrine cell body receives synapses from immune gold labeled GABA positive amacrine cell processes (small black spots, **Ga$^+$ A,** d) and GABA negative amacrine cell processes (**Ga$^-$ A**, e). (f) Glycine positive amacine processes (**gly$^+$ A**) also synapse upon the Toh-stained cell body (small black spots). From Kolb et al., (7).

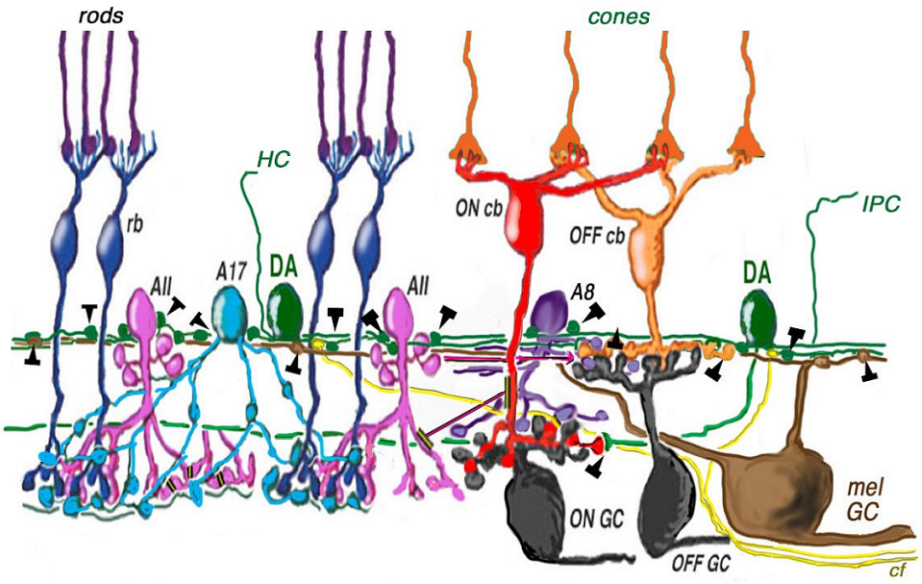

Figure 5. Summary diagram of the synaptic relationships of the dopaminergic amacrine cell (**DA**, green) in the *mammalian* retina. The **DA** cells are characterized by a dense plexus of processes in stratum 1, under the amacrine cell bodies, in the inner plexiform layer (IPL). In this plexus DA cells are postsynaptic to OFF cone bipolar cells (***OFF cb***, orange) and occasional ectopic synapses from ON cone bipolar cells (***ON cb***, red). Several glycinergic and GABAergic amacrine cells, the melanopsin Type 1 intrinsically photosensitive ganglion cell (***mel GC***, brown) and histaminergic centrifugal fibres that run in stratum 1 (***cf***, yellow) are synaptic upon the **DA** cell in that stratum of the IPL (black arrowheads). **DA** cells form presynaptic in rings upon amacrine cell bodies of ***AII*** cells (pink) *A8* cells (purple) and ***A17*** cells (light blue) (black arrowheads). A few DA processes run in stratum 3 of the IPL where they are postsynaptic to ribbon synapses of ON cone bipolar cells (***ON cb***, red bipolar, arrowhead). In addition, a few, scarcely observed, ascending processes go to the outer plexiform layer and seem closely applied to the non-dopaminergic mammalian interplexiform cell (***IPC***) and B-type horizontal cell bodies (***HC***). These attachments associate with clusters of dense cored vesicles. From Kolb et al (7).

ipRGCs see Melanopsin-expressing, Intrinsically Photosensitive Retinal Ganglion Cells (ipRGCs) in Webvision). All mammalian DA amacrine cells are ON-type, while amphibian DA amacrine cells showed excitatory ON and OFF responses (26). Inputs from ON-BCs probably account for the light-evoked ON-transient responses of mammalian DA cells, while inputs from ipRGCs likely account for ON-sustained DA cells.

Zhang et al. (12, 19, 27) found that all ON-transient, but not ON-sustained light responses of DA neurons were entirely eliminated in photoreceptor degenerate mouse retinas and under the influence of L-AP4, which blocked the transmission from rod/cones to ON bipolar cells. On the other hand, the ON-transient light responses persisted in melanopsin knockout mice, where all ON-sustained light responses were eliminated, supporting the dependence of the latter on the inputs only from ipRGCs. Other authors argued, however, that the nature of generated spike response (sustained or transient) of DA neurons depended only on stimulus intensity (25). Newkirk et al. (25) showed that the sustained spike trains were evoked by weak stimuli, whereas the transient trains were evoked by bright light, because the latter caused a depolarization block that limited the ON response to an initial transient burst of spikes. This was also the case in DA cells that generated exceptionally prolonged large depolarizing responses to strong stimuli, which they considered to be the result of direct excitatory input from ipRGCs. Newkirk et al. (25) suggested that a reduced light sensitivity of the retina in experiments of Zhang et al. (12, 19), due to differences in methodology, may account for the discrepancies between the results of the two groups. The reduced sensitivity may serve to reduce the amplitude of the depolarizing response evoked by excitatory input to a level that was not sufficient to cause a depolarizing spike block. This could explain the presence of sustained spike train in response to saturating light in experiments of Zhang et al. (12, 19). This suggestion could not explain, however, why all DA cells had transient responses in melanopsin knockout mice under the same conditions of stimulation and adaptation (27).

The relative contribution of different photoreceptor inputs to the light-evoked ON responses of DA cells was recently investigated in *mouse* retina (28). It was found that rods excited the dark-adapted DA amacrine cells across a wide range of stimulation intensities (6 log units) primarily (but not solely) through connexin-36-dependent rod pathways. This result is at odds with previous findings that DA cell threshold response to scotopic stimuli was generated only by inhibitory input at light onset from glycinergic ACs (25). The discrepancy between cited results is probably due to the different adaptation state of the retina. Zhao et al. (28) performed their recordings in dark-adapted retina, while Newkirk et al. (25) conducted their experiments under weak background illumination that could eliminate the ON-EPSPs evoked by dimmer light. Zhao et al. (28) found that the ON-responses of DA cells to prolonged adapting light were mediated by rods under dim lighting conditions, rods/M-cones/melanopsin under intermediate lighting conditions, and cones and melanopsin under bright lighting conditions (**Figure 7**). Thus, it appears that mammalian DA cells receive excitatory ON inputs from all photoreceptor types and can influence their target cells under different conditions of light stimulation and adaptation. It should be mentioned that not all DA cells have light-modulated responses. Some authors reported that 40% of mouse DA cells are unresponsive to light (12), while other authors (25) reported much smaller portion (1 out of 300 cells).

The light-evoked activity of DA cells is modulated also by inhibitory glycinergic and GABAergic AC synaptic inputs (25, 29). This inhibitory input can occur during light onset and/or at light offset. It appears that the ON inhibition is mediated by glycinergic ACs (25, 29), while the OFF inhibition is mediated by GABAergic ACs solely (25) or by GABAergic and glycinergic ACs (29). In addition to their intraretinal inputs, DA cells receive centrifugal influences from different brain structures. In *fishes* the activity of DA-IPCs cells was modulated by centrifugal fibers originating in the olfactory bulb and containing FMRFamide-like and luteinizing hormone releasing hormone (30, 31). In other species (*guinea pig, mouse, rat, monkey*) histaminergic centrifugal fibers originating in the tuberomamillary nucleus of hypothalamus innervated retina and they may also modulate the activity of DA cells (20).

The output synapses of DA amacrine cells are in the IPL, while DA interplexiform cells transmit signals from inner to outer retina. The main output synapses of mammalian DA amacrine cells in the IPL are onto two types of amacrine cells - AII (glycinergic) and A17 (GABAergic), which belong to the rod pathway (see Webvision: AII Amacrine Cells and Roles of amacrine cells). In addition, DA cells make reciprocal, conventional GABAergic synapses onto the presynaptic ON CBCs (16). These synapses probably function to exert an inhibitory feedback onto the presynaptic bipolar cell. DA amacrine cells synapse also onto ipRGS and thus can modulate their activity (17, 18) (see Webvison: Melanopsin-expressing, Intrinsically Photosensitive Retinal Ganglion Cells (ipRGCs). In cold blooded animals, DA amacrine cells make output synapses onto other amacrine cells, ganglion cells and axon terminals of bipolar cells (32, 33). The well-known synaptic outputs of DA IPCs in the OPL are on the GABAergic IPC as seen in *cat* (7, 8), horizontal cells of *cat* (7, 8), *Cebus monkey* and *goldfish* (34), *human* (6), and on bipolar cells of *Cebus monkey* and *goldfish* (34). In rodent retina, DA IPC distal processes have multiple varicosities that terminate throughout the INL, the OPL, and, rarely, in the layer of photoreceptor cells without making morphologically defined synapses (35). Dopamine is packed into membrane-bound compartments that are not conventional synaptic vesicles. These reside in the dendritic varicosities and can be released from them at multiple horizontal levels of the outer retina. Dopamine reaches its target cells by diffusion over distances of up to tens of microns giving rise to the concept of "volume transmission" (36, 37).

It is known that DA amacrine cells co-localize GABA, in *cat* (23, 38), *turtle, chick, mouse* (39) and *rat* (38, 40, 41). It was shown that a proportion of the secretory organelles in the cytoplasm of mouse DA cell bodies contained both GABA and dopamine and that both transmitters were released simultaneously by exocytosis upon depolarization of the cell membrane (22). The synapses made by rodent DA cells onto AII amacrine cells appeared to be GABAergic, since $GABA_A$ but not DA receptors were clustered in the postsynaptic active zone (42). A hypothesis exists that GABA, released by the DA cell, acts on the ionotropic GABA receptors clustered at the postsynaptic active zone of AII amacrine cell, whereas dopamine diffuses to more distant, slower-acting

metabotropic receptors (22, 42). This hypothesis is probably not true for rabbit retina, where synapses made by DA amacrine cells on AII cells were not GABAergic (43). Lee et al. (43) suggested that AII synaptic input from DACs in the rabbit retina may be mediated only by dopamine. This is consistent with earlier results showing that a very few rabbit DACs contained very low levels of GABA (38). GABA co-localization was not observed in DA cells of some lower vertebrates including amphibians and fishes (39).

Photic and circadian regulation of dopamine release

Much data indicates that endogenous dopamine release is low in darkness but increases during retinal exposure to constant or flickering light, as seen in *frog* (37, 44, 45), *turtle* (46), *pigeon* (47), *chick* (48, 49), *duck* (50), *rodents* (29, 51, 52), *rabbit* (53-56), *cat* (57), and *monkey* (58). These results led to the suggestion that dopamine functions as a chemical signal for light (59-62). However, there are some opposite results, indicating that the dopamine release was high in darkness and decreased during retinal illumination as seen in *cat* (63, 64). According to some authors the latter effect was seen only when the experiments were performed at night, not at day (65). There is some suggestion that in *mammalian retina* there is a U-shaped relationship between dopamine release and light intensity (66, 67). In total darkness, when DA cells receive no input, they fire spontaneously and release dopamine. The release of dopamine diminishes at the low scotopic range, because the DA cells are inhibited by GABAergic amacrine cells driven through the OFF system (67) or through rod BCs via AII amacrine cells (66). There is no consensus among the authors cited, however, at what intensity range the DA release increases again. According to Marshak (66) it occurs in the higher scotopic range, when the DA cells receive direct excitatory input from ON cone bipolar cells driven from the less sensitive rod pathway via rod-cone junctions (**Figure 8**). According to Pérez-Fernández et al. (67) it occurs at light intensities when transition from mesopic to photopic vision takes place (> 6 log units above ERG threshold). The latter authors suggest that under scotopic and mesopic light stimuli, although the glutamate release increases and stimulates synaptic AMPA/kainite receptors, it does not outweigh the inhibition caused by the GABAergic system and DA release is low (**Figure 9**). Under bright light conditions both inhibition and excitation are increased, but due to glutamate spill over to extra-synaptic NMDA receptors the level of excitation tips the balance and allows a large release of dopamine.

Pérez-Fernández et al. (67) presented evidence that DA release in mouse retina depended neither on cone photoreceptors nor on ipRGC function and they insist that it entirely depended on the rod pathway function. This suggestion is not supported by results of Cameron et al. (51), who reported that light-induced dopamine release was retained in mice lacking rod phototransduction, although the magnitude of this response was substantially reduced compared with wild-types. By contrast, light-induced dopamine release was not evident in mice lacking both rods and cones, indicating that light regulation of retinal dopamine release relies upon both rod and cone function.

Another hypothesis is proposed by Dowling (68), who suggested that different types of dopaminergic cells in mammalian retina, as described by Zhang (12), can account for the dopamine release under different conditions of light stimulation. The spontaneously active dopaminergic cells, which are not light-driven, would release dopamine in the dark. The ON-transient cells would release dopamine best when exposed to flickering light and the ON-sustained dopaminergic cells would release dopamine best in steady light. The amount of dopamine released, however, may be determined not only by spike frequency, but also by the pattern of spike activity (single spike, random, or bursting). It was shown that bursting stimulations were twice as potent as regularly spaced ones having the same average frequency in evoking dopamine release from brain dopaminergic neurons (69). In this regard, Cameron et al. (51) suggested that the slow sustained activation, typically associated with ipRGCs, could account for their inability to release measurable amounts of DA from the dopaminergic cells upon light stimulation, although ipRGCs send excitatory outputs onto the dopaminergic cells.

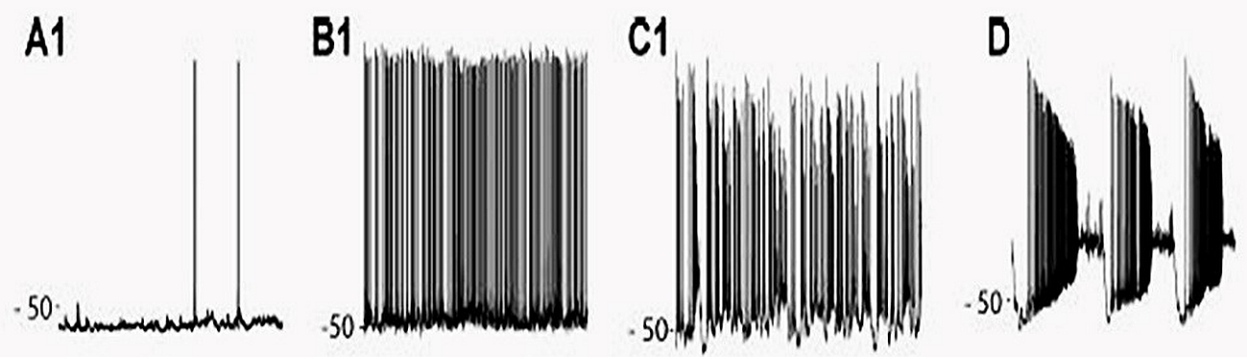

Figure 6. Cellular properties of dopaminergic cells in *mouse* retina. Resting spontaneous spike activities in 4 different cells provide examples of cells that are nearly silent (**A1**), continuously active (**B1**), or exhibit steady discharge with intermixed bursts of spikes (**C1**) or periodic bursts (**D**). Resting membrane potentials (in mV) are indicated at left of each trace. From Newkirk et al. (25).

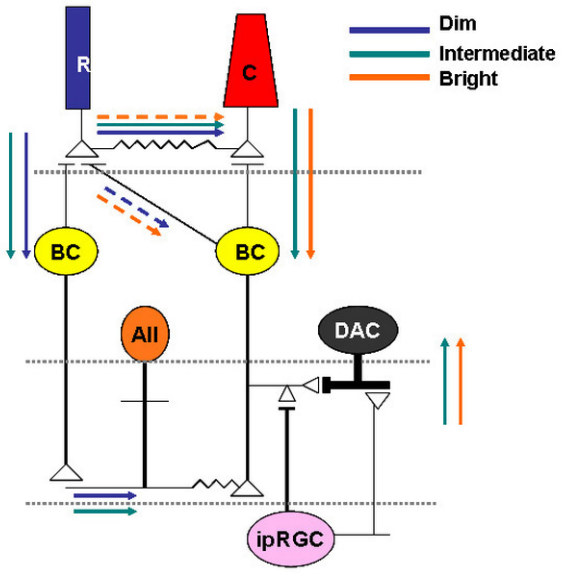

Figure 7. Proposed inputs from three distinct photoreceptor classes to dopaminergic amacrine cells (**DAC**) under different lighting conditions. Under dim lighting conditions, DACs receive equal input from rods (**R**) through the primary (rod — > rod BC — > AII amacrine — > cone BC) and secondary (rod — > cone) rod pathways (blue arrows) and possibly from the tertiary rod pathway (rod — > cone BC) (dashed blue line/arrow). Under intermediate lighting conditions, DACs receive input from rods (green arrows), cones (**C**) and melanopsin intrinsically photosensitive retinal ganglion cells (**ipRGC**) (green arrows). Under bright lighting conditions, DACs receive cone input (orange arrows) and melanopsin input (orange arrow); melanopsin may contribute to DAC signaling in the ventral retina as well (dashed orange line/ arrow). Under bright lighting conditions, rods may also excite DACs through the secondary and tertiary rod pathways (dashed orange line/arrow). Form Zhao et al. (28).

In some *non-mammalian species* (fishes, reptiles, birds), dopamine synthesis and release are controlled by a circadian clock so that dopamine release is highest during the daytime in light and lowest at night in darkness, as seen in *fish* (70-72), *iguana* (73, 74), *pigeon* (47), *turkey* (75), *quail* (76), *chick* (48, 49), and *duck* (50). In *fish retina*, the circadian rhythm of dopamine release was eliminated during the continuous presence of melatonin and melatonin receptor antagonists, indicating that the circadian rhythm of dopamine release was primarily driven by the circadian rhythm of melatonin (71). Similar results were obtained in *reptiles*, where the circadian rhythm of retinal dopamine content and metabolism was abolished in melatonin depleted eyes (73). Whether dopamine release is predominantly light-driven or controlled by a circadian rhythm in *birds* is a subject of dispute. It was shown that retinal DA content oscillated rhythmically in pigeons kept for 4 days under continuous dim light illumination, indicating the dominant role of circadian oscillator for retinal dopamine

release (47). In these cases, the dopamine rhythms were not just driven by melatonin rhythms, because inhibition of melatonin release by quinpirole did not always change dopamine level (77). However, in retinas of *chick* (49, 61), *quail* (76) and *turkey* (75), a progressive decline of rhythmic oscillations of DA, its synthesis and degradation products was observed in constant darkness, emphasizing the important role of light as a stimulatory signal for the retinal dopaminergic system, in addition to the circadian pacemaker. The authors cited proposed that the small circadian increase in dopamine synthesis, release, and metabolism resulted from disinhibition of dopaminergic neurons from the suppressive action of melatonin during the light phase of the cycle.

A consensus is lacking regarding the circadian regulation of dopamine metabolism in *mammalian retina*. Although the concentration and release of dopamine was higher during the day and lower at night in *mouse* (78, 79), *rat* (80-84), *rabbit* (55), *human* (85), some authors reported no circadian rhythm in dopamine synthesis and utilization in *rats* (81), *rabbits* (55), *mice* (79) kept in constant darkness. The latter authors suggested that the diurnal changes of dopamine synthesis and utilization are entirely dependent on the presence or absence of light and not driven by a circadian clock. Other authors, however, demonstrated circadian rhythm of dopamine content and turnover that persisted in constant darkness (78, 80, 84). The circadian rhythm of dopamine content and metabolism was evident in mice that synthesize melatonin, but not in mice that were genetically incapable of synthesizing melatonin. Daily injections of melatonin induced circadian rhythms of dopamine in retinas of mice that were unable to synthesize melatonin (78). These observations suggest that the circadian rhythm of dopamine synthesis in the mouse retina, like fishes and reptiles, is controlled by rhythmic release of melatonin from the photoreceptors. It is tempting to speculate that melatonin released from photoreceptor cells is required to entrain the circadian oscillators in dopamine ACs to the daily light-dark cycle. However, when photoreceptors degenerate (as in Royal College of Surgeons rats), the retinal dopamine content, its metabolites and melatonin synthesis still displayed circadian rhythms (80, 86), thus suggesting the presence of a circadian clock outside the photoreceptors. It was shown that the mouse dopaminergic neurons expressed core circadian clock genes (87-90), which supports the hypothesis that dopaminergic amacrine cells may contain an autonomous circadian clock.

It appears that at least two different circadian pacemakers are present in the mammalian retina. The first pacemaker drives the circadian rhythm of melatonin synthesis and is likely to be located in the photoreceptor cells, while the second pacemaker drives the circadian rhythm of dopamine and is located in neurons of the inner retina (91). It was postulated that the melatonin secreting photoreceptors and dopaminergic amacrine/interplexiform cells are components of a mutually interplaying system (in a negative manner) and act as chemical analogs of light and darkness, respectively (62, 92). Melatonin appears to contribute to the nocturnal suppression of DA release and to its circadian rhythm. Dopamine, on the other hand, feeds back to the photoreceptor cells to inhibit melatonin synthesis, contributing to the suppression of melatonin synthesis in the daytime. Dopamine also serves as a zeitgeber that together with light entrains the photoreceptor clock (**Figure 10**).

Some data suggest that the circadian regulation of dopamine synthesis in mouse retina depended also on melanopsin ipRGCs. It was shown that lack of melanopsin (in melanopsin$^{-/-}$knockout mouse retinas) prevented the light-dependent increase of tyrosine hydroxylase mRNA and of dopamine and, in constant darkness, led to comparatively high levels of both components (93).

Dopamine receptors in the retina

Dopamine actions are mediated by five G-protein-coupled receptors named D_1 to D_5. These receptors are allocated to two groups: **1.** The D_1-like (including D_1 and D_5 subtypes), which are generally coupled to $G\alpha_{s/olf}$ and stimulate the production of cyclic Adenosine Monophosphate (cAMP) and the activity of Protein Kinase A (PKA). **2.** The D_2-like (including D_2, D_3 and D_4 subtypes), which are coupled to $G\alpha_{i/o}$ and negatively regulate

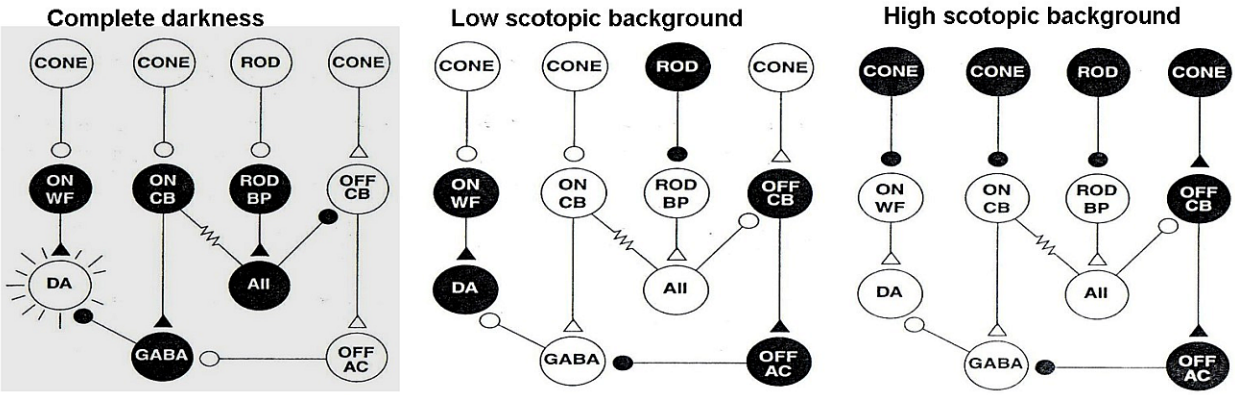

Figure 8. Marshak model for dopamine release. In the dark dopaminergic cells (**DA**) are spontaneously active and release high levels of dopamine. Rods, cones, cone OFF bipolar cells (**OFF CB**) and OFF ACs (**OFF AC**) are depolarized (white), while rod bipolar cells (**RB**), ON-cone BCs (**ON CB**), ON cone wild field BCs (**ON WF**), AII amacrine cells (**AII**) and GABAergic ACs (**GABA**) are hyperpolarized (black). In low scotopic backgrounds, rods are hyperpolarized and cones are depolarized. Rod BCs are depolarized, which leads to depolarization of **AII**, ON-cone BCs and GABAergic ACs. The latter inhibit DA cells and dopamine release decreases. In high scotopic backgrounds, rods and cones are hyperpolarized, which leads to depolarization of RBs, ON-WF, ON-CBs and GABAergic ACs, while OFF-CBs and OFF-ACs remained hyperpolarized. The activity of DA cells reflects a balance between excitatory input from ON-WF BCs and inhibitory input from GABAergic cells so that the release is greater than under low scotopic backgrounds. From Marshak (66).

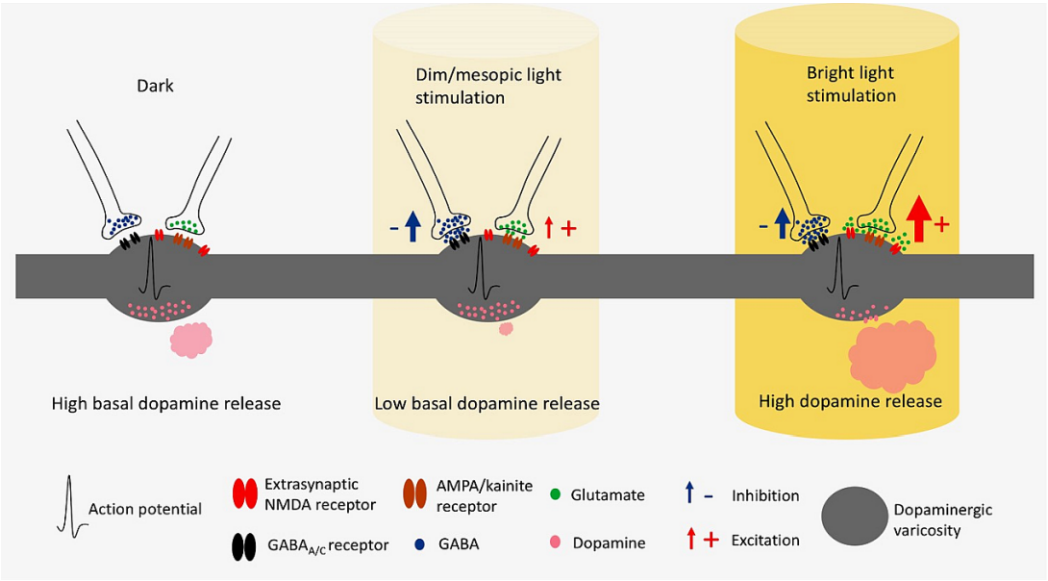

Figure 9. Model of Pérez-Fernández et al. for dopamine release. In the dark, the dopamine release is not inhibited, resulting in a high basal release. Under scotopic/mesopic light stimulation, rod activation drives GABAergic inhibition, and a small excitatory glutamatergic input only to synaptic AMPA/kainite receptors, causing reduced basal dopamine release. Under bright light stimulation, the rod activation also drives GABAergic inhibition, but activates extra-synaptic NMDA receptors via glutamate spillover resulting in more excitation than inhibition causing a large release of dopamine. From Pérez-Fernández et al. (67).

the production of cAMP, resulting in a decrease in PKA activity. This is reviewed in Beaulieu and Gainetdinov (94). Activation of PKA by D_1-like receptors also results in the phosphorylation of the cyclic AMP-regulated phosphoprotein, 32 kDa (DARPP-32), which is an inhibitor of protein phosphatase 1 and thus prevents dephosphorylation of activated proteins (**Figure 11**). In addition to this main pathway for intracellular signaling, dopamine receptors can also utilize other pathways. Some data indicate that the D_5 dopamine receptor can be coupled to Gαq to regulate PLC activity and intracellular calcium signaling, as reviewed in articles by Beaulieu

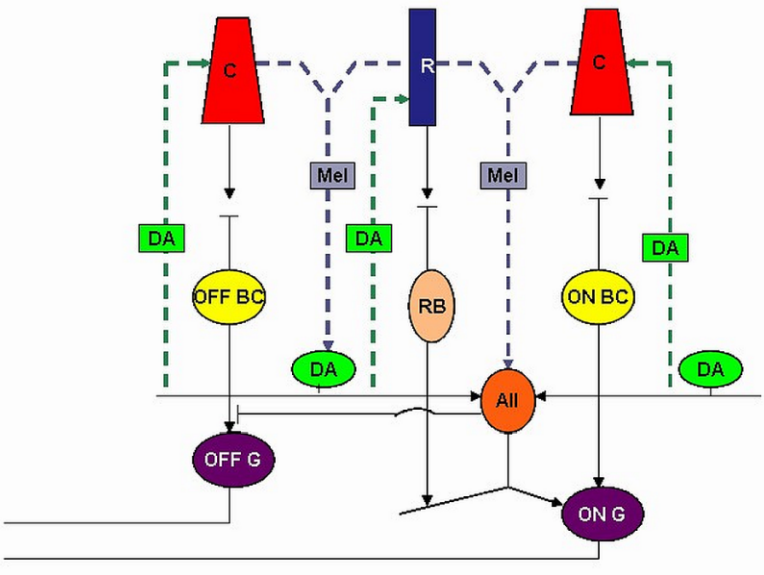

Figure 10. Melatonin–dopamine circadian clock network. Melatonin (**Mel**) is released from rods (**R**) and cones (**C**) at night and inhibits dopamine (**DA**) release both directly, and indirectly though GABA amacrine cells (not shown), thus contributing to the nocturnal suppression of DA release and to DA circadian rhythm. Dopamine, on the other hand, feeds back to the photoreceptor cells to inhibit melatonin synthesis, contributing to the suppression of melatonin synthesis in the daytime. This reciprocal paracrine feedback loop may function to stabilize circadian output in the inner and outer plexiform layer. Melatonin and dopamine probably have opposing effects on AII amacrine cell physiology. Modified from Iuvone et al. (92).

(94, 95) (**Figure 11**). The participation of the D_1 receptor in the same signaling pathway is uncertain. The D_2-like receptors acting through $G_{\beta\gamma}$ subunits of heterotrimeric G- proteins can increase the activity of inwardly rectifying potassium channels (94, 96) and reduce the activity of L-type and N-type calcium channels (97) (**Figure 11**). Similar to D_1-like receptors, D_2-like receptors can also modulate intracellular calcium levels (98, 99). Some of these actions may be mediated by $G_{\beta\gamma}$ subunits of heterotrimeric G-proteins that could activate PLC and thus lead to release of Ca^{2+} from intracellular stores (94, 100). Other data suggest, however, that the calcium signal from D_2-like receptor activation may originate from activation of D_1-D_2 or D_5-D_2 receptor hetero-oligomeric complexes, reviewed in Hasbi et al (101, 102).

It was shown that D_1–D_2 receptor heteromer activation (by SKF 83959) led to a rapid, transient, intracellular calcium mobilization (via Gq, PLC, PKC, IP_3), independent of extracellular calcium influx (**Figure 12**), that was not observed with either D_1R or D_2R activation alone. The activation of the D_5 receptor had similar effects, with the exception that the calcium signal depended on calcium influx. The formation of the D_2–D_5 receptor heteromers resulted in an attenuation of the D_5 receptor induced calcium signal, which could be restored only when both receptors are concomitantly activated (**Figure 13**).

Some authors question these results because SKF 83959 may not exhibit selective activation of D_1-D_2 heteromers, and also may show cross-reactivity to other receptors, as reviewed in Lee et al (103). One might conclude that current evidence does not allow us to determine the detailed mechanism by which D_1, D_5 or D_1–D_2 dopamine receptors participate in calcium signaling in target cells. In addition to their G-protein dependent action, the D_1 and D_2 receptors could directly alter the activity of the ion channels in the cell membrane. It was shown that both D_1 and D_2 receptors inhibited the activity of N-type calcium channels through a direct protein-protein interaction (104). Direct interaction of D_1 and D_2 receptors and Na^+-K^+-ATPase was also demonstrated (105, 106). Finally, there is strong evidence that dopamine receptors can signal *in vivo* by activating cAMP-independent mechanisms involving the multifunctional adaptor protein β-arrestin 2 and transactivation of receptor tyrosine kinases in different experimental systems, as reviewed by Beaulieu et al (95).

The D_1-like receptors are found exclusively postsynaptically on dopamine target cells, whereas D_2-like receptors are expressed both postsynaptically and presynaptically on dopaminergic neurons (107, 108). The presynaptic autoreceptors generally provide an important negative feedback mechanism, which regulates the synthesis and release of the neurotransmitter in response to changes in its extracellular concentration (109, 110). The D_2-like receptors, including those in the retina, are 2-3 times more sensitive to dopamine than D_1-like receptors (62, 98, 111-113).

All dopamine receptors undergo desensitization as a result of prolonged exposure to DA or its agonists (114-117). This is a characteristic feature of G-protein-coupled receptors. On the other hand, the receptors can undergo sensitization when an agonist does not activate them for an extended period. Some data indicated that retinal dopamine receptors in rat developed a state of hypersensitivity during period of prolonged light deprivation (118). The hypersensitivity of D_1-like receptors developed earlier (within 6 hours) in comparison with that of the D_2-like receptors (after 2 or, even better, 4 days). Hypersensitivity of D_2-like receptors regulating serotonin N-acetyltransferase activity was found in kainic acid treated chick retinas, where retinal levels of dopamine were markedly reduced (119).

The activity of all neurons in the retina might be modulated by dopamine because all express D_1- or D_2-like receptors. Rod and cone photoreceptors have D_2-like receptors in all species studied. This includes *frog* (120, 121), *salamander* (120), *turtle* (121), *fish* (121), *chick* (121, 122), *rat* (36, 121, 123-126), *bovine* (121, 127), *rabbit* (121, 123), and *human* (128). Some D_1R-immunoreactivity was observed on the axons of cones (129) and in the outer segments of the photoreceptor layer (36). It was shown that dopamine receptors on photoreceptors were of the D_4 type in the retinas of *rodents*, *birds* and *fishes* (120, 130-134). Horizontal cells (HC), bipolar cells (BC), amacrine and ganglion cells (GC) are thought to express mainly D_1-like receptors. The species studied were *frog* (135), *turtle* (135), *fish* (129, 136), *chick* (137), *rat* (124, 138, 139), and *mouse* (140-142). D_1-like receptors were expressed in a type-dependent manner on the ON-CBCs and OFF-CBCs, but not rod BCs (RBC) in mouse retina (140). In ON CBCs, they were expressed in transient, but not sustained cells, while in OFF CBCs they were expressed in sustained, but not transient cells. In addition to the photoreceptors, D_2-like receptors were localized on horizontal cells in *fish* (136), amacrine cells in *frog* (120), *salamander* (120), or *rat* (131), and in cells resembling amacrines and bipolars in the *chick* (121, 122), *rat* (36, 121, 125), *bovine* (121), *rabbit* (121), and *human* (128), and in the ganglion cell layer of *chick* (121, 122), *rat* (36, 121, 125), *bovine* (121), and *rabbit* (121) retinas. The dopaminergic neurons themselves express D_2-like autoreceptors, which function to inhibit dopamine release (125, 131, 143). The Műller glial cells also express dopamine receptors in *frog* (120, 135), *salamander* (120), *turtle* (135), *chick* (144), *mouse* (144), *rat* (129, 145) and *guinea pig* (145).

Effects of dopamine on photoreceptors

Dopamine has numerous effects on photoreceptors. It inhibits the synthesis of melatonin (119, 146), influences retinomotor movements, as reviewed by Popova (147), inhibits hyperpolarization-activated currents as seen in *frog* (148, 149) and *human* (149), modulates light-evoked responses, changes the coupling between photoreceptors, etc. Most of these effects are mediated through D_2-like receptors expressed on the photoreceptors. It was shown that activation of dopamine D_4 receptors in photoreceptors suppressed the light-sensitive pool of cAMP (130, 150-152), reduced the PKA activity and down-regulated the type1 Adenylyl cyclase (AC1) expression (153). In addition, the regulation of cAMP level in photoreceptors by dopamine may occur indirectly, via regulation of the intracellular calcium concentration (154). It was shown that dopamine, quinpirole and the selective D_4 receptor agonist PD 168,077 significantly suppressed K^+-stimulated uptake of Ca^{2+} and decreased $[Ca^{2+}]_i$ in *chicken* cones. The effects of the agonists were blocked by dopamine D_2/D_4 receptor antagonists or by pertussis toxin. Because quinpirole inhibited the increase in cAMP level elicited by K^+, which requires Ca^{2+} influx through voltage-gated Ca^{2+} channels, but not that induced by the calcium ionophore A23187, the authors concluded that the decrease of cAMP elicited by dopamine D_4 receptor

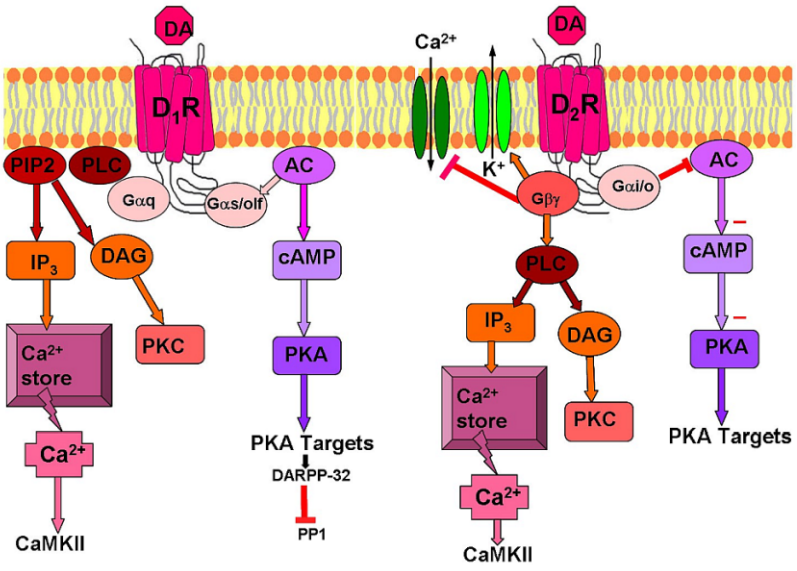

Figure 11. Signaling pathways regulated by dopamine through D_1-like (**D_1R**) and D_2-like (**D_2R**) receptors. Arrows indicate activation, red T-symbols indicate inhibition. Phosphatidylinositol 4,5-bisphosphate (PIP2), Inositol trisphosphate (IP3), Phospholipase C (PLC), Diacyl Glycerol (DAG), Protein kinase C (PKC), Gq, protein alpha subunit (Gαq), Guanine nucleotide-binding protein (Golf) subunit alpha (Gαs/olf), Adenylate cyclase (AC), cyclic Adenosine monophosphate (cAMP), Protein kinase A (PKA), dopamine and cyclic AMP-regulated phosphoprotein (DARPP-32), Protein phosphatase 1 (PP1), G beta-gamma (Gβγ), Gi protein alpha subunit (Gαi/o), Ca2+/calmodulin-dependent protein kinase II (CaMKII).

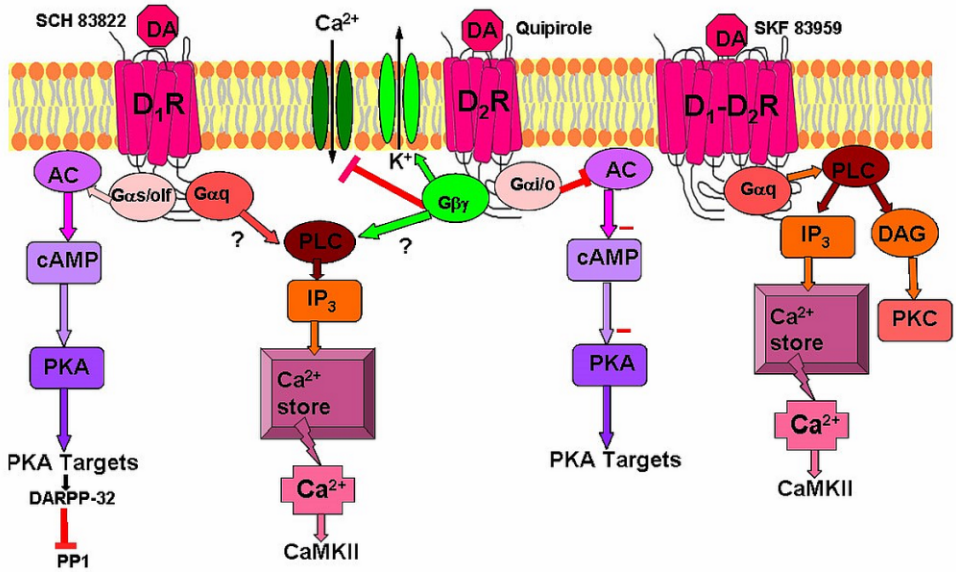

Figure 12. Signaling pathways through dopamine homomeric D_1 and D_2 receptors and heteromeric D_1–D_2 receptors. The respective agonists of the different receptor types are shown above the receptors. The abbreviations are as in Figure 11 legend. Modified from Hasbi et al. (102).

stimulation may be secondary to decreased $[Ca^{2+}]_i$. The latter was probably evoked by a direct action of dopamine on photoreceptor calcium permeability.

Other authors showed, however, that the suppressive action of dopamine and quinpirole on the influx of Ca^{2+} through L-type channels in *salamander* large cones depended on the activation of D_2-like receptors acting through $G_{i/o}$, AC1, cAMP and PKA pathway (155). A suggestion was proposed that dopamine via D_2-like

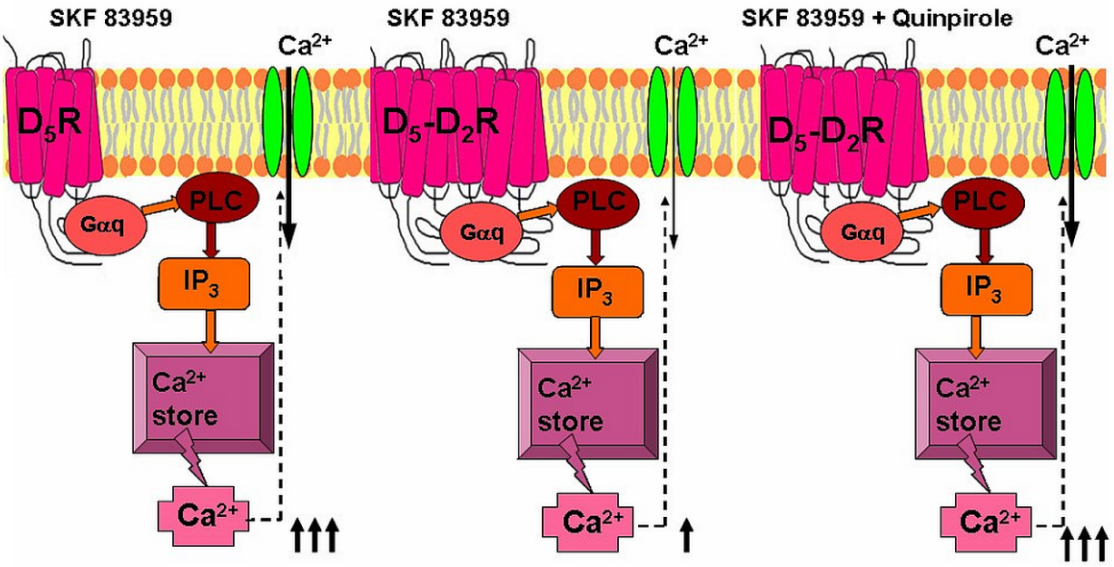

Figure 13. The activation of D_5 receptor homo-oligomers results in a robust rise in intracellular calcium due to PLC activation and extracellular calcium influx (left panel). The formation of the D_2–D_5 receptor heteromers results in an attenuation of the D_5 receptor induced calcium signal (middle panel), which could be restored only when both receptors are concomitantly activated (right panel). The abbreviations are the same as in Figure 11. Modified from Hasbi et al. (102).

receptors triggered two parallel intracellular calcium signaling pathways in photoreceptors (156). One pathway involved inhibition of AC1 (via Gi/o), leading to a decrease in $[cAMP]_i$, a decrease in PKA activity and to a reduction in the calcium permeability of photoreceptor plasma membrane channels. The other pathway included a direct action of dopamine on photoreceptor calcium permeability, leading to a decreased Ca^{2+} influx, a decrease in $[Ca^{2+}]_i$, a decrease in calcium-dependent AC1 activity, and a decrease in $[cAMP]_i$ (**Figure 14**). It was shown, however, that the dopamine effect on calcium influx current was not one and the same in all photoreceptors, but it strongly depended on the photoreceptor type (155). Dopamine reduced I_{Ca} in salamander large single cones, but enhanced I_{Ca} in rods and in all spectral subtypes of small single cones. Surprisingly, Stella and Thoreson (155) found that the intracellular mechanism of those opposite dopamine effects on I_{Ca} was one and the same - via Gi/o, AC1, cAMP and PKA. They proposed that differences among calcium channel subtypes may account for differences among photoreceptors in their responses to activation of the D_2-like receptors. Because of dopamine-induced changes in I_{Ca}, rods would have an augmented release of neurotransmitter, while the large cones would have a diminished release of neurotransmitter. Thoreson et al. (157) showed, however, that although the rod calcium currents were elevated, rod input to second order retinal neurons was diminished. They provided evidence that dopamine and D_2R agonists activated calcium-dependent chloride channels, leading to efflux of Cl^- from rods, resulting in subsequent fall of $[Ca^{2+}]_i$. Thus, the transmitter released by rods diminished without changing the membrane potential. In *mammalian (rat) retina*, however, it appeared that dopamine had no modulatory effect on the photoreceptor Ca^{2+} signals (evoked by high K^+ stimulus), because neither D_2R antagonist spiperone nor D_1R agonist SKF38393 had effect on them (158).

The effect of dopamine on the photoreceptor light responses is not well established. In *goldfish* dopamine did not affect the amplitude of light-evoked responses in green- and red-sensitive cones (159). The only effect of dopamine on the cone responses was to abolish the initial transient phase of membrane relaxation that occurred after the hyperpolarization peak (**Figure 15**). Similar results were obtained in *turtles*, where neither the rods, long-wavelength-sensitive, or medium-wavelength-sensitive cones exhibited any apparent change in responsiveness to light under the influence of dopamine (160). No dopamine-induced changes of rod light-evoked responses were seen in *Xenopus* retina (161) (**Figure 16 A**). In contrast to the above cited results, Hare and Owen (162) demonstrated that dopamine decreased the light-evoked responses of rods over the whole

intensity range tested in *tiger salamander* retina (**Figure 16 B**). In *mammalian retina*, the effects of dopamine on the rod light responses depended critically on the time of the day (163). Jin et al. (163) demonstrated that application of spiperone during the subjective day in *mice* decreased the amplitude and slowed the kinetics of rod responses, so that they resembled the responses typically observed at night. Application of the D_2R agonist quinpirole during the subjective night had opposite effects – enhancing the amplitude and speeding up the kinetics of rod responses. The same pharmacologic agents had no significant effect on the rod light responses, when they were applied during the opposite phase of the diurnal cycle. Jin et al. (163) concluded that a circadian clock in mouse retina controlled the light-evoked responses of rod photoreceptors and that the pathway of this control included dopamine and D_2-like receptors.

Much data indicates that dopamine influences the electrical coupling between rods and cones, but the effects described are contradictory. Some authors presented evidence that dopamine, acting through D_2-like receptors, increased the electrical coupling between rods and cones in *amphibian* retina (164-166). Krizaj (164) suggests that the effect is most important in the mesopic state, when both rods and cones are light responsive, and the electrotonic rod-cone bridges would permit one photoreceptor class to serve as a conduit for signals arising in the other class. At night or following prolonged dark adaptation, when dopamine levels are low, the rod-cone coupling is minimal, and this would prevent the shunting of the rod signal into the cones. Thus, the greater sensitivity to light of the rods would be preserved in postsynaptic cells. Neither light nor dopamine modulated rod-rod coupling in amphibian retina (165, 167), indicating that the modulation of electrical synapses between photoreceptors is specifically related to light adaptation. Other authors suggest, however, that the electrical communication between rods and cones in *fish* and *mammalian* retinas (*rabbit, mouse*) is weak during the day, when dopamine levels are high and robust at night, when dopamine levels are low (168-171). It was found that cones and cone-connected second order neurons could respond to very dim light stimuli in the scotopic range at night, but not during the day, indicating that rods could shunt currents to cones only during the night (170, 171). The authors suggest that the retinal circadian clock decreases both rod-cone tracer coupling and rod input to second order retinal neurons in the day by increasing dopamine D_2R, but not D_1R activation in the outer retina. The changes in photoreceptor coupling were driven by PKA-dependent phosphorylation of gap junctions (168, 169). There was a direct correlation between connexin 36/35 phosphorylation and rod-cone coupling such that both were high in darkness at night, and low under daytime illumination (168, 169, 172, 173). Pharmacological blockade of D_4 receptors under photopic light exposure in daytime resulted in significantly increased rod-cone coupling (169). This effect was also observed by the Li et al. (169) during adenosine A_{2a} receptor activation under the same conditions of light stimulation. Conversely, inhibiting A_{2a} or activating D_4 receptors in daytime dark-adapted retina decreased Cx36 phosphorylation with similar PKA dependence. Li et al. (169) concluded that adenosine and dopamine co-regulated photoreceptor coupling through opposite action on the PKA pathway and Cx36 phosphorylation (**Figure 17**).

This allows the photoreceptors to respond to extracellular cues that have opposite phases (dopamine: high in the day, low at night; adenosine: high at night, low in the day). Dopamine acting through D_2-like receptors during daytime not only suppressed rod-cone coupling in *mouse* retina, but it reduced the rod-rod coupling as well (163). The authors presented evidence that rod-rod coupling was weak during daytime (or subjective day) and stronger during nighttime (or subjective night). Application of quinpirole during the subjective night mimicked the daytime state, while application of spiperone during the subjective day mimicked the night-time state. It appears that a circadian clock in mammalian retina uses dopamine to control both rod-rod and rod-cone electrical coupling. It remains to be determined why dopamine, acting on D_2-like receptors, has no effect on rod-rod coupling in *amphibian* retina, but strongly modulates rod-rod coupling in *mouse* retina and why it has opposite effects on rod-cone coupling in *amphibian* vs *fish*, *mouse* and *rabbit* retinas. A possible explanation for the latter observation is that the decreased cAMP levels and suppressed PKA activity, due to D_2R activation, may have different effect on gap junction conductance in different species. It should be noted that electrophysiological studies on monkey photoreceptors failed to find any modulation of rod-cone coupling by dim backgrounds, dopamine or flupenthixol, a D_1/D_2 dopamine receptor blocker (174).

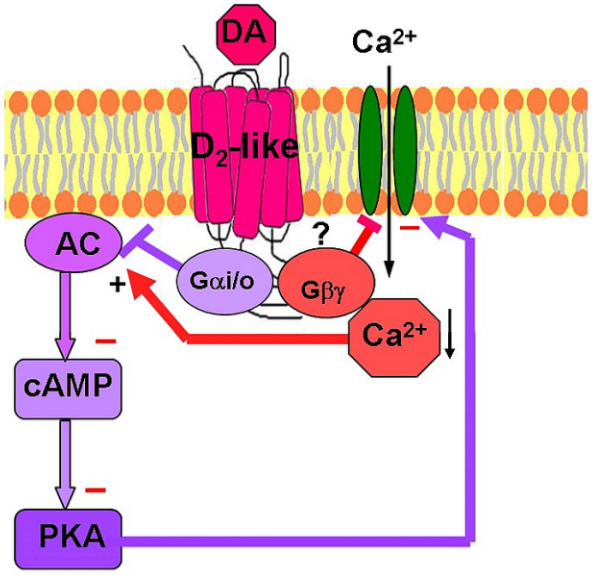

Figure 14. Action of dopamine on photoreceptor Ca^{2+} concentration. Dopamine via D_2-like receptors triggers two parallel intracellular calcium signaling pathways. One pathway involves reduction in the calcium permeability of photoreceptor membrane through $G_{i/o}$, AC1, cAMP and PKA. The other pathway includes a direct inhibitory action of dopamine on photoreceptor calcium permeability (via unknown mechanism, it may be Gβγ), that leads to a decreased $[Ca^{2+}]_i$, a decrease in calcium-dependent AC1 activity, and a decrease in $[cAMP]_i$. Type1 adenylyl cyclase (AC1). Model proposed by Firsov and Astakhova (156).

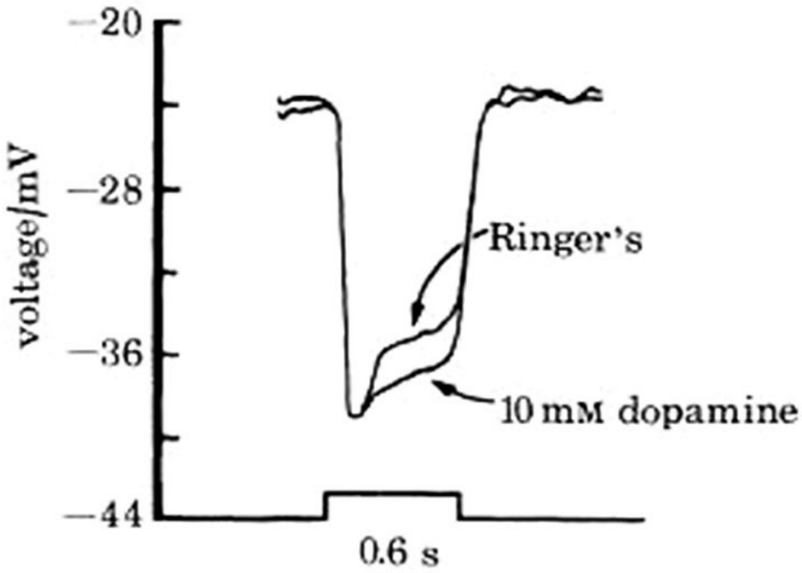

Figure 15. Red cone response to dopamine in *goldfish* retina. A response evoked in the presence of Ringer's solution is compared with one elicited after treatment with 10 mM dopamine. The flash duration is indicated by the raised bar. Both stimuli delivered 9 x 10^{10} photon·cm^{-2}·s^{-1}. Although the resting potential and response amplitude were unaffected by dopamine, the initial transient was abolished by the drug. From Hedden and Dowling (159).

Effects of dopamine on horizontal cells

Horizontals cells are one of major targets of dopamine actions in the distal retina. Dopamine reduced HC calcium currents through L-type channels via D_1R activation (175), affected spinule formation in HC dendrites, as reviewed in (147), strongly influenced the electrical coupling between adjacent HCs, changed HC responsiveness to light, and modulated the balance between HC rod and cone inputs, etc.

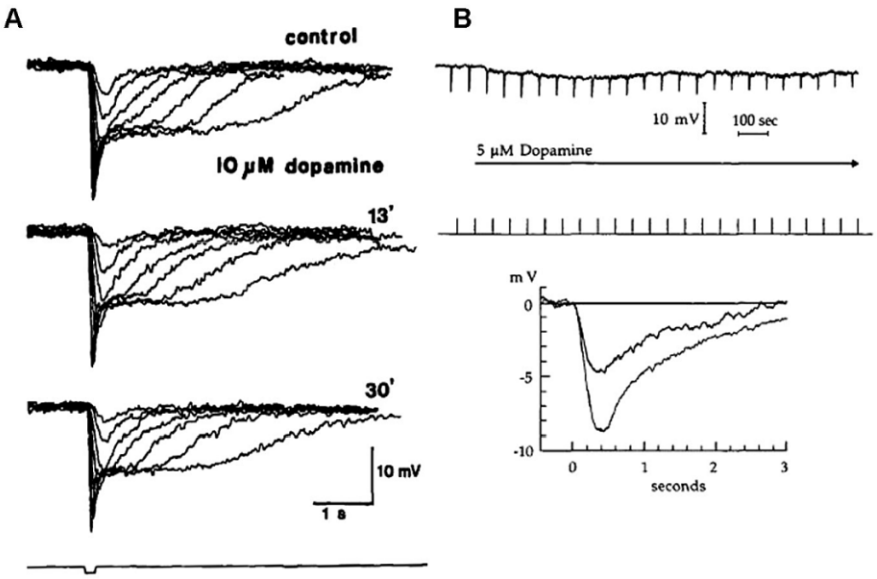

Figure 16. (**A**) Effect of dopamine on rod light-evoked responses in *Xenopus* retina. Voltage-intensity series from a rod recorded before (control) and during exposure (13 min, middle traces; 30 min lower traces) to 10 μM dopamine. The retina was stimulated with a 200 ms flash of 527 nm light (photocell trace is indicated at bottom). Stimulus intensities ranged from 9.68-12.27 log quanta·cm^{-2} ·s^{-1}. It is apparent that dopamine has no effect on light-evoked responses of Xenopus rods. From Witkovsky et al. (161). **(B)** Effects of dopamine on the dark potential and response amplitude of rods in *tiger salamander* retina. Stimuli were circular spots of 492 nm light, 600 μm in diameter, 20 ms in duration. Stimulus irradiance was fixed at 3.9 hv·μm^{-2} ·flash^{-1}. Typical responses of the same rod to the same stimulus recorded in control Ringer's solution (lighter trace) and 20 min after switching to a solution containing 5 μM dopamine (heavier trace) are presented on the lower row. It is apparent that dopamine caused a small hyperpolarization of the dark potential and attenuated the light-evoked responses of *salamander* rods. From Hare and Owen (162).

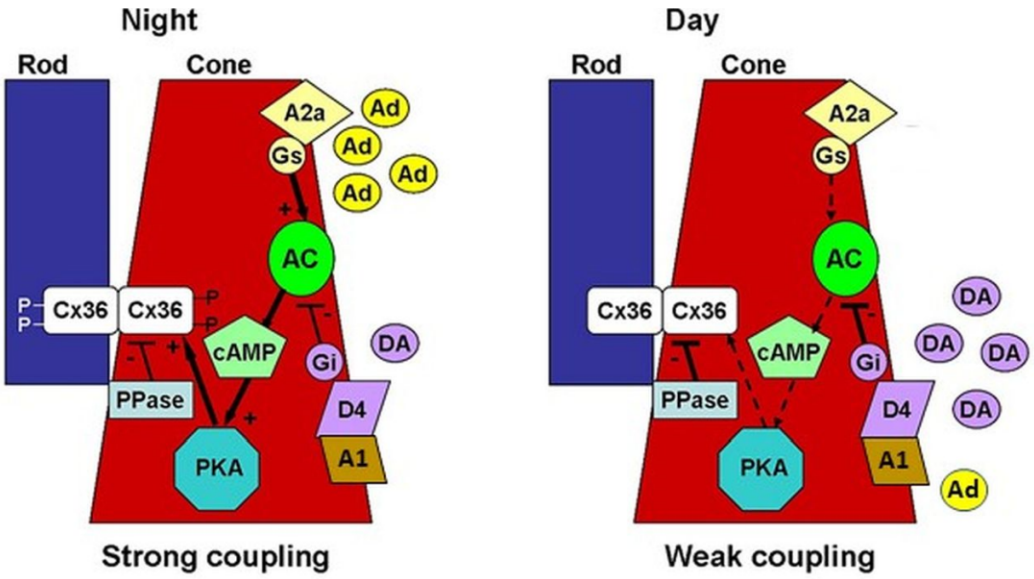

Figure 17. Molecular mechanisms that control photoreceptor coupling. At night, extracellular adenosine (**Ad**) is relatively high and dopamine (**DA**) relatively low, favoring activation of adenosine **A2a** receptors and stimulation of adenylyl cyclase (**AC**) and **PKA** through **Gs** signaling. **PKA** phosphorylates **Cx36** and thus increases coupling between rods and cones. In the day, extracellular dopamine is relatively high and adenosine relatively low, favoring activation of dopamine D4 receptors and adenosine A1 receptors. These both inhibit **AC** and **PKA** through **Gi** signaling and thus decrease the phosphorylation of **Cx36**. The phosphatase (**PPase**) is critical for regulation of coupling, but it is not known if its activity is constitutive or regulated. Modified from O'Brien (336).

The dopamine action on the electrical coupling between adjacent horizontal cells was studied in a number of species. Exogenous dopamine uncoupled horizontal cells in non-mammalian species: *amphibia* (162, 176), *reptiles* (177, 178), *fishes* (143, 179-187) and mammalian species: *rodents* (188-190), *rabbit* (191, 192). As a result, the response amplitude to a centered light spot increased, while that to an eccentric light spot or annulus decreased (64, 143, 177, 178, 180, 186-188, 193-197). According to Tornqvist et al. (64) this effect was seen in the first 5-7 minutes of dopamine application, while application of dopamine for longer periods of time (17–20 minutes) reduced the responses to both small and large spot stimuli. They suggested that the earlier effect was due to the uncoupling of HCs and the latter effect was due to suppressed responsiveness of HCs caused by dopamine (see below). Dopamine-induced uncoupling caused a marked reduction of the HC receptive field size (160, 177, 180, 186, 194, 195, 198, 199). Destruction of retinal dopaminergic neurons with 6-hydroxydopamine, on the other hand, broadened the receptive field profile of HCs (180, 186, 187, 199, 200). According to some authors this effect in fishes was seen only in cone-, but not rod-driven HCs (201, 202), while other authors observed it in rod-driven HCs as well (185, 203). The uncoupling effect of dopamine was mediated by D_1-like receptors, because D_1-, but not D_2-R agonists mimicked the uncoupling effect of exogenous dopamine and the effect was antagonized by D_1R, but not D_2R antagonists (162, 176, 178, 184, 188, 191, 192, 204) (**Figure 18**).

Whether the release of endogenous dopamine uncouples HCs via action on D_1R is a matter of debate. Some authors reported that application of D_1R antagonists alone had no effect on the coupling between HCs (184, 185, 192, 205), while other authors reported an increase of coupling between HCs and therefore insisted that HC coupling was tonically modulated by the endogenous dopamine (176, 188-191, 204). Activation of D_1R in HCs led to cAMP production, the latter likely modified the gap junction conduction between HCs by alteration in protein phosphorylation (**Figure 19**).

It was reported that elevated levels of cAMP in HCs decreased the electrical coupling between horizontal cells (178, 179, 181, 186, 189-192, 206). The effect in *fishes* and *mice* was independent of changes in $[Ca^{2+}]_i$ or pH (179, 190), while in *rabbit* retina, it was pH-gated and thus, may be mediated by a different mechanism (192). Dopamine reduced the open probability of gap-junction channels by reducing both the duration and frequency of channel opening (182, 183). The electrical coupling of HCs may be modulated also by dopamine acting on D_2-like receptors. Some authors found that D_2R agonists increased the HC coupling and D_2R antagonists decreased it (143, 176, 199, 207). The coupling effect of D_2R agonists was blocked completely by prior application of D_1R agonists or treatment with 6-OHDA. These results supported the suggestion that activation of D_2 autoreceptors on dopaminmergic IPCs inhibited dopamine release onto HCs so that the electrical coupling between *fish* horizontal cells increased (143, 199). In *turtle* retina, however, the effect of D_2 agonists was preserved in the presence of a D_1R antagonist, indicating that D_2R played a direct role in electrical coupling between HCs (207).

There is no consensus among authors how the electrical coupling and receptive field size of horizontal cells change with retinal adaptation. Some authors insisted that background illumination had no effect on the HC coupling and receptive field size (177, 208), while other authors stated that background light significantly decreased electrical coupling among HCs (176, 184, 204, 209-212). Still other authors reported that electrical coupling between horizontal cells increased during light adaptation (213) and had minimal values during prolong periods in darkness (64, 194, 195, 214). An interesting relationship between retinal adaptation state and HC coupling was suggested for *fish* and *rabbit* retina. Baldridge (209) proposed a triphasic model for adaptation changes of teleost H_1 cells. He suggested that the HC responsiveness and receptive field sizes were minimal during prolonged darkness but increased considerably when moderate illumination was applied after darkness. Coupling decreased again following exposure to bright illumination. Similar triphasic adaptation was suggested to exist in rabbit HCs (215). It was shown that the coupling between HCs was relatively weak in darkness as well as under background illumination with intensity higher than 3 log units above the rod threshold (**Figure 20**). The coupling between cells increased only under dim background illumination with intensity from one-quarter to 1.5 log units above the rod threshold (215).

Most authors related the changes of electrical coupling between HCs during dark or light adaptation to changes of endogenous dopamine release. According to some, dopamine mimicked the effect of a prolonged period of darkness, but not continuous light background (64, 195, 214), while others suggested that dopamine was responsible for the uncoupling effect of the adapting light (176, 212). The latter suggestion was supported by the fact that the uncoupling effect of both flickering and steady adapting light was blocked by nonselective DR antagonist fluphenazine (212) and selective D_1R antagonist SCH 23390 (176). Some authors argued that dopamine is not the signal of HC adaptation to steady illumination in *teleosts*, because DA depletion or application of DR antagonists did not alter the effect of background illumination upon fish horizontal cell coupling and receptive field size (209, 211). In the case of flickering light adaptation, however, dopamine did seem to be involved, because haloperidol blocked the reduction of HC receptive field size induced by a flickering light (211). In *primate* retina, SCH 23390 only partially blocked the effect of background light on the HC receptive field size, suggesting that other mechanisms, in addition to the dopaminergic system, may be involved in background-induced reduction of HC receptive field size (204).

Dopamine has an additional effect on the horizontal cells that is independent of its action on the electrical coupling between adjacent horizontal cells. It decreased the response of *fish* cone-HCs to full-field stimuli and enhanced glutamate- and kainate-induced currents (64, 143, 159, 194, 195, 199, 216). Thus, dopamine, by enhancing the potency of the photoreceptor transmitter, rendered the light-induced reduction of transmitter release from the photoreceptors less effective, leading to decreased amplitude of the HC response to light. Some authors suggested that dopamine was responsible for the strongly suppressed light responsiveness of cone HCs in prolonged darkness (64, 194, 195, 202).

Yang et al. (202) demonstrated that HCs became highly responsive to illumination in dopamine depleted retinas maintained in prolonged darkness (**Figure 21**). Furthermore, application of DA to dopamine-depleted or light-sensitized retinas strongly suppressed the responsiveness of cone HCs, mimicking the effects of prolonged darkness. The effect was probably mediated by D_1-like receptors, because SCH 23390 (a specific D_1R antagonist), enhanced the responsiveness of cone HCs in prolonged darkness, mimicking the effect of background illumination. It was suggested that DA was released in the dark by the IPCs and enhanced the potency of the photoreceptor transmitter (202, 217). Dowling (217) proposed a hypothesis that dopamine increased cAMP which activated kinases that phosphorylated both glutamate-gated channels and gap-junction channels (**Figure 19**). Destruction of dopaminergic neurons significantly decreased, but not fully eliminated the suppressive effect of prolonged darkness on responsiveness of fish cone HCs in vivo (218). The latter result suggests that a substance or substances other than dopamine may contribute to the dark suppression effect. In *turtle* retina, dopamine reduced the responsiveness of all except L_1-type horizontal cells (160). A reduction of the response amplitude to full field stimuli caused by dopamine was observed in *mammalian* rod-driven HCs (188, 219). The effect was mediated by D_1-like receptors, because it was reversed effectively by the co-application of the D_1R antagonist SCH 23390, but not by the D_2R antagonist L-sulpiride (219) (**Figure 22**). SCH 23390 alone, but not sulpiride, enhanced the responses to full-field light stimuli, revealing an active endogenous DA input to HCs. Because the DA effect on HCs was not seen in preparations with blocked synaptic transmission, Hankins and Ikeda (188) suggested that dopamine action resulted from modulation of the L-glutamate activated currents of these cells. The described two effects of dopamine on horizontal cells – decreasing light responsiveness and shrinking receptive field size – are effective ways to lessen HC influence upon the other retinal neurons. It was suggested (159, 194, 195) that these effects of dopamine may account for the reduced or fully eliminated antagonistic surrounds of ganglion cells with prolonged time in the dark (**Figure 23**). Baldridge (209) proposed that the reduction of HC receptive field size following light adaptation would narrow the receptive filed surround of GCs and therefore permit spatial contrast analysis to be done more locally.

Much data indicate that dopamine effects on the HC light responses depend on the photoreceptor input. Separate horizontal cells in *fishes* receive inputs from cones or rods. It was shown that dopamine had apparent effects on light responses of cone-driven HCs, while contradictory results exist concerning its effects on the light

responses of rod-driven HCs. Some authors found that dopamine effects on the rod-driven HCs were similar to those on cone-driven HCs (196), other authors obtained much smaller effects on rod- than cone-driven HCs, as in *perch* (64, 195, 202) and still other authors found no dopamine effects on the rod-driven HCs in *skate* (208), *dogfish* (220) or *goldfish* (159). In *amphibian* retina, where horizontal cells receive converging synaptic inputs from both rods and cones, dopamine enhanced the amplitude of the cone-mediated component of the HC response, but diminished the amplitude of the rod-mediated one (161, 162, 164, 221). The authors cited suggested that dopamine decreased the gain of the rod-HC synapse and increased the gain of the cone-HC synapse. Dopamine action was probably mediated by postsynaptic D_1-like receptors, because D_1 activation eliminated the rod component of the flash response and caused the HCs to display all the signs characteristic of the photopic state (164). The effect of injecting cAMP was identical to that obtained by the application of the D_1R agonist or by adapting the retina with strong background light. Krizaj (164) concluded that dopamine via D_1R acted as a postsynaptic switch modulating the balance between the rod and cone pathways, and that intracellular cAMP could play an important role in regulating the relative weight of rod and cone information in retinal cells. Other authors argued, however, that the dopamine effect on the rod-cone balance in amphibian HCs was mediated synergistically by both D_1- and D_2-like receptors (162, 221). How dopamine influences the balance between rod and cone inputs to *mammalian* HCs is not well evaluated. Ribelayga and Mangel (170) reported that the blockade of D_2R, but not D_1R during the day increased the absolute and relative light sensitivity of *rabbit* A-type HCs, so that their responses resembled those typically recorded at night. The authors proposed that the retinal circadian clock increased the dopamine levels and D_2R activation in the outer retina during the day, so that rod input (via rod-cone coupling) to A-type HCs was greatly reduced. On the other hand, Pflug et al. (222) found that D_1R agonists depolarized somata of both A- and B-type HCs in rabbit retina and enhanced the overall and flicker amplitudes of their scotopic responses, but almost completely suppressed the cone flicker amplitudes of the photopic responses, without changing the overall response amplitude (222). The authors proposed that the dopamine-induced HC depolarization caused a shift of the cone I_{Ca} activation curve to more positive values and thus reduced the transmission of the most hyperpolarizing cone signal component, i.e. the cone flickering part of the light response. Pflug et al. (222) imply that shifting the operating range of cone synapses to more depolarized levels increases the gain for low amplitude rod signals which enter cones through rod-cone gap junctions but did not elaborate on the mechanism, whether at the rod-cone gap junctions, or at the tuning of the cone synapse itself. More studies are needed to fully understand how the dopamine action upon mammalian HCs depends on the photoreceptor input.

Dopamine may participate in the control of spectral responses of cone luminosity (H_1) and chromaticity (C-type) horizontal cells in *fish* and *turtle* retina. Mangel and Dowling (195) reported that dopamine reduced the responses to long wavelength full-field light stimuli more than the responses to short wavelength stimuli in one third of carp H_1 cells. Contrary to this observation, other authors found that dopamine increased the responses of carp H_1 cells to long wavelengths (223, 224), but had no effect (224) or decreased (223) responses to short wavelengths. In the latter case, dopamine decreased the blue/red response amplitude ratio in a way similar to that induced by red-background adaptation (223). The effect of light adaptation, however, was also recorded in dopamine depleted retinas and in the presence of haloperidol, indicating that dopamine was not responsible for the effect of light adaptation on the spectral response characteristics of H_1 cells. Djamgoz et al. (223) suggested that spectral responses of H_1 cells were controlled independently by light-adaptation (primarily by long wavelengths) and dopamine. The effects of dopamine on C-type HCs are not well understood. No differential spectral response effects of dopamine on C-type HCs were observed in turtle (160) or carp retina (195). In goldfish retina, dopamine increased the hyperpolarizing component evoked with white light, but decreased the depolarizing component evoked with red light in half of C-type HCs, while in the other half it had no effect irrespective of the cell subtype (159). In roach retina, haloperidol increased the hyperpolarizing component (to blue-green light), but decreased the depolarizing component (to red light) of biphasic (green/red) H_2 horizontal cells (225). In addition, haloperidol prevented the enhancement of the depolarizing component induced by light adaptation. Destruction of the DA cells with 6-OHDA also prevented the enhancing effect of red flickering light

on the depolarizing response of R/G HCs in carp retina (226). The effect was probably mediated by D_2R, because application of D_2R, but not D_1R antagonists was similar to that of 6-OHDA. Liu et al. (226) suggested that the activation of D_2R in the OPL might be related to the synaptic plasticity of the GABAergic pathway between HCs and cones, which is responsible for the change in red flickering induced responsiveness in the R/G HCs.

Effects of dopamine on bipolar cells

There are not many studies undertaken to evaluate dopamine action on retinal bipolar cells; however, the effects of DA on the ionic currents (Ca^{2+}, Na^+, K^+), membrane potential, light-evoked responses and responses to other neurotransmitter of retinal BCs have been reported. It was shown that dopamine and D_1R agonist ADTN potentiated the voltage dependent Ca^{2+} currents in presynaptic terminals of all bipolar cells in *fish* retina (227, 228). The effects of dopamine antagonists on the same currents, however, depended on the BC type (ON or OFF) (227). The D_1R antagonist SCH 23390 strongly suppressed Ca^{2+} currents at all stimulus intensities in OFF BCs but in ON BCs, SCH 23390 augmented Ca^{2+} currents at lower stimulus intensities but did not change them at higher intensities. The D_2R antagonist sulpiride had similar effect as SCH 23390 upon the ON BCs, while it enhanced the Ca^{2+} currents at lower stimulus intensities and diminished them at higher intensities in the OFF BCs. The mechanism for the differential effects of dopamine antagonists on the ON and OFF pathways is still not clear. In *amphibian* retina, dopamine had no apparent effect on Ca^{2+} entry into the bipolar terminals, but it blocked the GABAergic inhibition on this entry and thus increased the transmitter release (229). The effect was similar for the ON and OFF BCs. In addition to Ca^{2+} currents, dopamine, via D_1R, modulated the voltage-gated Na^+ currents in amphibian transient ON BCs (230). The dopamine receptor agonist ADTN markedly reduced the Na^+ currents in dim light conditions, while SCH 23390 prevented the depressing effect of light adaptation on these currents. Dopamine modulated also the K^+ currents in retinal BCs. Dopamine acting via D_1R-coupled G-protein pathways decreased the voltage-dependent K^+ currents in ON BCs in *zebrafish* retina (231). In *goldfish* retina, dopamine depressed K^+ currents but only in high concentrations, while in low concentrations it enhanced these currents in mixed rod-cone ON bipolar cells (Mb) (232, 233). Both the enhancement and suppressive effects were blocked by SCH23390, indicating involvement of D_1-like receptors. Fan and Yazulla (233) proposed that D_1R activation should make the ON response of Mb BCs more phasic by enhancing K^+ currents. Depletion of retinal dopamine reduced by about half the amplitude of voltage-dependent K^+ currents in Mb BCs (234).

The actions of dopamine on membrane potential and light-evoked responses of retinal BCs were investigated mainly in fish and amphibian retina. In *fish* retina dopamine produced a hyperpolarization of the membrane potential of cone BCs and rod BCs (159, 220, 235). Dopamine enhanced the center light responses, but it reduced the antagonistic surround responses of both ON and OFF BCs under conditions in which the responses were mediated by cones (159, 235) (**Figure 24**). This effect is consistent with the suppressive action of dopamine on HC responsiveness, because the latter cells are thought to mediate the antagonistic surround of BC receptive field (68). In the all-rod retina of dogfish, dopamine reduced the responses to light flashes of ON RBCs (220) (**Figure 25**). The suppressive effect of dopamine on RBCs was not due to its effect on HCs, because neither the membrane potential nor the light responses of rod HCs were influenced by dopamine. Thus, it appears that dopamine enhanced the responses of fish cone BCs but suppressed the responses of rod BCs.

In *amphibian* retina, where bipolar cells receive mixed rod and cone inputs, dopamine produced variable effects upon the dark membrane potential of OFF BCs, but upmodulated their glutamate-gated currents through D_1R and cAMP-PKA pathway (236). Dopamine caused a significant reduction in the amplitudes of rod-driven responses, while it enhanced the cone-driven responses elicited from the receptive field center (162). It did not change the balance between center and surround of the BC receptive field, when the responses were rod-driven, but it favored the center over surround, when the responses were cone-driven. Opposite results were reported for the action of dopamine on the light responses of cone-driven transient ON BCs in the same species (230). It was

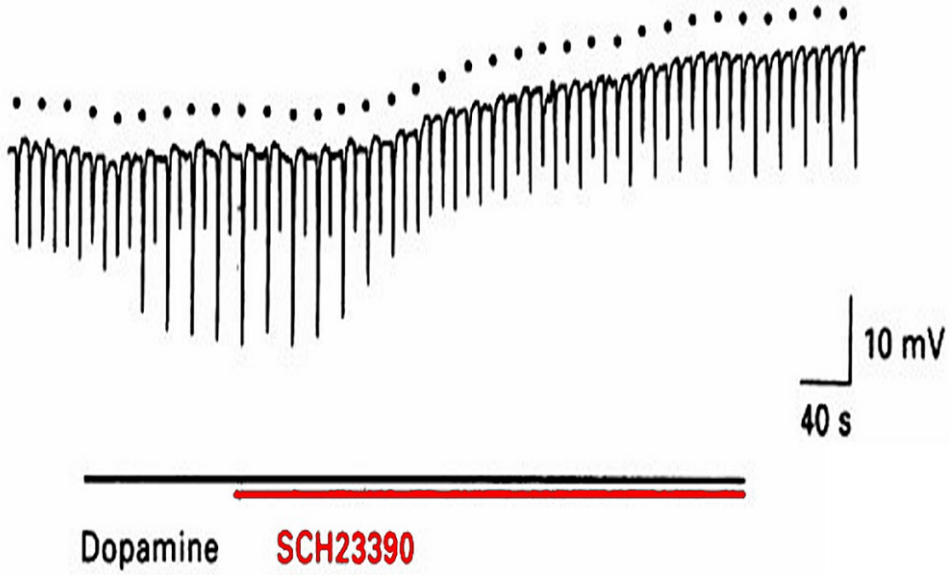

Figure 18. Effect of exogenous dopamine and SCH23390 on horizontal cell responses to center and surround illumination in dark adapted *mudpuppy* retina. Responses to alternating spot (indicated by dots) and annulus stimuli are presented. Dopamine decreases the responses to annular stimuli and increases the responses to spot stimuli. SCH23390 blocks the effect of exogenous dopamine. From Dong and McReynolds (176).

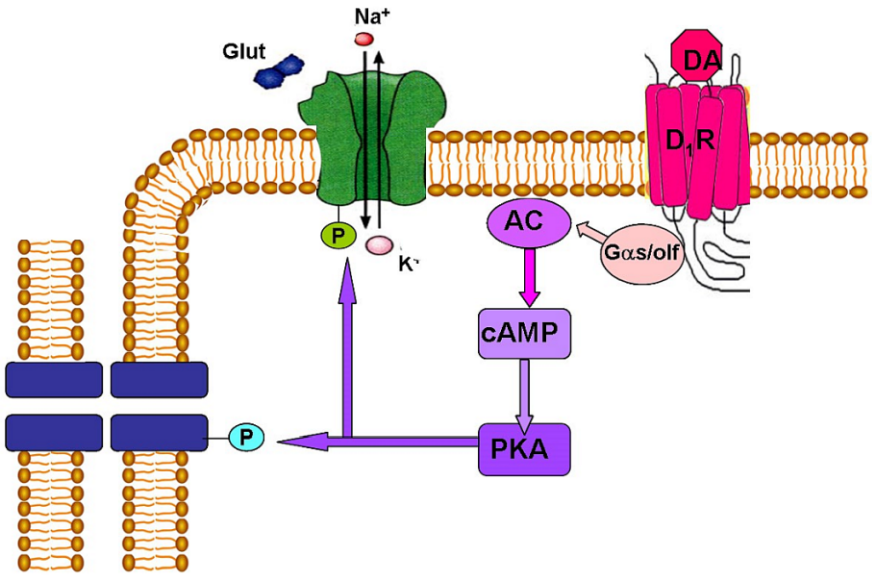

Figure 19. Scheme showing the effects of dopamine (**DA**), acting via D_1-like receptors (**D_1R**), on the fish horizontal cells. Dopamine via **cAMP**-**PKA** pathway causes phosphorylation (**P**) of the gap-junction channels and glutamate (**Glut**) channels and thus reduces the electrical coupling between horizontal cells but increases their responsiveness to L-glutamate (the photoreceptor transmitter). Modified from Dowling (217).

shown that D_1 agonist SKF38393 reduced the L-EPSPs in dim light conditions and thus mimicked the effect of bright light. On the other hand, D_1 antagonist SCH23390 blocked the suppressive effect of bright light on L-EPSPs. The effect was seen in transient, but not sustained ON BCs. The authors concluded that dopamine released in bright light, attenuated the sodium channel-dependent amplification of L-EPSPs in transient cone-driven ON BCs and thus prevented response saturation. It remains to be determined if the opposite, depressing effects of D_1R activation on the cone-mediated responses of ON BCs (230) and enhancing effects on OFF BCs (162) are species specific or they represent general ON/OFF asymmetry in dopamine action on BCs. The effects

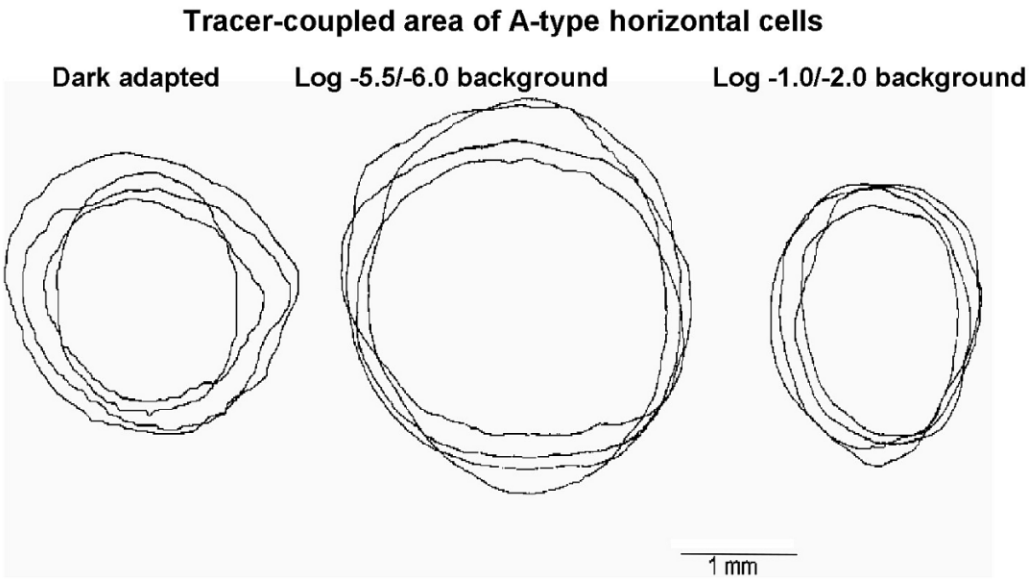

Figure 20. Tracer-coupling area of A-type horizontal cells in different conditions of light adaptation in *rabbit* retina. Each drawing outlines the area occupied by a group of tracer-coupled A-type cells. Four outlines, representing four different Neurobiotin injections, are shown for each level of adaptation. For dark-adapted cells, each outline represents the largest tracer-coupled group in each quartile of 12 total cells. From Xin and Bloomfield (215).

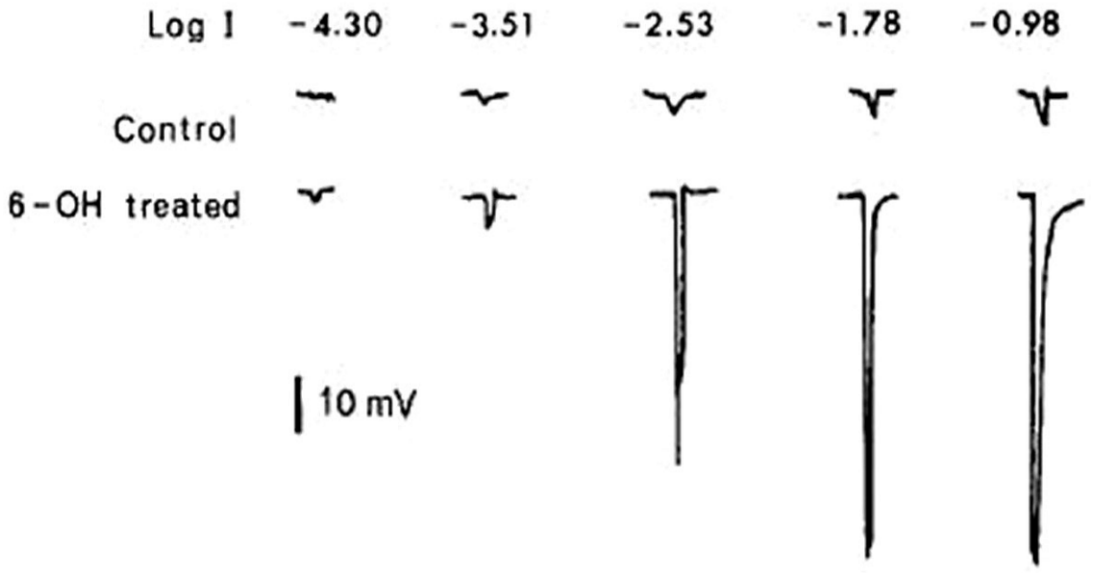

Figure 21. Responses of L-type cone horizontal cells to full-field white flashes recorded in an untreated *white perch* retina (upper row) and in a 6-OHDA-treated retina (lower row) maintained in prolonged (> 2 hr) darkness. The responses recorded from the 6-OHDA-treated retina were much larger in size and had faster-rising phases and on-transients. Intensities of the light flashes, indicated above the response traces, are in relative log units. Form Yang et al. (202).

of dopamine on the *mammalian* bipolar cells are largely unknown. It was shown that dopamine induced changes of receptive field organization of *rabbit* ON-CBCs in the dark similar to those observed during light adaptation (237). During dopamine treatment, the ON-CBCs exhibited center and surround responses similar to those of bright-light-adapted ON-CBCs in intact retinal preparations. The dopamine effect was probably mediated by D_1-like receptors, because the surround responses were not observed during D_1R blockade but were preserved during D_2R blockade.

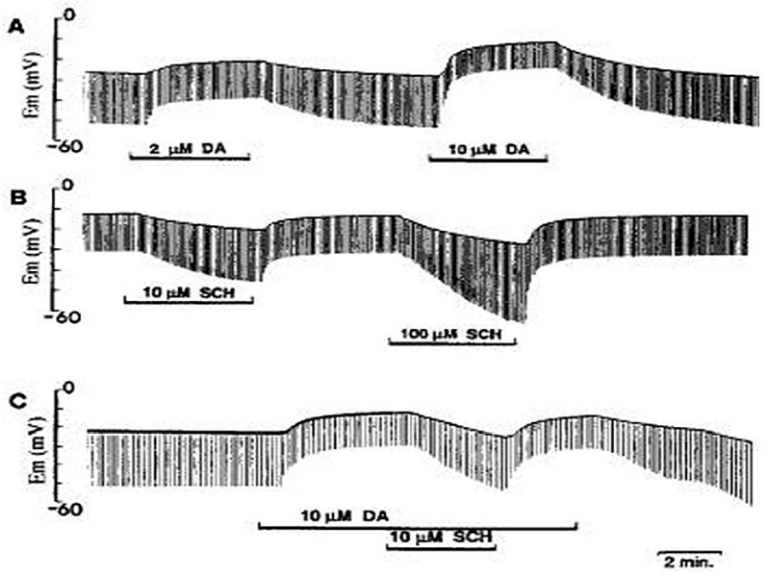

Figure 22. Effects of dopamine and SCH23390 on the membrane potential and the light-evoked S-potentials of rod-driven (A-type) horizontal cells in *rat* retina. **(A)** Dopamine (2 and 10 µM) evokes a dose-related depolarization associated with a significant reduction in the full-field light response. **(B)** SCH23390 (SCH; 10 and 100 µM) evokes a dose-dependent hyperpolarization accompanied by a significant enhancement of the full-field light response. **(C)** The effects of exogenous dopamine (10 µM) on the membrane potential and light responses of HCs are effectively reversed by the co-application of 10 µM SCH 23390. From Djamgoz et al. (219).

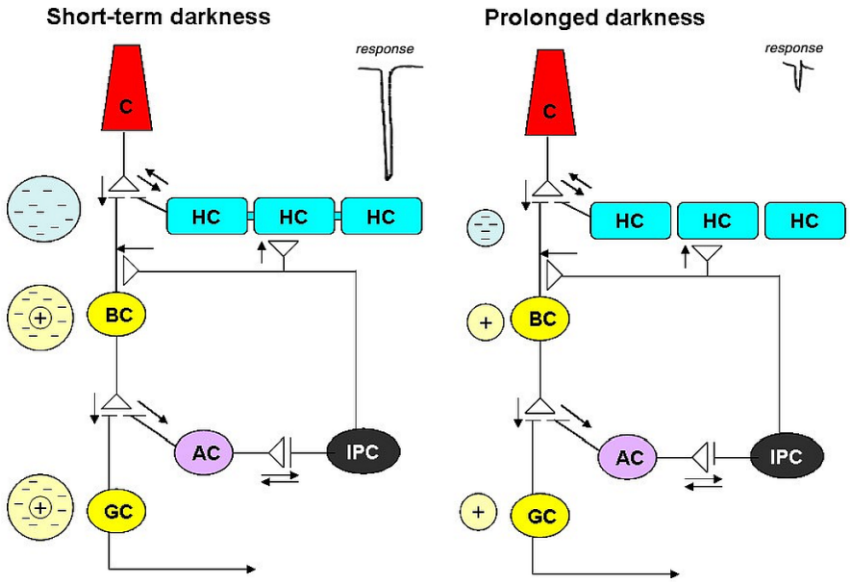

Figure 23. Changes of coupling between cone horizontal cells (**HC**) and receptive field profiles of HCs, bipolar cells (**BC**) and ganglion cells (**GC**) in short-term darkness and prolonged darkness in fish retina. Dopamine, released by interplexiform cells (**IPC**) in prolonged darkness, decreases the responsiveness of HCs to light and uncouples HCs (depicted here as disconnected cells) thus leading to reduction of the size of HC receptive fields. These effects of dopamine lead to reduction of antagonistic receptive field surrounds of BCs and GCs in prolonged darkness. Plus symbols (+) refer to receptive field centers of BCs and GCs, while dashes (-) refer to the receptive field of HCs and to the receptive field surrounds of BCs and GCs. Modified from Mangel and Dowling (195).

Dopamine may modulate the responses of bipolar cells to other neurotransmitters such as glutamate and GABA. Dopamine enhanced the response to glutamate in *amphibian* OFF BCs (236). The effect was mediated by D_1-like receptors, because it was blocked by D_1R antagonist SCH 23390, but not the D_2R antagonist spiperone. Activation of D_1 receptors in the dendrites of bipolar cells led to stimulation of Adenyl cyclase, which through

cAMP and PKA enhanced a glutamate-gated current in BC dendrites. Dopamine plays a very important role in modulating the GABAergic inhibition onto BCs as a part of the light adaptation process. It was shown that activation of D_1R significantly decreased the frequency and amplitude of spontaneous inhibitory postsynaptic currents (S-IPSCs) and the amplitudes of light-evoked inhibitory postsynaptic currents (L-IPSCs) evoked by full-field stimuli in dark adapted *mouse* rod BCs, the effect being similar to light adaptation (238, 239). Flood et al. (238) showed also that D_1R activation directly diminished the inhibitory output of non-reciprocal ACs onto rod BCs, in the absence of serial inhibition. They proposed the following model for the inhibition of rod BCs under dark adapted conditions and D_1R activation. In dim light, rod BCs receive reciprocal inhibition from A17 amacrine cells and lateral inhibition from wide-field GABAergic ACs, as well as narrow-field glycinergic ACs. When light stimuli of sufficient size are used, the strength of lateral inhibition to rod BCs is diminished by serial inhibition. When D_1Rs are activated, the inhibition to rod BCs is greatly decreased, because the strength of serial inhibition is increased and the GABA release by ACs that mediate lateral inhibition is decreased (**Figure 26**).

However, unlike light adaptation, D_1R activation did not shorten L-IPSC decays in rod BCs and its effect on the amplitude of L-IPSCs was smaller than that of light adaptation, indicating that some D_1R independent component also played a role in the modulation of rod BC inhibition with light adaptation (238). Dopamine modulated also the GABAergic inhibition on the cone BCs. It was recently shown that bright-light-induced activation of D_1Rs located on the ON CBC dendrites in *rabbit* retina increased the expression and activity of $GABA_A$ receptors on the dendrites of the cell (237). Endogenous activation of these receptors participated in the generation of the surround light responses of CBCs, which were diminished in maintained darkness and during D_1R blockade (with SCH 23390). Dopamine via D_1R modulated also the local glycinergic, but not GABAergic inhibition to *mouse* OFF cone bipolar cells (239). D_1R activation significantly decreased the frequency and amplitude of S-IPSCs and L-IPSCs in OFF CBCs, evoked by local light stimuli in the dark (238, 239). The effect of D_1R activation on the glycinergic L-IPSCs was similar, but not identical to the effect of light adaptation. D_1R activation had no significant effect on the time course of the glycinergic L-IPSCs, while those currents become more transient with light adaptation. Mazade et al. (239) concluded that D_1 receptors were not the only neuromodulator influencing light adapted changes in local inhibition of OFF BCs.

The overall activity of BCs in living animals could be monitored by recording the electroretinogram (ERG), because the b-wave (in response to stimulus onset) and the d-wave (in response to stimulus offset) are thought to depend mainly on the activity of ON and OFF bipolar cells, respectively, as reviewed by Frishman (240), see also Webvision: The Electroretinogram. Thus, the significance of dopaminergic neurotransmission for bipolar cell function could be investigated by exploring the effects of dopamine and DR agonists and antagonists on the ERG b- and d-waves.

Effects of dopamine on the diffuse electroretinogram

The ERG b-wave amplitude displayed a *circadian rhythm* in constant conditions in *fishes* (241), *birds* (76, 242-244), *reptiles* (245, 246), and *mammals*: *rabbit* (247, 248), *mouse* (249-252). Generally, the b-wave amplitude was highest during the subjective day and lowest during the subjective night. In dopamine depleted nonmammalian animals, no circadian rhythm of the b-wave amplitude was seen (**Figure 27**), indicating that retinal endogenous dopaminergic system is essential for the circadian rhythm of the b-wave amplitude as seen in *zebrafish* (241), *iguana* (74) and *quail* (76). The circadian rhythm was markedly changed during D_2R, but not D_1R manipulation in *quail*, indicating involvement of D_2R mechanisms in its generation. Li and Dowling (241) found, however, that not all circadian effects were absent in dopamine-depleted *fishes*. In the latter animals, an ERG OFF-response was observed at subjective dusk, but not at subjective dawn, as also found in the control fishes (**Figure 27**). In *mice*, the cone-, but not rod-mediated ERG was under circadian control (249-251, 253). The role played by endogenous dopamine in this control is an object of debate. Sengupta et al. (251) observed that the circadian regulation in the photopic ERG was absent in *mice* lacking melatonin receptor type 1,

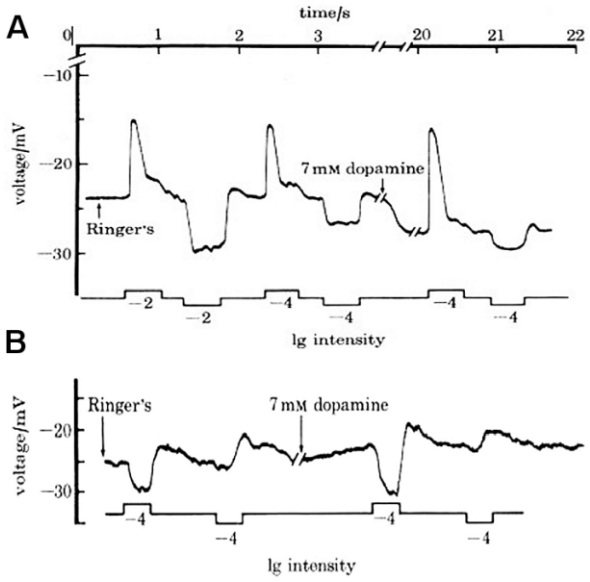

Figure 24. Responses of *goldfish* cone-driven bipolar cells to dopamine. Responses of an ON bipolar cell **(A)** and an OFF BC **(B)** obtained with alternately flashed spots (raised bars) and annuli (lowered bars) are presented during the control period (Ringer) and during treatment with dopamine. The intensities are given on the figure. Dopamine evoked an enhanced central response and a depressed surround response in both cells. From Hedden and Dowling (159).

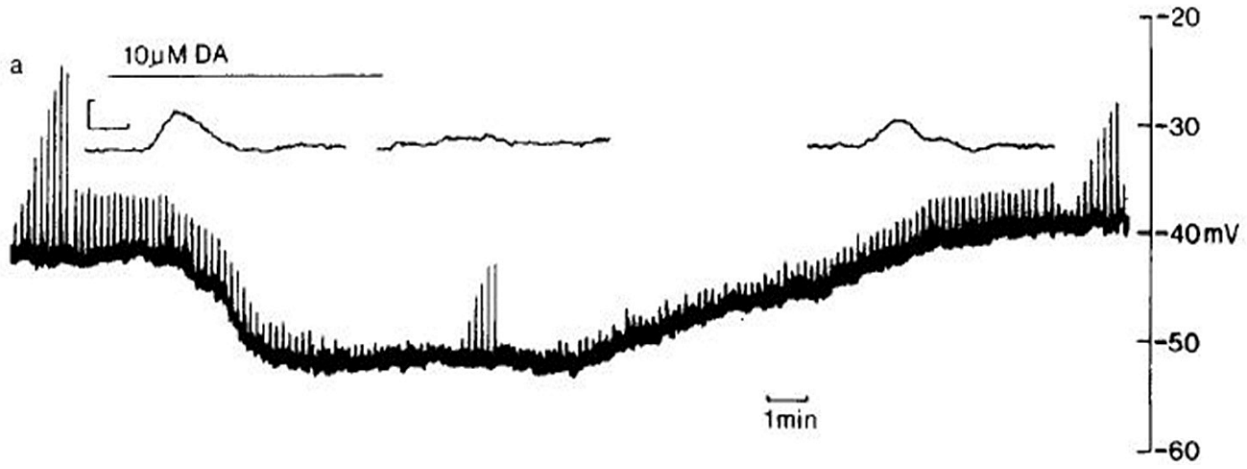

Figure 25. Effect of dopamine (**DA**) on the membrane potential and response to light of a rod ON bipolar cell in *dogfish* retina. Test flashes of constant low intensity and of 15-ms duration were applied every l0 s. At intervals, the cell's light intensity-response relation (which appears as a decreasing, then increasing staircase of responses) was determined by changing the light intensity by factors of approximately 2. 10 μM **DA** was applied for the duration indicated by the bar. Above the continuous trace are shown single responses on an expanded timescale, corresponding to the test responses following the intensity-response determinations. Bars = 5 mV, 200 ms. From Shiells and Falk (220).

although the circadian regulation of dopamine turnover was preserved. These results led to the suggestion that the circadian regulation of dopamine turnover did not drive the mouse cone-mediated ERG rhythm. Jackson et al. (253) reported, however, that the circadian rhythm of the light-adapted b-wave amplitude was lost in mice lacking retinal dopamine (with disrupted tyrosine hydroxylase), indicating that endogenous dopamine was essential for the circadian rhythm of the mouse ERG. This action of dopamine was probably mediated by D_4 receptors, because the circadian rhythm was abolished in D_4R-KO mice, but not in D_1R-KO mice. However, D_4Rs did not maintain circadian rhythm at DD1 (18–30 h in dark), since a substantial b-wave decrease was observed at midnight relative to midday in D_4R-KO mice. Smith et al. (254) presented evidence that the robust

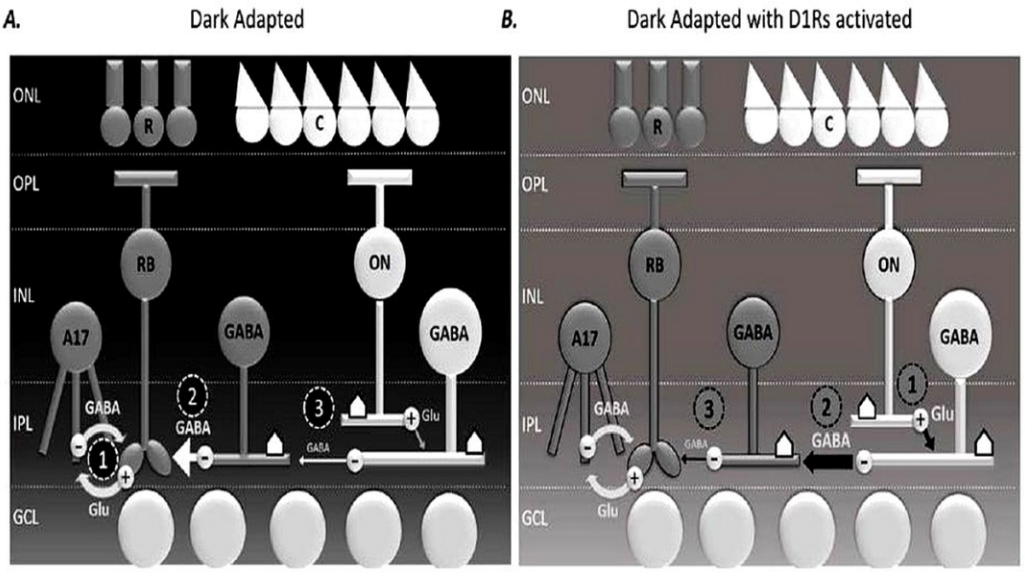

Figure 26. Sources of inhibition to rod bipolar cells under dark-adapted conditions and upon D_1 receptor activation in *mouse* retina. **(*A*)**. In darkness, rod BCs (**RB**) receive reciprocal inhibition from A17 amacrine cells, '**1**' and lateral inhibition from wide-field GABAergic amacrine cells '**2**'. When light stimuli of sufficient size are used, the strength of lateral inhibition to rod BCs is diminished by serial inhibition '**3**'. **(*B*).** When D_1Rs are activated, the strength of serial inhibition is increased '**2**' and the GABA release by amacrine cells that mediate lateral inhibition is decreased and becomes independent of serial inhibitory influences '**3**'. These effects lead to diminished inhibition upon rod BCs. From Flood et al. (238).

circadian rhythm seen after 6–18 h in dark (DD1) was controlled predominantly by D_1R and Na_V channels. They proposed that circadian modulation of cone pathway function in mice involved an early mechanism based on D_1Rs and Nav channels on ON-CBCs that acted in the short-term time scale (DD1, 6–18 h) and a longer-term modulation taken over by a mechanism based on D_4Rs affecting persistent circadian rhythms after 42 h (DD2). Melanopsin-containing retinal ganglion cells probably are also involved in the circadian regulation of mouse cone-mediated b-wave, because genetic ablation of melanopsin blunted the circadian rhythm of b-wave amplitude and speed (249). Barnard et al. (249) suggested that melanopsin-containing retinal ganglion cells could influence dopaminergic amacrine cells via gap junctions and thus entrain a local retinal clock in inner retina.

There is no consensus among the authors about the role played by the dopaminergic system for the *non-circadian* regulation of ERG b-wave amplitude in *nonmammalian* retinas. In *fish* retina, some authors observed no apparent changes of the b-wave amplitude during blockade of retinal dopaminergic transmission in either dark or light adapted eyes (241, 255, 256), while other authors reported that the D_1R agonist SKF 38393 as well as exogenous dopamine increased, while D_1R antagonist SCH 23390 either decreased the cone-mediated b-wave amplitude (257), or led to a separation of the signal into transient peaks, emphasizing those components, and sharpening the peaks (258). Manipulation of D_2R had opposite effects to those described for the manipulation of D_1R (257, 258) (**Figure 28**). The conflicting results obtained in fish retina may be due in part to differences in light stimulation used by the authors. While Kim and Jung (257) used a small spot light, other authors (241, 255, 256) used full field light stimuli. This suggestion is supported by the fact that meclofenamic acid (a non-specific gap junction blocker), which had similar action to that of dopamine on the fish ERG, had 5 times greater effect on the b-wave obtained with small spot than large spot (257).

In *amphibian* retina, a reduction of the suprathreshold b- and d-wave amplitudes was reported during blockade of the dopaminergic transmission (259-261). The isolated blockade of D_1R with SCH 23390 and D_2R with sulpiride had differential effects on the ERG waves depending on photoreceptor input (262-264). Both blockers enhanced the rod-mediated suprathreshold b- and d-waves, while the action on the cone-mediated responses

was in an opposite direction. The D_1R blocker enhanced the amplitude of the cone-dominated b- and d-waves, while D_2R blocker diminished them (**Figure 29**). These results suggested that activation of D_1R by endogenous dopamine inhibited frog ERG ON and OFF responses, which was opposite to its action on fish photopic ON response (257). The inhibitory effect of endogenous dopamine on the frog b- and d-wave amplitudes may be due to D_1R-induced GABA release, because this effect was prevented during ionotropic GABA receptor blockade (265).

In *chicken* retina, exogenous dopamine had no effect (266) or it had diverse effects on the b- and d-wave amplitudes depending on light stimulation conditions (267). The blockade of dopaminergic transmission (with haloperidol) caused a reduction of the b-wave amplitude at all stimulus intensities, indicating that endogenous dopamine had an enhancing effect on the chicken ERG ON response recorded under conditions of dim ambient illumination (268). In *quail*, the b-wave amplitude was reduced by the D_2R agonist quinpirole injected during the subjective night and increased by D_2R antagonist eticlopride injected during the subjective day, while manipulation of D_1R had no effect (76). These results suggest that endogenous dopamine via D_2R decreased the b-wave amplitude during the day in quail. In *iguana*, the manipulation of D_1R had no effect on the dark-adapted b-wave, while D_2R manipulation had opposite effects to those observed in quail (74). Quinpirole increased the amplitude of the b-wave, when it was injected during the subjective night and eticlopride reduced the b-wave amplitude, when it is injected during the subjective day. Miranda-Anaya et al. (74) suggested that endogenous dopamine increased the b-wave amplitude during the subjective day directly via D_2R and indirectly by inhibiting melatonin synthesis. Because the phases of the rhythm of dopamine synthesis were similar in quail and iguana (74, 76), whereas the phase of the rhythm of b-wave amplitude and the effect of quinpirole and eticlopride were opposite, it seemed likely that dopamine exerted its effects on the ERGs of the two species by different mechanisms.

The dopaminergic modulation of *mammalian ERG* was investigated in many studies. Most of the authors reported that application of exogenous dopamine, its nonselective agonist apomorphine and the dopamine uptake blocker nomifensine decreased the amplitude of the b-wave as seen in *rabbit* (269-274) and *cat* (275, 276).The blockade of dopaminergic transmission, on the other hand, caused an increase of the suprathreshold b-wave amplitude as seen in *cat* (275, 277, 278), *rabbit* (272, 279) and *monkey* (280) without altering the dark adapted threshold ERG (275). The b-wave *V - log I* curve was shifted to the left along the intensity axis, indicating an increased relative sensitivity of the response during dopaminergic blockade (277). The effects of dopaminergic manipulation were maximal under scotopic conditions but were also seen in mesopic and photopic conditions (270, 278) (**Figure 30 A**).

All these results suggested that endogenous dopamine had a general suppressive influence on retinal ON channel activity in rabbits, cats and monkeys and that this influence did not depend critically on conditions of light adaptation. The DA receptors involved in this suppressive action appear to differ among species. In *cats*, the inhibitory effect of endogenous dopamine on the ERG b-wave was probably mediated through D_2-like receptors, because sulpiride, similar to 6-OHDA, caused an increase of the scotopic b-wave amplitude (277, 278) (**Figure 30 B**). In contrast to cats, in *rabbits* the inhibitory action of exogenous dopamine and apomorphine upon the b-wave amplitude was probably mediated by D_1-like receptors, because D_1R agonists (SKF38393, A77636), but not a D_2R agonist (NPA) decreased the b-wave amplitude in all conditions of illumination (281) (**Figure 30 C**). Contrary to these species, in *patients with Parkinson's disease*, who had lower than normal retinal dopamine concentration, a reduction of both the scotopic and photopic b-wave amplitude was reported (282-284). Treatment with L-DOPA in these patients increased the amplitude of the scotopic and photopic b-wave (285), while treatment with L-DOPA in healthy humans increased the scotopic, but not the photopic b-wave amplitude (286-288). It appears that endogenous dopamine has an overall stimulating action on the ON-BC activity (reflected in ERG b-wave) in human retina opposite to its suppressive action in monkey, rabbit and cat retina. What types of dopamine receptors mediate this stimulating action in human retina is not determined yet.

Similar to humans, a decrease of the b-wave amplitude was reported in *mouse* retina when dopaminergic transmission was compromised (253, 289, 290). This effect probably involved D_1R, because SCH 23390 also diminished the b-wave amplitude (291). The action of SCH 23390 on the rod-mediated b-wave amplitude resembled the ERG phenotype of the D_1R knockout mouse. In both cases a substantial reduction in dark sensitivity and compression of the operational range of the b-wave was observed. The authors reported that similar changes were seen when retinal $GABA_CR$, but not $GABA_AR$ signaling was prevented. In addition, Herrmann et al. (291) demonstrated that the lack of D_1R-mediated signaling could be completely masked by exogenous GABA, consistent with a role for D_1R in modulating a $GABA_CR$ input onto rod-driven ON BC (**Figure 31**).They proposed that dopamine via D_1R caused a release of GABA (possibly by HCs), which acted on $GABA_CR$ on rod BCs and thus increased their sensitivity and operational range. Travis et al. (141) eliminated the horizontal cells as a potential source of GABA release in this mechanism, because rod BC sensitivity was unaffected by horizontal cell-specific knockouts of either D_1R or VGAT. The wide-field amacrine cells, whose activity is regulated by $GABA_AR$-dependent serial inhibition, probably had an important role in GABA-induced rod BC sensitization (141, 292). Smith et al. (292) demonstrated that blocking of D_1R did not suppress rod-driven ON-BC sensitivity when $GABA_A$-mediated serial inhibition was blocked by gabazine, suggesting that the reduction in rod-driven BC sensitivity in the absence of D_1R receptors was due to disinhibition of serial inhibitory GABAergic circuitry rather than a direct facilitatory effect on GABA release, as proposed by Herrmann et al. (291). Smith et al. (292) suggested that D_1Rs may be expressed in all wide-field amacrine cells in this circuit, while Travis et al. (141) concluded that D_1R-mediated regulation took place at the secondary GABAergic cell, responsible for the serial inhibition of the primary cell (**Figure 32**). This suggestion is supported by the fact that neither D_1R full agonist SKF81297 not D_1R antagonist SKF83566 changed the rod bipolar cell sensitivity when serial inhibition was blocked. Regardless of the exact mechanism of D_1R-mediated action, it is clear that endogenous dopamine acting via D_1-like receptors caused a sensitization of mouse rod BCs. Confirming this, a reduction of the b-wave amplitude was obtained by other authors working with D_1R knockout mice (253, 293, 294). Lavoie et al. (294) reported that the b-wave amplitude decreased over the entire intensity range in scotopic and photopic conditions, while He et al. (293) observed reduced b-wave amplitude only for some stimulus intensities mostly towards the higher light intensities. All cited results obtained in mouse retina indicate that activation of D_1R by endogenous dopamine has an enhancing effect on the ERG b-wave amplitude in both scotopic and photopic conditions.

Smith et al. (254) reported, however, that the D_1R agonist SKF38393 reduced the mouse photopic b-wave amplitude at all stimulus intensities during daytime (**Figure 33 A**). They presented evidence that this suppressive effect was due to a direct inhibition of Na_v channels in ON-cone BCs. The D_1R antagonist SKF83566 increased the light-adapted b-wave amplitude during circadian midnight, but surprisingly it reduced the light-adapted b-wave amplitude during circadian midday (**Figure 33 B**). The authors proposed that at night, dopamine released during light adaptation was able to strongly suppress Nav channels via D_1R, while at midday the light adaptation was unable to cause enough dopamine release to strongly suppress Na_v channels on the ON-cone BCs. The D_2-like receptors appeared to have a smaller role in dopamine actions on *mouse* ERG than D_1-like receptors. In D_2R knockout mice no significant changes of the b-wave amplitude were observed in either scotopic or photopic conditions (291, 294). The b-wave amplitude was decreased, however, in D_4R-KO mice in the first 10 minutes of dark adaptation after turning off a rod desensitizing ganzfeld background (151). Nir et al. (151) suggested that both rod and cone photoreceptors of the D_4R-KO mouse had limited capacity to adapt to prolonged bright light exposure, although dopamine did not appreciably impact the phototransduction response to a flash stimulus. A decrease of the b-wave amplitude was obtained under photopic conditions of illumination, but not in the dark in D_4R knockout mice (151, 253). Because the effect was similar to that obtained in D_1R-KO *mice*, Jackson et al. (253) concluded that "both D_1 and D_4 receptors act to increase the amplitude of the light adapted ERG b-wave, with D_4 receptors acting through circadian regulation of the ERG and D_1 receptors acting on baseline amplitude in a non-circadian manner". Thus, it appears that dopamine receptors belonging to the two main classes (D_1 and

D_2) may have similar action on *mouse* cone-mediated b-wave amplitude (253), but opposite action on cone-mediated b-wave amplitude in *fishes* (257, 258) and *frogs* (262, 264).

Effect of dopamine on amacrine cells

One of the most studied effects of dopamine on the amacrine cell network was the effect it had on the electrical coupling of AII ACs, which are critical elements in the primary rod pathway of the *mammalian* retina (see Webvision chapter on AII Amacrine Cells, see also Webvision chapter Myriad roles for gap junctions in retinal circuits). It is well known that these cells receive excitatory input from ON-rod BCs (RBC) and they in turn form sign-conserving electrical synapses with the axon terminals of ON-cone BCs (CBC), and sign-inverting glycinergic chemical synapses with the axon terminals of OFF-CBCs (see chapter on AII ACs in Webvision). AII amacrine cells form homotypic gap junctions with neighboring AII amacrine cells, involving connexin 36 (Cx36) as seen in *rat* (295), *rabbit* (296) and *mouse* (297-299). Exogenous dopamine reduced the tracer coupling between adjacent AII amacrine cells in *rabbit* (300-302) (see Webvision chapter on AII ACs). The effect was mediated through activation of D_1R, because it was mimicked by the specific D_1R agonist SKF38393 and blocked by selective D_1R antagonist SCH23390, an action seen in both *rabbit* (300, 303) and *mouse* (142). The dopamine antagonist SCH 23390, on its own, in low concentration (10 μM) did not increase significantly the extent of tracer coupling (142, 299, 300), while in higher concentration (100 μM) it increased the coupling (303). The exact mechanism underlying the D_1R mediated uncoupling of AII ACs is a matter of debate. Some authors (299-302) suggested that uncoupling of gap junctions involved phosphorylation via protein kinase A of Cx36. Other authors, however, presented evidence that D_1R-driven uncoupling of the AII network resulted from protein kinase A activation of protein phosphatase 2A and subsequent dephosphorylation of Cx36 (303). The AII amacrine cells undergo well-known and prominent changes in electrical coupling driven by light adaptation that contribute to rewiring retinal circuitry from rod-pathway-dominated during dim light conditions to cone-pathway-dominated during bright light conditions. In *rabbit* retina, changes in light adaptation affected the coupling between AII amacrine cells in a triphasic manner (215, 304). Dark-adapted AII cells were coupled in relatively small groups and showed relatively small receptive fields. Exposure to dim background light increased both parameters approximately sevenfold allowing for summation of coincident signals and improved signal to noise ratio. Further light adaptation brought about a decrease in coupling to levels similar to those seen in dark-adapted retinas, which may act to prevent contamination of cone photoreceptor signals in cone bipolar cells by saturated rod signals in AII amacrine cells (See Webvision chapter on AII ACs). It is apparent that modulation of gap junctions between AII ACs is of physiological importance since it regulates the balance between sensitivity and spatial resolution in adjustment to the ambient light. Dopamine signaling alone cannot account, however, for the described 'inverted U' shaped AII coupling-background light relationship, because dopamine release increased steadily with increasing background illumination (54). It was shown that activation of extrasynaptic NMDA receptors on AII ACs led to increased phosphorylation of Cx36 and increased coupling between ACs (305). Kothmann et al. (305) proposed that the glutamate released from some rod BCs under scotopic conditions would depolarize AII ACs via postsynaptic AMPA receptors and would drive opening of nonsynaptic NMDA receptors on depolarized AII dendrites, thus leading to increased local coupling between ACs. The coupling between ACs would increase with increased background illumination in the scotopic range, because the latter would stimulate more strongly a larger pool of rod BCs. This glutamate-driven increase in Cx36 phosphorylation and AII coupling is opposed by dopamine-driven decrease in Cx36 phosphorylation via D_1R (305). Retinal dopamine secretion would be increased by bright light adaptation and it would be sufficient to overwhelm the pathway favoring increased Cx36 phosphorylation (**Figure 34**). This push-pull organization would result in the 'U-shaped' relationship between AII coupling and background illumination.

Modulation of the heterocellular gap junctions between AII amacrine cells and ON-cone bipolar cells by dopamine and cAMP is a matter of debate. In older studies it was reported that AII/CBC coupling, in contrast to AII/AII coupling, was modulated by NO through increases in cGMP concentration, but not by dopamine and

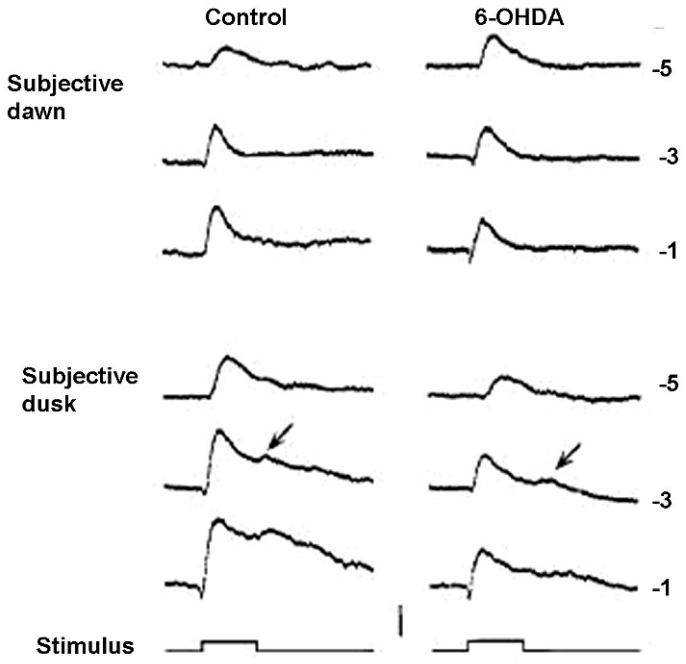

Figure 27. Electroretinograms recorded from a control and a DA depleted (6-OHDA) *zebrafish* at subjective dawn and dusk in animals kept in constant darkness. It is seen that the ERG b-wave amplitudes generated at all light intensities were reduced at subjective dawn as compared with those generated at subjective dusk in the control animal, while the b-wave amplitudes were similar when determined at subjective dusk and dawn in a DA depleted animal. Note at subjective dusk, both ON and OFF responses were recorded in both the control and DA-depleted fish, while no OFF responses were evident at subjective dawn in either fish. OFF responses are indicated by *arrows*. Stimuli, 500 msec. Calibration, 100 mV. From Li and Dowling (241).

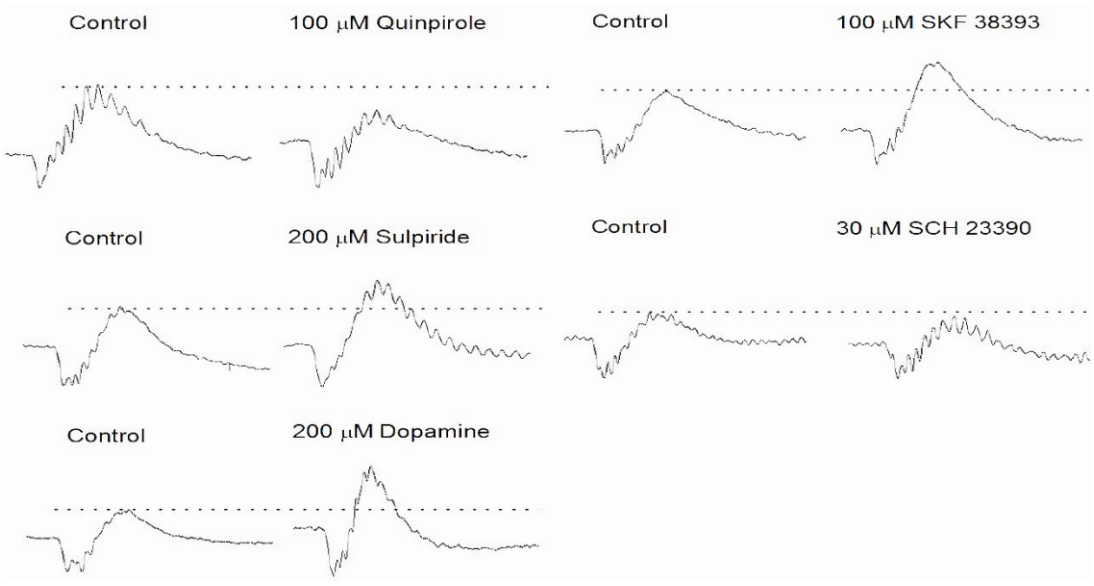

Figure 28. Effects of dopamine, D_1R agonist (SKF38393), D_1R antagonist (SCH23390), D_2R agonist (quinpirole) and D_2R antagonist (sulpiride) on the ERG b-waves in light adapted *goldfish*. Dopamine and the D_1R agonist increased, while The D_2R agonist decreased the b-wave amplitude. Antagonists had opposite effects of those seen during agonist treatment. Dotted lines indicate the peak amplitudes of control b-waves. From Kim and Jung (257).

cAMP (300, 301). In more recent studies evidence was presented that the AII/ON-CBC coupling was reduced by dopamine, D_1R agonists and intracellular cAMP, and enhanced by D_1R antagonist SCH23390 and thus resembled modulation of AII/AII coupling, as seen in both *mouse* (142, 299) and *rabbit* (302). Xia and Mills

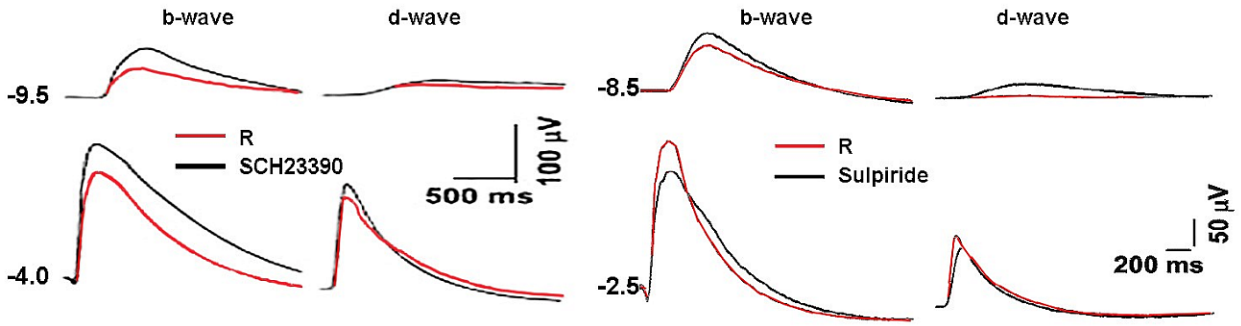

Figure 29. Effects of D_1R antagonist SCH23390 and D_2R antagonist sulpiride on the ERG b- and d-waves in dark adapted *frog* eyecups. ERGs were recorded with two different stimulus intensities (indicated on the left) during the control period (R – red lines) and during antagonist treatment (black lines). Both antagonists increased the b- and d-wave amplitude at lower stimulus intensity, while SCH23390 increased, but sulpiride decreased the b- and d-wave amplitude at higher intensity. Adapted from Popova and Kupenova (264).

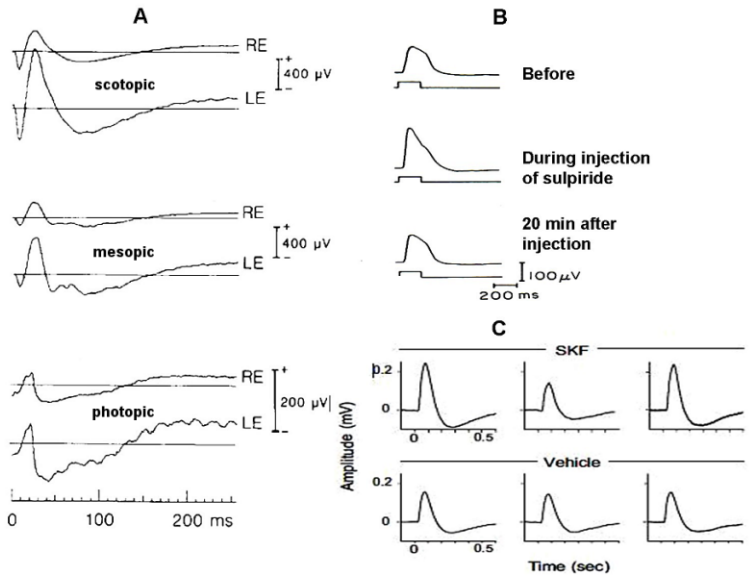

Figure 30. **(A)** Original ERGs recorded simultaneously from the right (RE) and left eye (LE) of *cats* were elicited by 20 flashes of intensity $9.3x10^4$ cd/m^2. The left eye was injected with 20 µg 6-OHDA 23 hours previously while the right eye was injected with saline. The larger ERG amplitudes were recorded from the 6-OHDA-injected left eye. The effect was most pronounced in the scotopic conditions. From Skrandies and Wässle (278). **(B)** Effect of D_2R antagonist sulpiride of the b-wave in dark adapted *cat*. Sulpiride caused a reversible b-wave amplitude increase. From Schneider and Zrenner (277). **(C)** Effect of D_1R agonist SKF38393 on the *rabbit* scotopic b-wave. SKF38393 caused a reversible reduction of about 30% of the b-wave amplitude. Injection of sterile water (vehicle) in the contralateral eye failed to modify the ERG waveform (bottom traces). From Huppé-Gourgues et al. (281).

(302) showed, however, that dopamine reduced the AII/AII coupling more than AII/ON-CBC coupling, while cAMP affected them equally. The authors proposed that cAMP modulated gating in both hemichannels, while dopamine modulated gating on only the AII side of the channel, because dopamine-induced cAMP elevations normally occurred on only the AII side (**Figure 35**).

Nitric oxide, on the other hand, modulated the AII/ON-CBC hemichannel, but not AII/AII hemichannel and it acted independently of dopamine. Xia and Mills (302) suggested that the functional role of dopamine is to reduce both the scotopic flow via the AII pathway into cone pathway as well as the photopic flow from ON-CBCs into AII ACs, when light level (and dopamine) increases. Further reduction might occur with independent rises in cGMP in ON cone BCs possibly arising from nearby nitric oxide generators. There is no evidence,

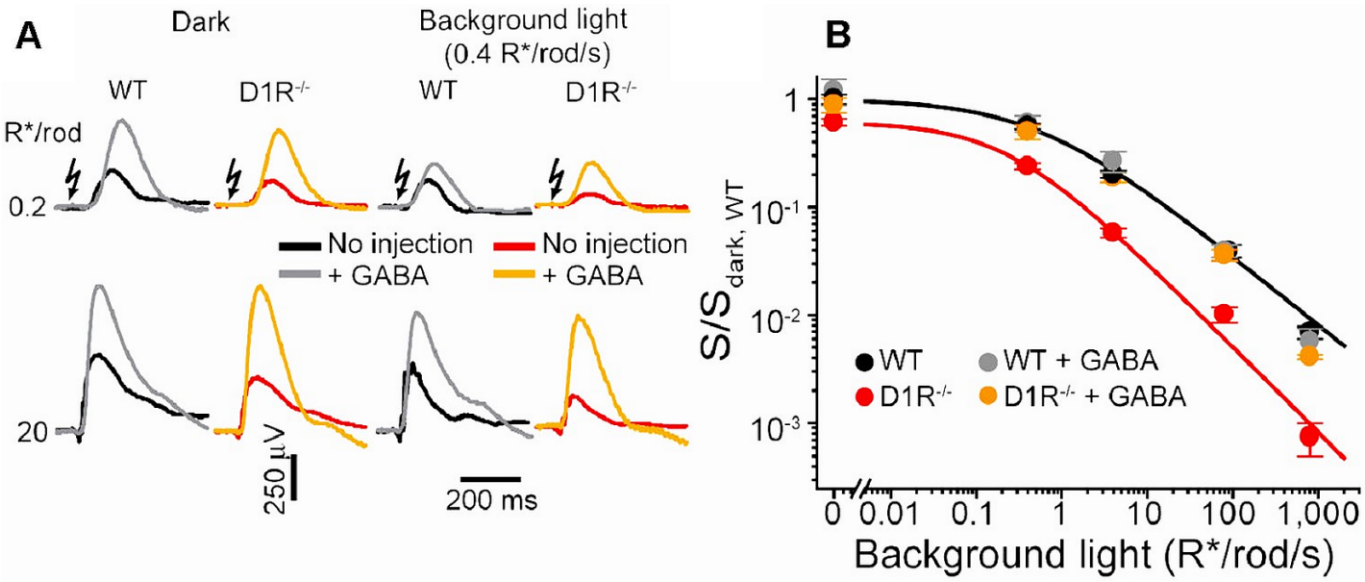

Figure 31. GABA increases b-wave sensitivity, but GABA release is inhibited by D_1R. **(A)** ERG recordings from dark- or light-adapted wild type (WT) and D_1R knockout ($D_1R^{-/-}$) *mice* with and without GABA injections. **(B)** WT and $D_1R^{-/-}$ ERG b-wave sensitivity plots in the absence or presence of injected GABA. Stimuli given in photoexcited rhodopsin molecules per rod per second (R^*/rod/s). Sensitivity (S/S_{dark}) is normalized. From Herrmann et al. (291).

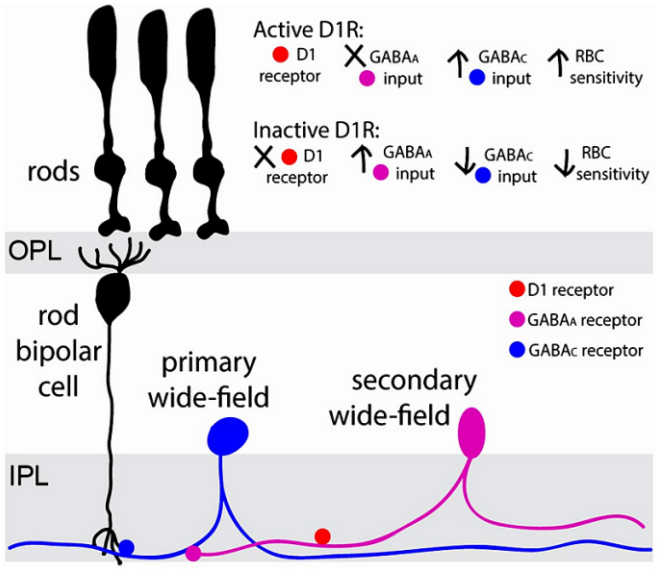

Figure 32. The circuit responsible for rod bipolar cell sensitization by the dopamine and GABA dependent mechanism. A subset of wide field amacrine cells (primary wide-field cell in blue) provides sustained GABA release onto $GABA_CRs$ located in the rod bipolar cell axon. This GABA release can be suppressed by upstream amacrine cells (secondary wide-field cell in magenta), which release GABA onto $GABA_ARs$ located at the primary wide-field amacrine cell. This serial inhibition is suppressed by dopamine acting through the D_1 receptors located on the secondary cells. When these D_1Rs are blocked, secondary cells inhibit primary cells through the $GABA_AR$-dependent mechanism, which ultimately causes reduction in rod bipolar cell sensitivity. From Travis et al. (141).

however, that the AII/ON-CBC coupling is modulated by background light as it was shown for the AII/AII coupling. Bloomfield et al. (306) could not find any light-induced modulation of AII/ON-CBC gap junctions under the 1000-fold range of background light intensities studied. No effect on Cx36 phosphorylation of AII/AII and AII/ON-BC gap junctions was found, when dark adapted retina cultures were submitted to day lighting conditions (299). Urschel et al. (299) proposed that the dopamine released upon light stimulation was diluted

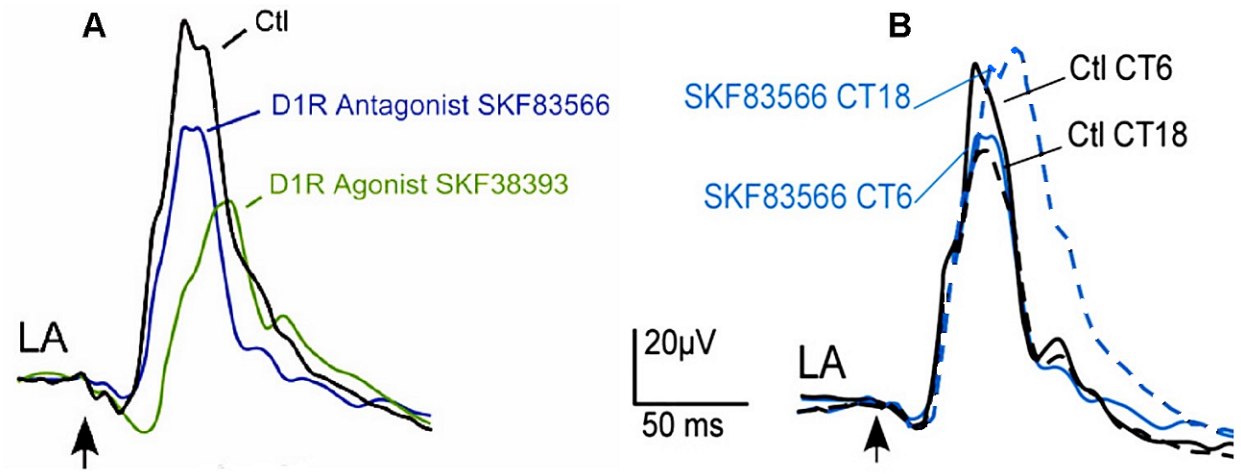

Figure 33. **(A)** ERG recordings in daytime from light-adapted *mice* (LA) during control conditions (black) and after injecting D_1R antagonist SKF83566 (blue) or D_1R agonist SKF38393 (light green). Stimulus intensity: 1.0 log cd s m^{-2}. Both agonist and antagonist caused a decrease of the b-wave amplitude. **(B)** ERG recordings from light-adapted (LA) *mice* obtained during the circadian midday (CT6, solid lines) and circadian midnight (CT18, dotted lines) in control conditions (black) and after injection of D_1R antagonist SKF83566 (blue). The D_1R antagonist decreased the b-wave amplitude during the circadian midday but increased the b-wave amplitude during the circadian midnight. In other experiments the sodium channel blocker TTX blocks actions of D_1R ligands. From Smith et al. (254).

too fast into the surround culture medium and therefore it could not reach threshold concentration to affect Cx36 phosphorylation.

Dopamine modulates the gap junctions formed by other types of ACs and between ACs and GCs. It was shown that dopamine decreased homotypic coupling between AC1 (GABAergic) cells via D_1R and PKA-induced phosphorylation, while DA acting via D_2R inhibited PKA and decreased phosphorylation of homotypic gap junctions between OFF α GCs in *rabbit* retina (54). A surprising inference is that, in contrast to AC1cells, ganglion cell hemichannels were closed by a decrease in phosphorylation. The heterotypic gap junctional channels between AC1 and OFF *α* GCs likely involved differential modulation of the two different types of hemichannels. One hemichannel was closed by phosphorylation on the side of AC1 cells, while the other hemichannel was opened by phosphorylation on the GC side. This differential modulation of the two hemichannels was accomplished by employing different dopamine receptors and opposite responses of two different hemichannels to PKA phosphorylation. Mills et al. (54) proposed that in the dark, where dopamine levels are minimal, both types of hemichannels may be relatively open and neighboring GCs will fire synchronously. As dopamine increases with background light, D_2R will be activated first and will cause decrease in phosphorylation and closure of the GC channels. Ganglion-amacrine gap junctions would also be closed, although to a lesser extent, because there is only a single D_2-sensitive hemichannel on the GC side. As dopamine levels increase with higher background intensities, activation of D_1R accelerates the closure of the ganglion-amacrine cell channels and begins uncoupling the amacrine cells as well (**Figure 36**).

Thus, dopamine might regulate both the strength and spatial extent of inhibition mediated by the coupled AC1 GABAaergic amacrine cells as well as the degree of synchronous firing of the ganglion cells. It was shown, however, that light adaptation resulted in a dramatic increase instead of decrease in the coupling of *α*-GCs to both neighboring ganglion cells and amacrine cells in *mouse* and *rabbit* retina (307), which did not support the model of Mills et al. (54).

In contrast to the AII cells, dopamine, the D_1R agonist SKF38393 and D_1R antagonist SCH23390 did not modulate the homotypic and heterotypic gap junctions made by *mouse* A8 ACs (glycinergic), although the latter cells expressed D_1 receptors and formed Cx36-containing junctions just like AII cells (142). A8 cells formed gap

junctions with OFF bipolar cells, whereas AII cells only contacted ON CBCs via electrical synapses. It appears that dopaminergic regulation of amacrine cell gap junctions depends both on type and functional role. Exogenous dopamine did not influence the electrical coupling between ACs in *carp* retina, although it decreased coupling between horizontal cells (308).

How dopamine modulates the light-evoked responses of ACs is largely unknown. In *goldfish* it was shown that exogenous dopamine had no effect on the sustained ACs, while it depolarized the transient ACs and reduced their responsiveness to light stimuli (159).

Effect of dopamine on ganglion cells

Dopamine can modulate homotypic coupling among retinal GCs of the same subtype, which underlies the coherent firing of neighboring cells. This concerted firing is thought to form a separate stream of information to the brain, in addition to the asynchronous signals from individual ganglion cells (309, 310) (see also Webvision chapter Myriad roles for gap junctions in retinal circuits). Hu et al. (307) found that the D_1R agonist SKF38393 and the D_1R antagonist SCH23390 produced no significant change in the coupling of dark-adapted OFF α-GCs, while D_2R antagonists (eticlopride and spiperone) produced a dramatic increase of homotypic (GC/GC) and heterotypic (GC/AC) coupling in OFF α-GCs and increased the concerted activity of α-GC neighbors in *rabbit* and *mouse* retina. These effects were like the effects obtained by the authors during light adaptation. Application of D_2R agonists on light adapted retinas had no effect on coupling, while the D_1R antagonist SCH23390 reduced both the coupling and the number of cells showing correlated light-evoked spike activity. Inhibition of adenylate cyclase and PKA in light adapted retinas had similar effect to those obtained with SCH23390. The authors proposed that the basal levels of dopamine in dark-adapted retinas activated high-affinity D_2R resulting in an inhibition of adenylate cyclase, a dephosphorylation of connexins and a reduction in the permeability of α-GC gap junctions. Under mesopic/photopic conditions, dopamine levels increased and activated low-affinity D_1R which, via a cAMP-mediated activation of PKA, increased connexin phosphorylation, and as a consequence, increased the coupling of the α-GC network (**Figure 37**). Thus, light-induced enhancement of GC coupling was due to activation of D_1R, while uncoupling of dark-adapted GCs was due to activation of D_2R. It is evident that the model of Hu et al. (307) differs markedly from the model of Mills et al (54), although they concern one and the same type of GC in rabbit retina.

Dopamine can modulate coupling among GCs in *amphibian* retina as well. Dopamine enhanced the synchronization of dimming detector (sustained OFF GCs) firing in bullfrog retina (311, 312). In addition, dopamine prevented the changes in synchronization and receptive field size induced by contrast adaptation. Li et al. (312) showed that single neuronal receptive field size was reduced during contrast adaptation, which was accompanied by weakening in synchronization strength between adjacent neurons' activities. Dopamine increased the synchronization strength index and the mean receptive field size, indicating that dopamine caused a significant strengthening of the gap junctional connections among dimming detectors. Dopamine eliminated both the adaptation-related receptive field area shrinkage and the synchronization weakening. Application of the D_2R antagonist sulpiride, but not D_1R antagonist SCH23390, had effects similar to that obtained with dopamine. Li et al. (312) proposed that in early-adaptation, light-induced increase in dopamine release activated D_1R and desensitized D_2R. Thus, the gap junction conductance between ganglion cells was enhanced to a relatively high level, resulting in stronger synchronization. In late adaptation, as dopamine release declined, both the decrease in D1R activation and probable recovery of D_2R from desensitized status in low dopamine concentration induced the decrease of gap junctional conductance. Bu et al. (311) found that the spatial correlation of dimming detector activity was enhanced, while temporal correlation in a single spike train was greatly decreased during dopamine treatment. The D_2R antagonist sulpiride, but not D_1R antagonist SCH23390 had similar effects to those of exogenous dopamine and Bu et al. (311) suggested that "endogenous dopamine influence on spatial and temporal correlation of firing activities of dimming detectors might be due to the activation of D_1R". Li and Liang (313) reported, however, that the exogenous dopamine did not alter the

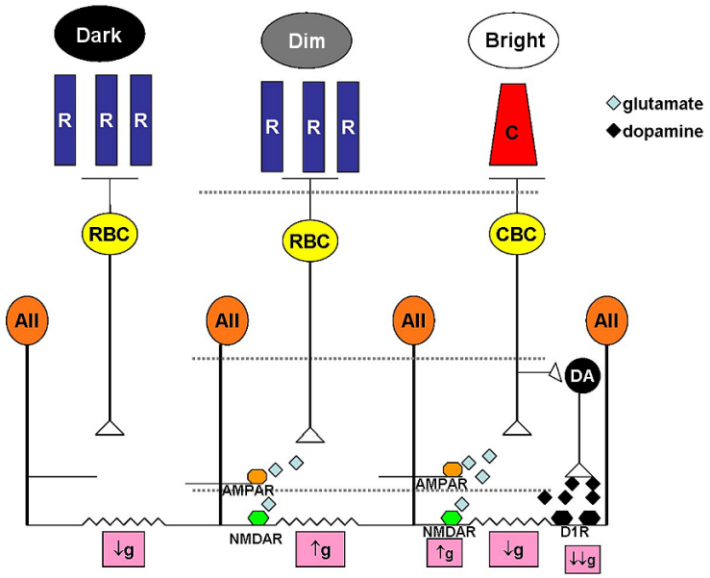

Figure 34 Mechanisms that control AII amacrine cell coupling under different conditions of light adaptation. In the dark (left panel), rod BCs (RBC) are hyperpolarized and release no glutamate. The AII amacrine cells (AII) are uncoupled (↓g). In dim light (middle panel), non-synaptic NMDA receptors associated with the Cx36 gap junctions are activated by spillover glutamate derived from RBCs in response to light. NMDA receptor activation in turn activates CaMKII and phosphorylates Cx36 to enhance coupling (↑g). In the presence of bright light (right panel), dopaminergic amacrine cells (DA) secrete dopamine, which activates D_1 receptors on AII amacrine cells, leading to activation of AC-PKA-PP2A and dephosphorylation of Cx36 to reduce coupling (↓↓g). This action of dopamine is enough to overwhelm the pathway favoring increased Cx36 phosphorylation. Modified from O'Brien (336).

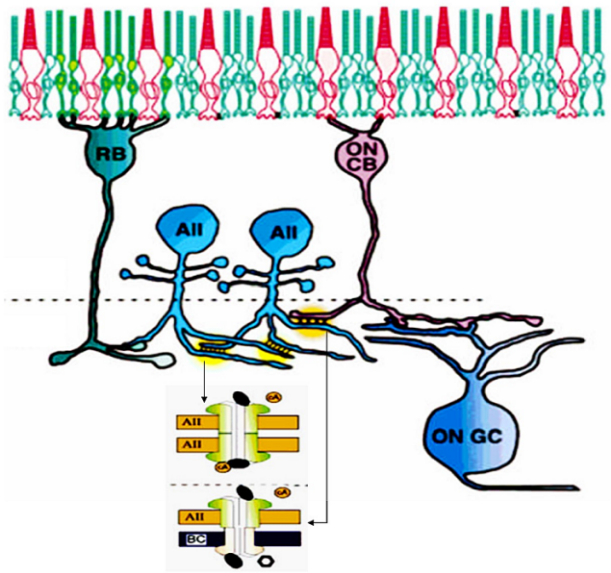

Figure 35. AII amacrine cells (**AII**) relay input from rod bipolar cells (**RB**) to ON cone bipolar cells (**ON CB**), which contact ON ganglion cells (**ON GC**). Each AII amacrine cell makes gap junctions both with neighboring AII amacrine cells and with ON CBs. The model predicts two cAMP-sensitive gap-junction hemi-channels gate signals between AII pairs, and between AII and ON CB pairs, but cAMP is elevated on only the AII side, leading to lesser modulation of the AII to ON CB junction. From Xia and Mills (302).

temporal structure of the firing sequences in single bullfrog neurons, although it decreased firing rates in response to three different stimulus patterns. Dopamine enhanced the synchronization of the GC population activity but decreased the rate of correct stimulus pattern discrimination and eliminated the linear correlation between correct rate and group size. Exogenous dopamine attenuated also the encoding of information about

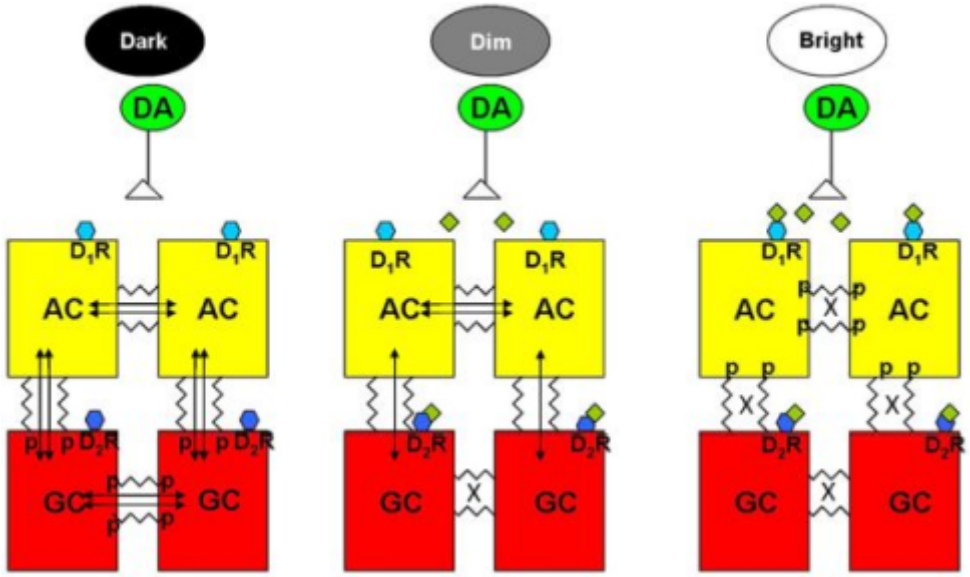

Figure 36. Effects of dopamine on the gap junctions between AC1 amacrine cells and OFF α GCs in rabbit retina. In the dark (left panel), no dopamine is released, and the gap junctions are open. The gap junctions between neighboring ACs are dephosphorylated, while these between neighboring GCs are phosphorylated (p). The gap junctions between AC and GCs are phosphorylated on the GC site and dephosphorylated on the AC site. In dim light (middle panel), small amounts of dopamine are released and act on the more-sensitive D_2Rs on GCs, leading to dephosphorylation of the gap junctions and their closure. In the presence of bright light (right panel), dopamine levels increase and activate both D_1R on ACs and D_2R on GCs leading to closure of their gap junctions. Model proposed by Mills et al. (54).

the stimulus duration carried by the response latency and not by the firing rate, although it increased the firing rate and shortened the latency of both the ON and OFF responses of bullfrog ON-OFF GCs (314).

Dopamine changes the sustained lateral inhibition of *amphibian* GCs during light adaptation (315). It was shown that both light adaptation and dopamine caused a decrease in the sustained lateral inhibition produced by distant windmill stimuli and an increase in the sustained lateral inhibition produced by nearby windmill stimuli. The authors suggested that the observed effects were due to a dopamine induced decrease of electrical coupling in the OPL and IPL and this might serve to increase contrast detection at higher spatial frequencies. Dopamine had no effect on the transient lateral inhibition of GCs, which was evident in light, but not in dark adapted amphibian retina. This type of inhibition was mediated by transient ACs and spread laterally via action potentials.

In cell culture dopamine may act directly on retinal ganglion cells to regulate excitability by affecting voltage-gated currents. It was shown that dopamine did not change the membrane potential or membrane resistance but reduced the excitability of dissociated GCs through activation of D_1R in nonmammalian retina as seen in both *turtle* (316) and *goldfish* (317, 318). In *turtles*, the dopamine effect was attributed to changes in conductance of voltage-gated Ca^{2+} channels (316), while in *goldfish* the effect did not depend on voltage-gated Ca^{2+} currents (318) and it was probably due to a reduction of the voltage-gated Na^{+} current amplitude (317). Reduced excitability of dissociated GCs by the action of dopamine was obtained also in *rat* retina, but the underlying mechanism is a matter of debate (319-321). Chen and Yang (319) showed that exogenous dopamine, acting via D_1R, induced a small depolarization of GC membrane potential, associated with decreased membrane resistance and diminished number of current-evoked action potentials (**Figure 38**).

The membrane potential effects of dopamine were prevented by the blockade of hyperpolarization-activated cation currents (I_h) with ZD7288, while dopamine alone increased the amplitude of I_h. Therefore Chen and Yang (319) suggested that the depressing effects of dopamine on rat GCs may be, at least in part, mediated by increasing the I_h amplitude through the cAMP- and PKA-dependent pathway. Hayashida et al. (320) suggested

that dopamine and D_1R agonists inhibited GC spiking primarily by reducing Na^+ currents, because dopamine reduced the amplitude of both voltage-gated Na^+ currents and current-evoked action potentials and it also slowed the rising and repolarizing sides of each spike. The reported effects were not affected by the blockade of I_h. Involvement of intracellular Ca^{2+} in the depressant effect of dopamine on current-evoked GC spiking was proposed by Ogata et al. (321). The authors demonstrated that dopamine and SKF 83959 (an agonist that activates heteromeric, but not homomeric DR) induced a Ca^{2+} influx in GCs, which was prevented by lowering of extracellular Ca^{2+}, by SCH23390 and by eticlopride. The blockade of IP_3-mediated Ca^{2+} release also prevented the dopamine-induced rise in intracellular Ca^{2+}. All these data indicated that rat GCs possessed heterodimeric D_2-D_5 receptors that mediated the dopamine-induced Ca^{2+} influx. Ogata et al. (321) showed that D_1R and D_2R antagonists blocked also light-induced rises in cAMP and activation of Ca^{2+}/calmodulin-dependent protein kinase II, suggesting that dopamine may activate two pairs of signaling pathways in rat GCs: cAMP and PKA, and Ca^{2+} and CaMKII. Dopamine may modulate K^+ currents of dissociated rat GCs as well. Li et al. (322) demonstrated that D_1R agonist SKF81297 suppressed the GC outward K^+ currents, mainly mediated by Gb-sensitive and 4-AP-sensitive components, through the intracellular PKA and CaMKII signaling pathways. Cui et al. (323) reported that D_1R activation suppressed K_{ir} currents through cAMP/ PKA signaling pathway and thus leading to enhancement of the temporal summation of EPSPs in GC dendrites. They showed that D_1R activation increased the spontaneous firing of GCs and induced cell depolarization (**Figure 39**), strongly suggesting that D_1R activation increased the excitability of rat GCs, instead of decreasing it (319, 320). The cause for these opposite results obtained in rat retina, is unclear.

Dopamine acting via the D_1R signaling pathway (cAMP/PKA) directly affected the intrinsically photosensitive retinal ganglion cells (ipRGCs) in *rat* retina (324). Dopamine and D_1R agonist SKF38393 attenuated the ipRGC photocurrent and dramatically reduced the light-evoked cell spiking. D_1R activation caused a modest depolarization and input resistance decrease of ipRGCs without significantly altering the number of spikes evoked by injection of depolarizing current. The authors suggested that the effects of D_1R activation on membrane properties of ipRGCs were due to modulation of the I_h and not of voltage-gated Na^+ channels, while the exact mechanism of the effects on melanopsin phototransduction cascade was unclear. Van Hook et al. (324) proposed that dopamine acting via D_1R activation contributed to light-driven desensitization in ipRGCs and thus supported a form of light adaptation. On the other hand, Sakamoto et al. (83) found that dopamine via D_2R modulated the photic and circadian regulation of melanopsin mRNA in rat ipRGCs. Thus, it appears that the two classes of dopamine receptors have distinct roles in regulating activity of rat ipRGCs.

Much data suggests that dopamine depresses retinal ganglion cell activity in *intact mammalian retina*. In *cat* retina dopamine reduced the spontaneous and light-evoked firing of GCs irrespectively of their type (ON or OFF, transient or sustained) and these effects were essentially the same under scotopic, mesopic and photopic conditions (325-327) (**Figure 40**). Dopamine antagonists haloperidol (mixed D_1/D_2R antagonist), flupenthixol (selective D_1R antagonist) or sulpiride (selective D_2R antagonist) had no effect on spontaneous or light-induced activity of GCs, suggesting there was no endogenous dopamine present on the dopamine receptors of retinal GCs (325). Ikeda et al. (325) suggested that the retinal GCs may initially be innervated by dopaminergic cells, but the connection is eliminated during formation of GABA and glycine synapses. Other authors showed, however, that the impairment of dopaminergic transmission (with 6-OHDA or haloperidol) in adult cat retina led to a marked ON/OFF asymmetry in transient GC activity under photopic conditions of illumination (328, 329). The maintained activity of OFF-Y GCs was decreased, while that of ON-Y GCs was increased during either treatment (6-OHDA or haloperidol). Maguire and Smith (329) found that the proportion of OFF, but not ON GCs, which displayed nonlinear spatial summation was larger in the 6-OHDA treated than in the control eyes. The modulation of shift response (elicited with a peripheral square-wave grating) became larger in OFF-Y, but smaller in ON-Y GCs and the light-evoked responses of OFF-Y cells became even more transient in 6-OHDA treated eyes. The effect of haloperidol on the shift response of ON-Y GCs was like that of 6-OHDA, while its effect on the shift response of OFF-Y GCs showed great dynamics with time. The response disappeared at 25 min postinjection, but reappeared and increased to supranormal levels reaching a 50% increase in response

modulation over control at 4 h 30 min (328). The peak firing rate of the center responses to flashing spots was greatly decreased at all stimulus intensities during haloperidol and SCH23390 treatment in the OFF Y GCs, while in the ON Y GCs the response diminution was much smaller (328). Whether the impairment of dopaminergic transmission caused a similar ON/OFF asymmetry in sustained (X) GC activity in cats is a matter of debate.

Maguire and Smith (329) found that the intensity-response function of center responses was unaffected for both ON and OFF X cells during 6-OHDA treatment, while Maguire and Hamasaki (328) found that the same function was shifted to the right for the OFF-X cells and not changed for the ON-X cells during haloperidol application. It was also shown that the blockade of D_1R with SCH23390 altered the dark-adaptation function of OFF-Y and OFF-X GCs so that no rod-cone break was observed; rather the threshold of the cell fell quickly in a single exponential function to rod levels (328) (**Figure 41**). Therefore, the authors proposed that one of the operations of retinal dopamine may be to eliminate rod input to GCs during brief periods of decreased retinal illumination. Maguire and Hamasaki (328) suggested that without dopamine acting on D_1-like receptors, "rapid changes from light to dark would allow the rod photoreceptors to activate GCs and lead to a noisy system with poor spatial and temporal resolution".

An ON/OFF imbalance of ganglion cell activity, caused by dopamine, was described also in *rabbit* retina (330-333). It was shown that exogenous dopamine increased the spontaneous activity of OFF GCs, but reduced the spontaneous activity of ON GCs (330, 331). In accordance with these findings, dopamine nonselective antagonists (haloperidol, fluphenazine, cis-flupenthixol) caused a decrease in the spontaneous activity of OFF GCs and an increase of the spontaneous activity of ON GCs, indicating that there was a continuous dopamine release in light adapted rabbit retinas (331-333). These results are similar to those obtained in cat retina (328, 329). The involvement of the two DR types in the observed effects was studied with selective D_1R and D_2R agonists and antagonists. It was demonstrated that D_2R agonist LY 141865 and D_1R antagonist SCH 23390 decreased the spontaneous activity of OFF GCs and increased of the spontaneous activity of ON GCs, while D_2R antagonist sulpiride decreased the spontaneous activity of both OFF GCs and ON transient GCs (331). The authors proposed that D_1R mediated the effects of dopamine on spontaneous firing of GCs, while D_2R may function at presynaptic autoreceptors that reduced the release of dopamine. It remained unclear why both activation and blockade of D_2R decreased the spontaneous activity of OFF GCs. How exogenous dopamine affected the light-evoked responses of rabbit GCs is a matter of debate. Ames and Pollen (330) reported that the light-evoked responses of OFF GCs were usually unaffected by dopamine, while Jensen and Daw (331) demonstrated that dopamine reduced the light-evoked responses of these cells and shifted the intensity-response function of cell center and surround response to the right by an equal amount. Thus, exogenous dopamine reduced OFF GC sensitivity to light without altering the center-surround balance. Exogenous dopamine exerted a suppressive action also on the light-evoked responses of two thirds of ON and ON-OFF GCs (330). Dopamine suppressed the light responses of all ON-transient GCs and ON-OFF GCs, while it had no effect on the responses of the ON-sustained GCs (331). The blockade of dopamine receptors revealed effects on the GC light responses that were not seen during the action of exogenous dopamine. Application of haloperidol reduced and delayed the antagonistic surround responses in both OFF and ON brisk GCs and shifted their center-surround balance in favor of the center (333). Similar effects were found with D_1R antagonist SCH23390, but not D_2R antagonist sulpiride (**Figure 42**) with the exception of OFF large field units (331).

In the latter, sulpiride also caused a shift in center-surround balance in favor of the center. Thus, it appears that D_1R mediated the effects of endogenous dopamine on the center-surround balance of ON-brisk GCs, while both D_1R and D_2R mediated those effects on the OFF large field units. An interesting observation was reported for ON brisk-sustained GCs, in which haloperidol and SCH23390, but not sulpiride, caused a reduction of sustained ON activity to spots of light and in some of the cells, in others the sustained excitation to spots of light actually turned into sustained inhibition (331, 333). The latter effect was not seen during application of dopamine. Endogenous dopamine, acting via D_1R was probably involved also in the directional selectivity of rabbit GCs. It

was shown that haloperidol and SCH23390, but not sulpiride, reduced the leading edge response, while either not affecting or increasing slightly the trailing edge response to a moving light stimulus of the ON-OFF directionally selective cells (331, 333). Exogenous dopamine had similar action in 3 out of 5 directionally selective cells.

The effects of dopamine on the activity of other mammalian GCs (except cat and rabbit) are not thoroughly investigated. It was shown that in light-adapted *mouse* retina, D_1R antagonist (SCH23390) decreased, while D_2R antagonist (spiperone) increased the light-evoked OFF responses of GCs, indicating that D_1 and D_2 receptors played opposite roles in OFF response generation (334). Simultaneous inhibition of both receptor types (D_1 and D_2) increased the OFF responses, showing that the D_2R-mediated effect was stronger and it dominated over that mediated by D_1R. The authors gave no proposal for the mechanism underlying the OFF-response enhancement caused by D_2R blockade. In *rat* retina, the D_2/D_3 receptor antagonists (sulpiride and eticlopride) had no significant effect on the spontaneous activity of either ON or OFF GCs in a dimly lighted environment (335). On the other hand, the specific D_4R antagonist L-745,870 reduced the spontaneous activity of OFF GCs but had no significant effect on the spontaneous firing of ON GCs. In addition, L-745,870 decreased both the light sensitivity (by 0.32 log unit) and the maximum peak response of the ON and OFF GCs, while sulpiride and eticlopride reduced only light sensitivity (0.23 log unit) without changing the maximum peak response. Jensen (335) proposed that D_4R, like D_2R, functions to regulate dopamine release, but did not provide any suggestion why the effect of D_4R blockade inhibited the GC spontaneous and light-evoked activity more strongly than D_2R blockade. More studies are needed to fully understand the role of dopamine in ganglion cell function in both mammalian and nonmammalian retina.

Summary

Dopamine is synthesized and released by a group of cells in the retinal amacrine cell layer. This group represents less than 1% of cells in this layer. Dopaminergic cells are morphologically either interplexiform cells, with dendritic arbors in both inner and outer plexiform layers, or large-bodied amacrine cells. The latter typically have dense, wide-field dendritic arbors in stratum S1 of the inner plexiform layer, adjacent to the amacrine cell layer, but sparse branching in more proximal inner plexiform layer strata. Dopaminergic amacrine or interplexiform cells synapse directly on other retinal neurons, but much of the dopaminergic action is thought to be 'paracrine', exerted by diffusion of dopamine to different target cells. Dopaminergic cells release other neurotransmitters such as GABA. Dopamine release appears to be circadian, with high release levels during the day in many species, and is a counterpart to circadian rhythms in melatonin, which is released at night. Consistent with a role as a humoral neuromodulator, dopaminergic actions are found in every retinal cell type, mediated through both D_1-like and D_2 like G-protein coupled receptors. One particularly prominent action is diurnal modulation of gap-junction coupling between horizontal, amacrine, ganglion cells, clearly observed in the regulation of tracer molecule spread among like cell types. In mammals gap-junction modulation corresponds to a retinal circuitry reconfiguration in rod and cone pathways so as to optimize nocturnal and diurnal vision. Further actions are found in the modulation of voltage-gated channels and chemical neurotransmission. Nonetheless, there are no general rules concerning dopaminergic action, which vary considerably depending on species, neural cell type, and the experimental context.

Acknowledgements

The author thanks Helga Kolb (University of Utah) for giving the idea for writing this chapter and her valuable support during the whole process of chapter construction. She especially helped for writing the section concerning the morphology and circuity of retinal dopaminergic cells. The author thanks also Dr. Ralph Nelson (NIH) for chapter editing and helpful comments.

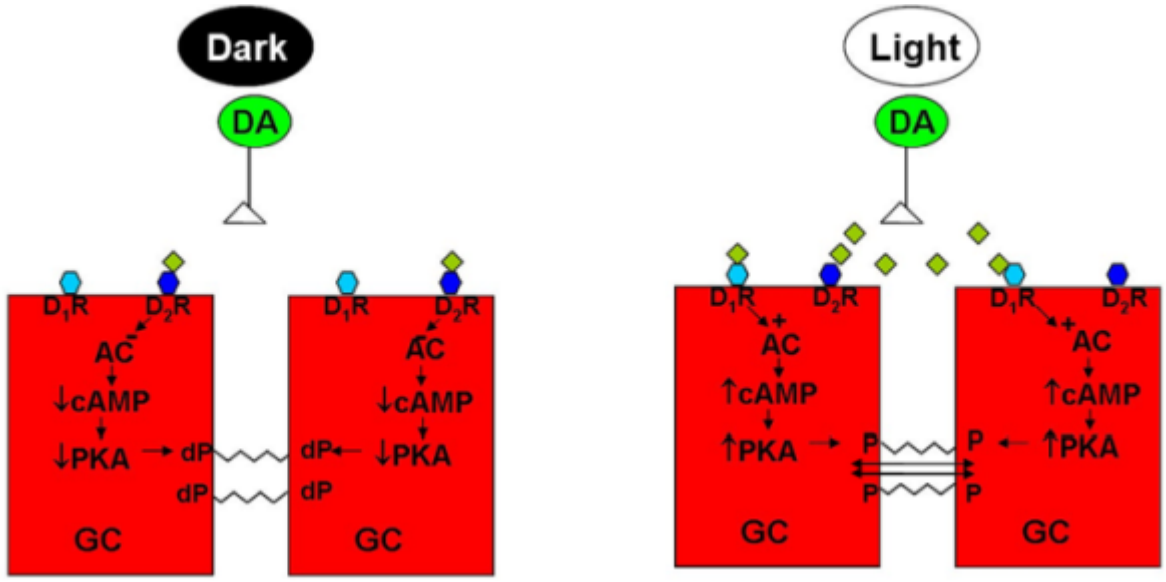

Figure 37. Schematic diagram of the intracellular pathway proposed to control the conductance of α-GC gap junctions under dark- and light-adapted conditions. In the dark (left panel) dopamine levels are low and dopamine activates the more sensitive D_2 receptors, which, through reduction of cAMP and PKA activity, cause dephosphorylation (dP) of connexin protein and a reduction of gap junction permeability. During light adaptation (right panel) dopamine levels increase and dopamine activates D_1 receptors, which, through an increase of cAMP and PKA activity, cause phosphorylation (P) of connexins and an increase in gap junctional conductance. Modified from Hu et al. (307).

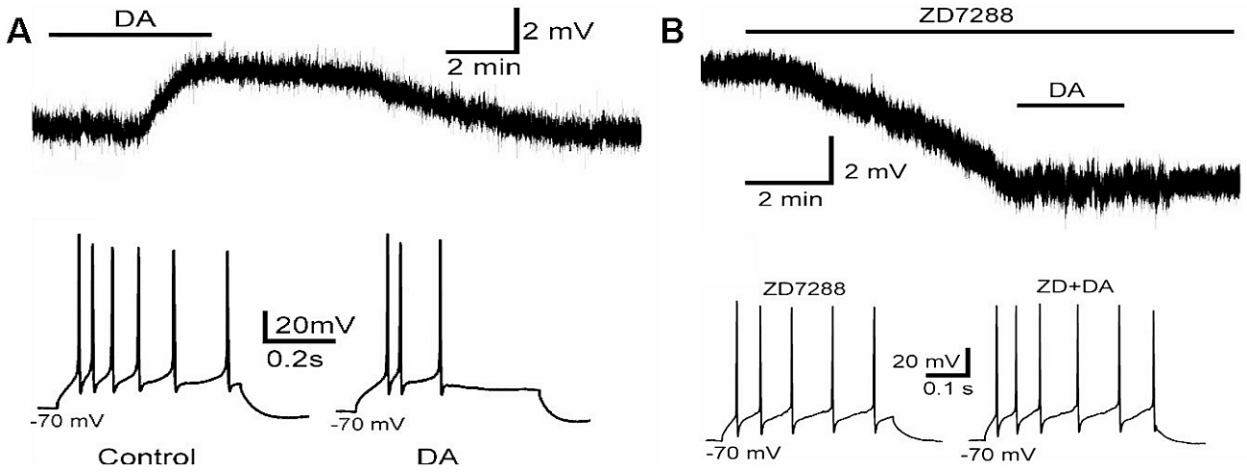

Figure 38. Modulation of membrane properties and excitability of *rat* ganglion cells by dopamine (DA) in a retinal slice preparation. **(A)** Bath application of 10 μM DA produced a small and reversible depolarization of the membrane potential (upper row). Action potentials evoked by depolarizing current injection (80 pA, 400 ms) at a holding potential of -70 mV in the lower row. **(B)** Application of 30 μM ZD7288, an HCN channel blocker, produced a hyperpolarization of the membrane potential, and addition of DA (10 μM) failed to further change the membrane potential (upper row). Effects of DA on the number of evoked action potentials are prevented when the cell was incubated with ZD7288 (lower row). From Chen and Yang (319).

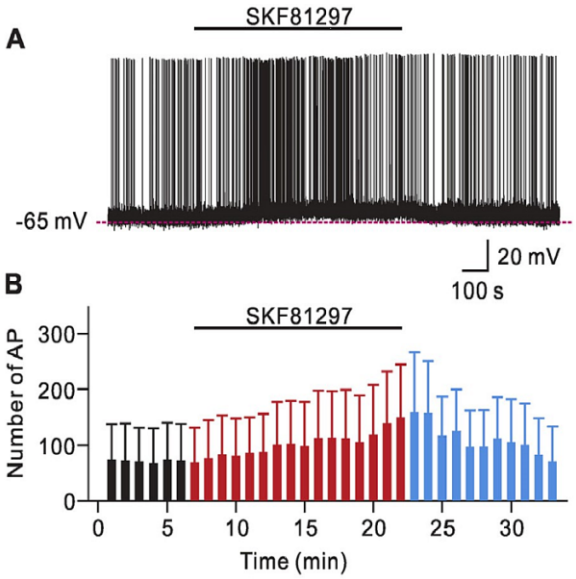

Figure 39. Effects of D1 receptor activation by the agonist SKF81297 on the membrane potential and spontaneous firing of *rat* retinal ganglion cells. **(A)** Representative trace recorded from an RGC, showing that the perfusion of SKF81297 significantly increased the spontaneous firing and induced a small depolarization of Em. (**B)** Bar chart showing SKF81297-induced increase in the number of spontaneous action potentials (AP) as a function of time. Bin size: 1 min. From Cui et al. (323).

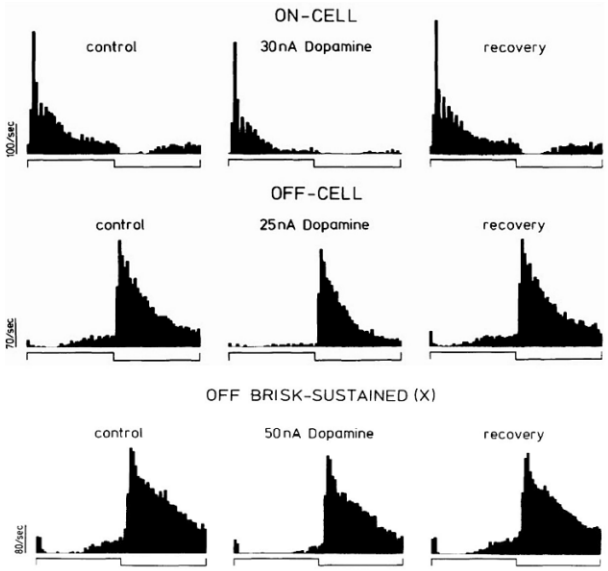

Figure 40. Effects of dopamine on the optimal spot response histograms of 3 different ganglion cells in *cat* retina. Responses of ON brisk-transient (Y) cell (top row), OFF brisk-transient (Y) cell (middle row) and OFF brisk-sustained (X) cell (bottom row) are presented prior to, during and after the administration of dopamine. The stimulus was on when the trace beneath the histograms was shifted upwards. All histograms summed 32 stimulus representations. Stimulus period 1024 ms with light on for 512 ms. Note that dopamine reduces the firing rate in both ON and OFF phases of the response. Dopamine applied to individual cells by iontophoresis from a 7 barrel pipette with iontophoresis current given in nanoAmperes (nA). Adapted from Thier and Alder (327).

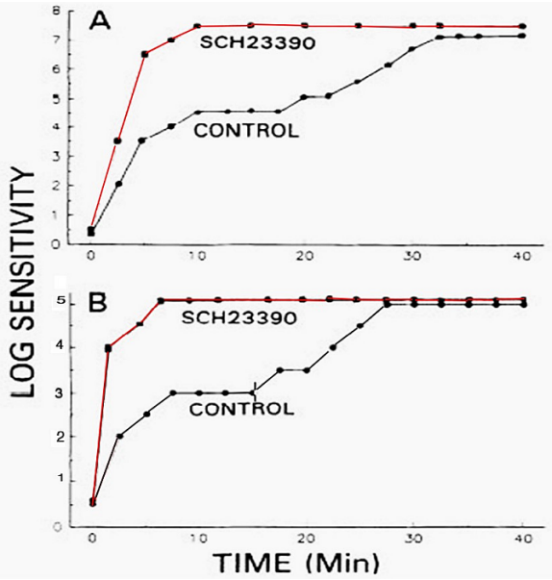

Figure 41. Effects of the D_1R antagonist SCH23390 on the dark-adaptation curves of OFF GCs in *cat* retina. Changes of light sensitivity were measured in a 40 min period immediately after extinguishing white background light with luminance of 61 cd/m^2. **(A)** Dark-adaptation curve for an OFF Y-GC. It is evident that in control conditions the dark adaptation curve has two branches (first: cone-mediated, second: rod-mediated), while after administration of SCH23390 (50 pg) the curve quickly sensitizes to that branch representing the rod system. **(B)** Dark-adaptation curve for an OFF X-GC as described above for the OFF Y-GC. From Maguire and Hamasaki (328).

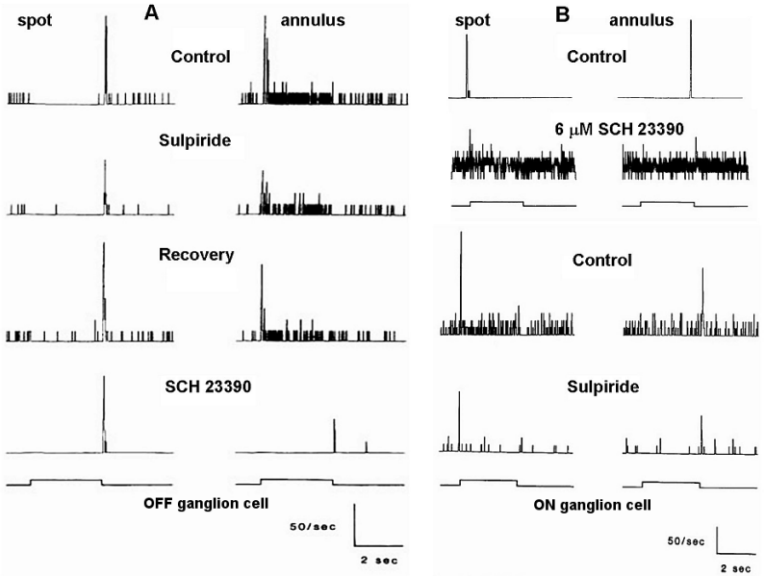

Figure 42. Effects of the D_2R antagonist sulpiride and the D_1R antagonist SCH-23390 on the light-evoked responses of *rabbit* retinal ganglion cells. **(A)** Effects of sulpiride (143 μM) and SCH 23390 (25 μM) on the responses of an OFF ganglion-cell. Responses to a spot (0.5 mm square) and an annulus (0.7 mm inner diameter and 3.0 mm outer diameter) of light are presented. Recovery records were taken about 7 min after application of sulpiride. Stimulus intensity, 1.7 log lux. **(B)** Effects of SCH 23390 (6 μM) and sulpiride (78 μM) on the responses of an ON transient ganglion cell to a spot and annulus of light. Stimulus intensity, 1.1 log lux in SCH23390 and 0.5 log lux in sulpiride experiment. From Jensen and Daw (331).

About the author

Dr. Elka Popova, MD, PhD, was born in Sofia, Bulgaria. She received a Medical Degree from Medical University of Sofia in 1979 and started her work as assistant professor in the Department of Physiology at the same university. Dr. Popova worked in the visual electrophysiological laboratory of the department and received her Ph.D. in 2001 and her associated professor position in 2003. Her work is in the field of retinal physiology and includes investigation of various excitatory and inhibitory neurotransmitters (GABA, glycine, dopamine, histamine, serotonin, purines, enkephalins) and ion channel (Na_V, HCN) modulation on the electroretinogram and ganglion cell activity in cold blooded species. She has a special interest in revealing the differences between retinal ON and OFF channels and the interaction between the two channels at different retinal levels. Dr. Popova investigates how some of these differences and interactions depend on different neurotransmitter systems and ion channels.

Phototransduction and Photoreceptor Synaptic Pathways

Phototransduction in Rods and Cones

Yingbin Fu, PhD[1]

Created: April 1, 2010.

1. Introduction

Vertebrates rely on retinal rods and cones for the conventional, image-forming vision while non-image-forming vision is mediated by intrinsically photosensitive retinal ganglion cells (ipRGCs) (see chapter on Melanopsin Ganglion Cells). Rods are specialized for low-light vision. They are extremely sensitive and can signal the absorption of single photons. Cones mediate daylight vision (Figure 1). They are much less sensitive to light than rods, but have higher temporal resolution. They also mediate color vision by several cone types with different pigment spectra sensitivity.

Great progress has been made in understanding rod phototransduction since the introduction of the suction-electrode recording technique in the late 1970s (1). Individual amphibian and mammalian (including primate) photoreceptors can be recorded with this method. Bovine retina, on the other hand, has been a favorite preparation for studying phototransduction by biochemists because of the abundance of tissue available. The mouse, however, has become an increasingly popular animal model for study in the past decade through the advent of gene-targeting techniques. When combined with electrophysiology, mouse genetics provides unmatched power in elucidating the in vivo functions of key phototransduction proteins, most of which have been knocked out, overexpressed or mutated in rods, yielding a rich body of information on the mechanisms underlying the amplification, recovery and adaptation of rod/cone photoresponses (Table 1, Figure 2, Figure 3).

I shall first give a brief description of the structure and the development of mouse photoreceptors, followed by a summary of recent studies on rod phototransduction with emphasis on information gleaned from mouse models. Finally, a recent advance in studying mouse cones will be mentioned.

Author Affiliation: 1 University of Utah.

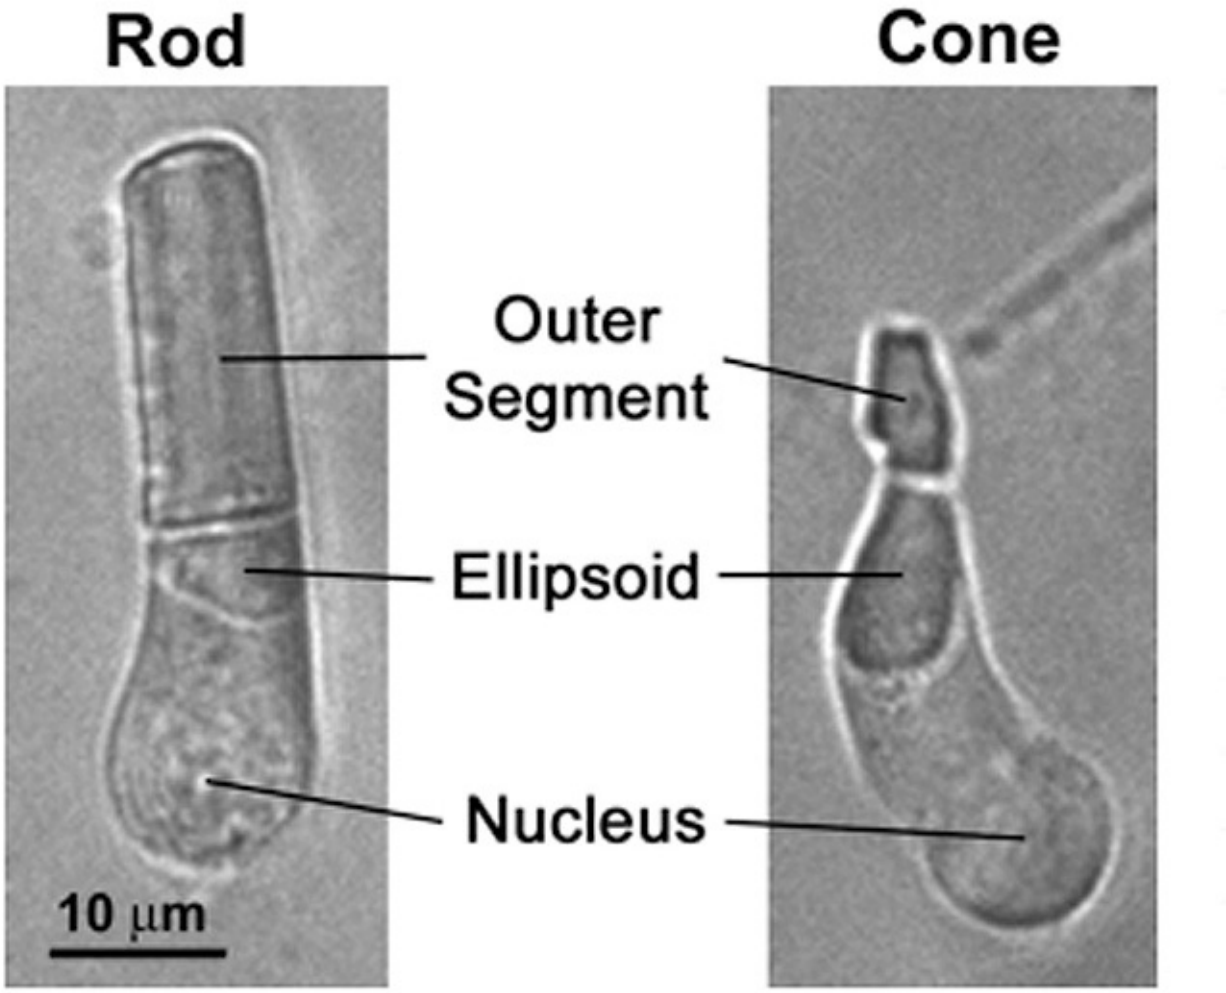

Figure 1. Brightfield images of living rod and cone photoreceptors isolated from a salamander retina. Phototransduction takes place in the outer segment, while the ellipsoid is densely packed with mitochondria. Rods are responsible for dim light vision, cones for bright light vision. Courtesy of Yiannis Koutalos.

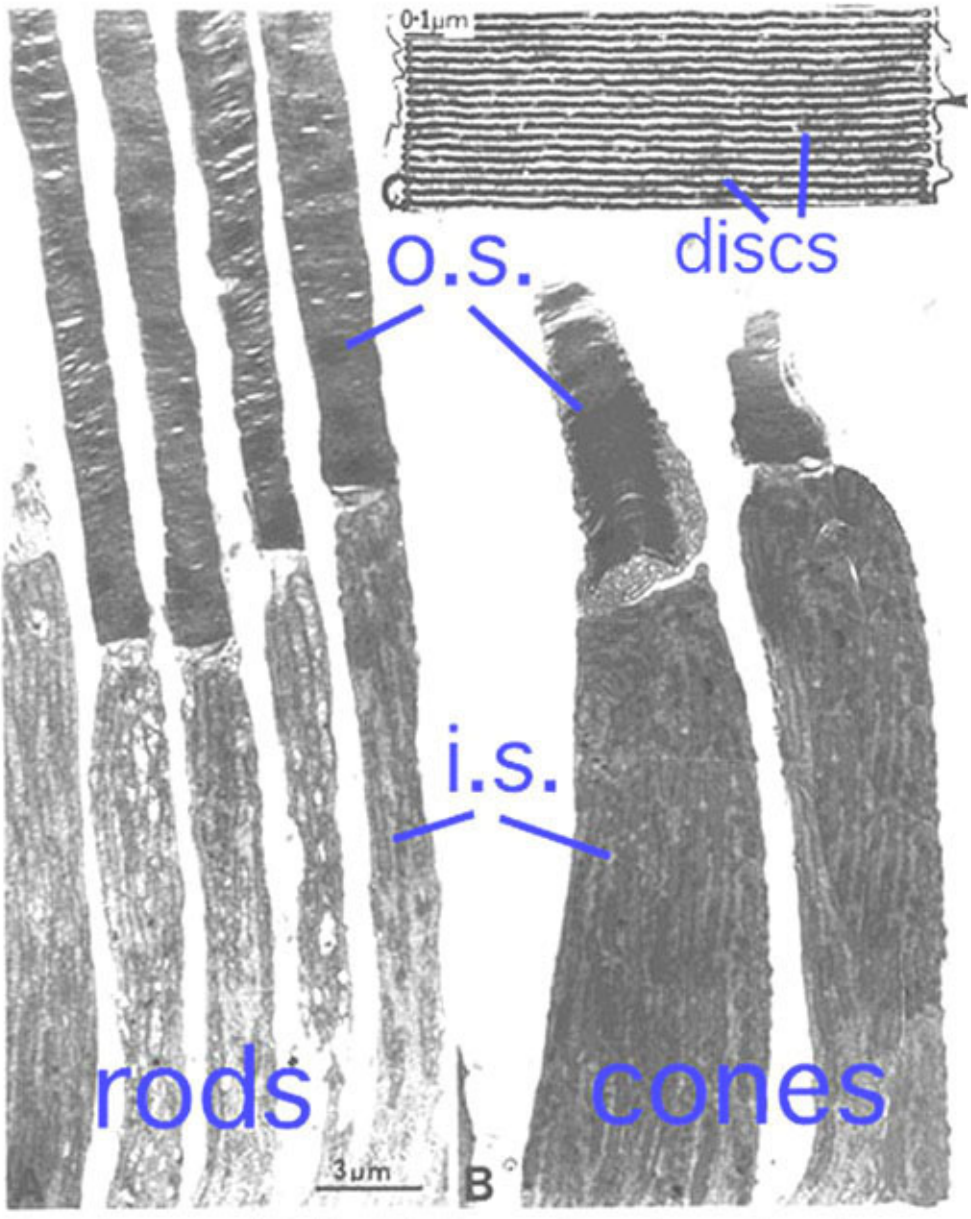

Figure 2. Low magnification EM image of monkey rods and cones with an enlargement of the outer segment discs.

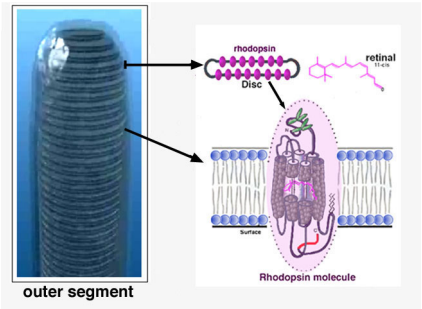

Figure 3. Schematic diagram of rhodopsin in the outer segment discs. When the outer segments are magnified further, stacked membrane disks are visible inside. The disks are studded with thousands of rhodopsin complexes. Each rhodopsin consists of a membrane-traversing protein with a retinal molecule embedded in its core.

Table 1. List of major proteins involved in mouse rod and cone phototransductions that have been knocked out, overexpressed or mutated.

Proteins	Manipulation	Phenotype	References
Rhodopsin	knockout	no ROS formation, no rod photoresponse	Humphries et al., 1997; Lem et al., 1999 (3, 4)
Transducin $G\alpha_{t1}$	knockout	no rod photoresponse	Calvert et al., 2000 (85)
Transducin $G\alpha_{\gamma 1}$	knockout	down regulation of $G\alpha_{t1}$ & $G_{\beta 1}$, reduced rod sensitivity, retinal degeneration	Lobanova et al., 2008 (210)
Transducin $G\alpha_{\gamma 1}$	S70L mutation	deficit in light adaptation in rods	Kassai et al., 2005 (90)
phosducin	knockout	reduced rod sensitivity	Krispel et al., 2007 (211)
PDE_{β}	mutation	rd mouse, retinal degeneration	Bowes et al., 1990; Pittler and Baehr, 1991(105, 106)
PDE_{γ}	knockout	reduced PDE activity, retinal degeneration	Tsang et al., 1996 (102)
PDE_{γ}	overexpression	reduced gain, accelerated shutoff in rods	Tsang et al., 2006 (212)
PDE_{γ}	W70A	reduced sensitivity, slow shutoff in rods	Tsang et al., 1998 (109)
CNGB1	knockout	no rod photoresponse, retinal degeneration	Huttl et al., 2005; Zhang et al., 2009 (127, 213)
CNGA3	knockout	no cone photoresponse, slow cone degeneration	Biel et al., 1999a (121)
GRK1	knockout	slow shutoff in rods & cones	Chen et al., 1999; Nikonov et al., 2005 (139, 146)
GRK1	overexpression	normal rod photoresponse	Krispel et al., 2006 (77)
Arrestin1	knockout	slow shutoff in rods	Xu et al., 1997 (155)
Arrestin1& 42	Double knockout	slow shutoff in rods and cones	Nikonov et al., 2008 (168)
Recoverin	knockout	reduced rod sensitivity, decreased signal transfer between rods and rod bipolar cells	Makino et al., 2004; Sampath et al., 2005 (154, 214)
RGS9-13	overexpression	accelerated shutoff in rods	Krispel et al., 2006 (77)

1 Due to space limitation, not all the genetically engineered mouse lines are listed. For those included, only the most salient phenotypes are listed, please refer to the text for more complete description.
2 Arrestin4 is also called cone arrestin or X-arrestin (168, 216).
3 RGS9-1 overexpression was achieved by overexpressing R9AP, which resulted in overexpression of all three components of the GAP complex, RGS9-1, Gβ5-L and R9AP.

2. Structure of rods and cones.

Rods constitute ~97% of mouse retinal photoreceptors, with cones accounting for the remainder (2). The mouse photoreceptors are broadly similar to primate photoreceptors in physical dimensions (Table 2, Figure 2). The outer segment is about 1.4 μm in diameter and 24 μm in length for rods, and, correspondingly, about 1.2 μm and 13 μm for cones. These dimensions are significantly smaller than those of amphibian photoreceptors (Figure 1), which explain physiologists' longtime favor for the latter.

Rods and cones have four primary structural/functional regions: outer segment, inner segment, cell body and synaptic terminal. The outer segment is connected to the inner segment through a thin connecting cilium. The outer segment is filled with a dense stack of membrane discs (Figure 2 and Figure 3), spaced at intervals of about 28 nm. The discs carry the visual pigment (rhodopsin in rods and cone pigment in cones) and other transduction components either as transmembrane or peripheral membrane proteins (Figure 3). Visual pigment is the most abundant protein in the outer segment. The importance of visual pigment as a major structural component is demonstrated by the rhodopsin-knockout mouse, the rod outer segments of which fail to form (3, 4). The rod photoreceptors of this mouse degenerate, followed suit by cones. The packing density of pigment molecules on the discs is remarkably uniform across different vertebrate species, being ~25000 mm^2, corresponding to a concentration of ~ 3mM (5). The total number of pigment molecules in the outer segment can thus be calculated roughly from its envelope volume. The dense stack of discs greatly increases the probability of photon capture. An interesting difference between rods and cones is that the rod discs (except for the nascent discs at the base of the outer segment) are completely internalized and therefore physically separate from the plasma membrane, whereas the cone discs remain as foldings of the plasma membrane. The open cone discs offer a much larger surface area for rapid fluxes of substances between the cell exterior and interior, such as chromophore transfer for pigment regeneration and fast calcium dynamics during light adaptation.

The inner segment contains the endoplasmic reticulum and the Golgi apparatus. It is also packed with mitochondria immediately adjacent to the outer segment (Figure 2, Figure 3) in order to meet the high demand for metabolic energy associated with phototransduction. All proteins destined for the outer segment must pass through a narrow connecting cilium between the outer and the inner segments.

The synaptic terminal transmits the light signal to the second-order neurons in the retina: the bipolar and horizontal cells. In darkness, there is a steady inward current (the "dark current") through a cation conductance on the outer-segment membrane (6), depolarizing the rod or cone and maintaining a steady synaptic release of glutamate. Light closes this cation conductance (the "light-sensitive" conductance, consisting of cGMP-gated channels) to stop the dark current and produce a membrane hyperpolarization as the response. This hyperpolarization decreases or terminates the dark glutamate release. The signal is further processed by other neurons in the retina before being transmitted to higher centers in the brain.

Table 2. Physical dimensions of the outer segment of mouse rods and cones. Salamander and primate photoreceptors are included for comparison purpose.

		Rods			Cones

3. Can we see a single photon?

The minimum number of photons required to produce a visual effect was first successfully determined by Hecht, Schlaer and Pirenne in a landmark experiment (7). Human subjects were allowed to stay in the dark for 30 minutes to have optimal visual sensitivity. The stimulus was presented 20 degrees to the left of the point of focus so that the light would fall on the region of the retina with the highest concentration of rods. The stimulus was a circle of red light with a diameter of 10 minutes (1 minute=1/60th of a degree). The subjects were asked whether they had seen a flash. The light was gradually reduced in intensity until the subjects could only guess the answer. It was found that between 54 and 148 photons were required in order to elicit visual experience. After corrections for corneal reflection (4%), ocular media absorption (50%) and photons passed through retina (80%), only 5 to 14 photons were actually absorbed by the retinal rods. The small number of photons in comparison with the large number of rods (500) involved makes it very unlikely that any rod will take up more than one photon. Therefore, one photon must be absorbed by each of 5 to 14 rods in the retina to produce a visual effect.

In the same publication (7), Hecht and co-workers determined the visual threshold of human vision by the famous "frequency-of-seeing-curves" experiment. The theory is that photon absorptions vary according to a Poisson probability distribution. If *a* is the average number of photons absorbed per flash, the probability Pn that any number *n* will be absorbed is: $Pn = a^n/(e^a n!)$. Some of these Possson integral curves (n from 1 to 9) are shown in Figure 4. By measuring the frequency of seeing against the logarithm of the brightness experimentally, one can fit the experimental curve with one of the probability distribution in Figure 4b to reveal the value *n*, which lies between 5 and 8 (Figure 4b). This agrees well with the value 5 to 14 photons absorbed by rods!

4. Development of mouse photoreceptors

Rods and cones renew their outer segments continually (8, 9). Newly formed disks at the base of the outer segment progressively displace previously synthesized disks toward the apical end. The disks reaching the apex of the outer segment are shed and phagocytosed on a daily basis by the adjacent retinal pigment epithelium (RPE) (10). The rate of formation and disposal of the disks are roughly equal so that a constant outer-segment length is maintained in the adult retina.

The mouse rod outer segment (ROS) changes little in diameter during development, but it elongates at a rapid and almost linear rate from postnatal day (P) 11 to 17, reaching adult length by P19-25 (11). The increase in ROS length parallels the almost linear rise in rhodopsin content from P8 to P23 (12). At the peak rate of growth during P13-P17, ~120 disks are synthesized per day compared with 75 disks in adult retina (8, 11).

The dark current recorded in developing mouse rods increases roughly in direct proportion to the length of the mouse ROS between P12 (around the time of eye-opening in neonate) and P45 (adult) (13). The kinetics of the dim-flash response changes rather little during development and the flash sensitivity of rods increases by approximately 1.5-fold, reflecting the presence in neonatal rods of a small percentage (~1%) of free opsin (i.e.

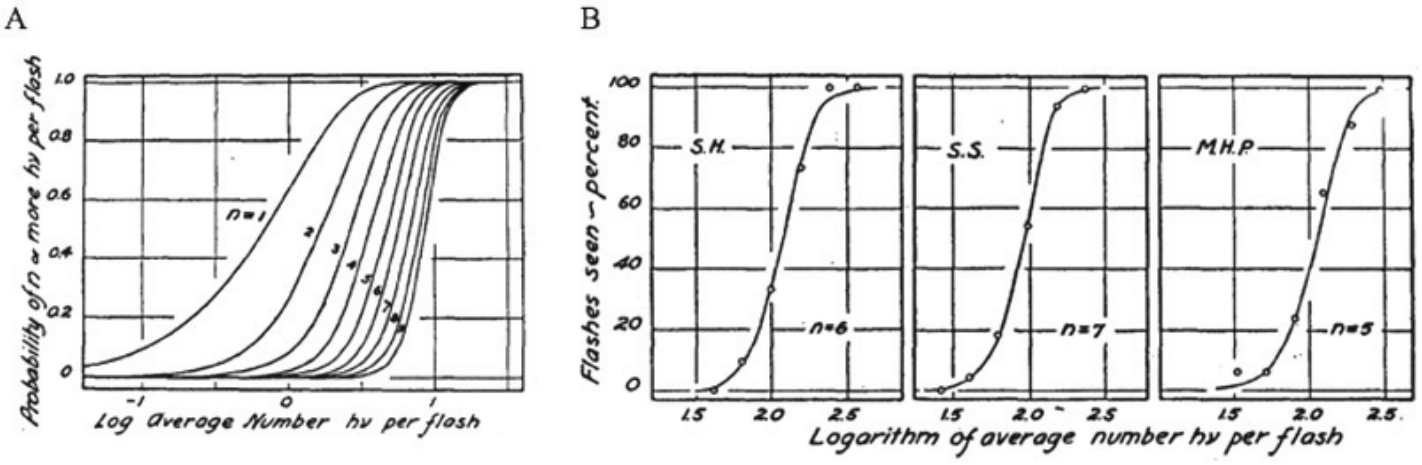

Figure 4. Frequency of seeing curve experiment. (A) Poisson probability distribution. For any average number of quanta (hv) per flash, the ordinates give the probabilities that the flash will deliver to the retina *n* or more photons, depending on the value assumed for *n*. (B) Relation between the average energy content of a flash of light (in number of (hv)) and the frequency with which it is seen by three observers. From Figs. 6 & 7 of Hecht et al (7).

devoid of chromophore) even after overnight dark-adaptation. The constitutive activity of this small amount of opsin mildly triggers adaptation mechanisms and therefore causes a small reduction in the sensitivity of the cell (see later). A similar small, age-dependent increase in rod sensitivity was found for rat. Previously, a 50-fold increase in rod sensitivity was reported for rat from neonate to adulthood (14), but now this appears to be incorrect.

5. Vertebrate rods are highly efficient photon detectors

Psychophysical experiments performed by Hecht, Schlaer and Pirenne in 1942 suggested that human retinal rods can detect single photons (7) (Figure 4). Thirty seven years later, suction pipette recordings from isolated toad rods by Baylor, Lamb and Yau confirmed this remarkable ability of vertebrate rods (Figure 5) (15). The amazing ability of vertebrate rods to detect single photons can be attributed to at least three factors: high quantum efficiency of photoactivation, low intrinsic noise, and a powerful signal amplification cascade. Two other factors greatly increase the photon capture ability of vertebrate rods, numerical dominance of rods over cones and a highly specialized outer segment structure. The dense stack of discs of the rod outer segment ensures that virtually every photon traveling axially will be captured. In a sense, vertebrate rods can be viewed as sophisticated three-dimensional photon capture devices.

6. Phototransduction in rods: a G-protein-signaling pathway

Rod phototransduction is one of the best-characterized G-protein-signaling pathways (Figure 6, Figure 7, Figure 8). The receptor is rhodopsin (R), the G protein is transducin (G), and the effector is cGMP phosphodiesterase (PDE or PDE6). Upon photon absorption, the rhodopsin molecule becomes enzymatically active (R*) and catalyzes the activation of the G protein transducin to G*. Transducin, in turn, activates the effector phosphodiesterase (PDE) to PDE*. PDE* hydrolyzes the diffusible messenger cGMP. The resulting decrease in the cytoplasmic free cGMP concentration leads to the closure of the cGMP-gated channels on the plasma membrane. Channel closure leads to localized reduction on the influx of cations into the outer segment, which results in membrane hyperpolarization, i.e. the intracellular voltage becoming more negative (Figures 6).) This hyperpolarization decreases or terminates the dark glutamate release at the synaptic terminal. The signal is further processed by other neurons in the retina before being transmitted to higher centers in the brain.

This phototransduction cascade is shown in Figures 6 and 7.

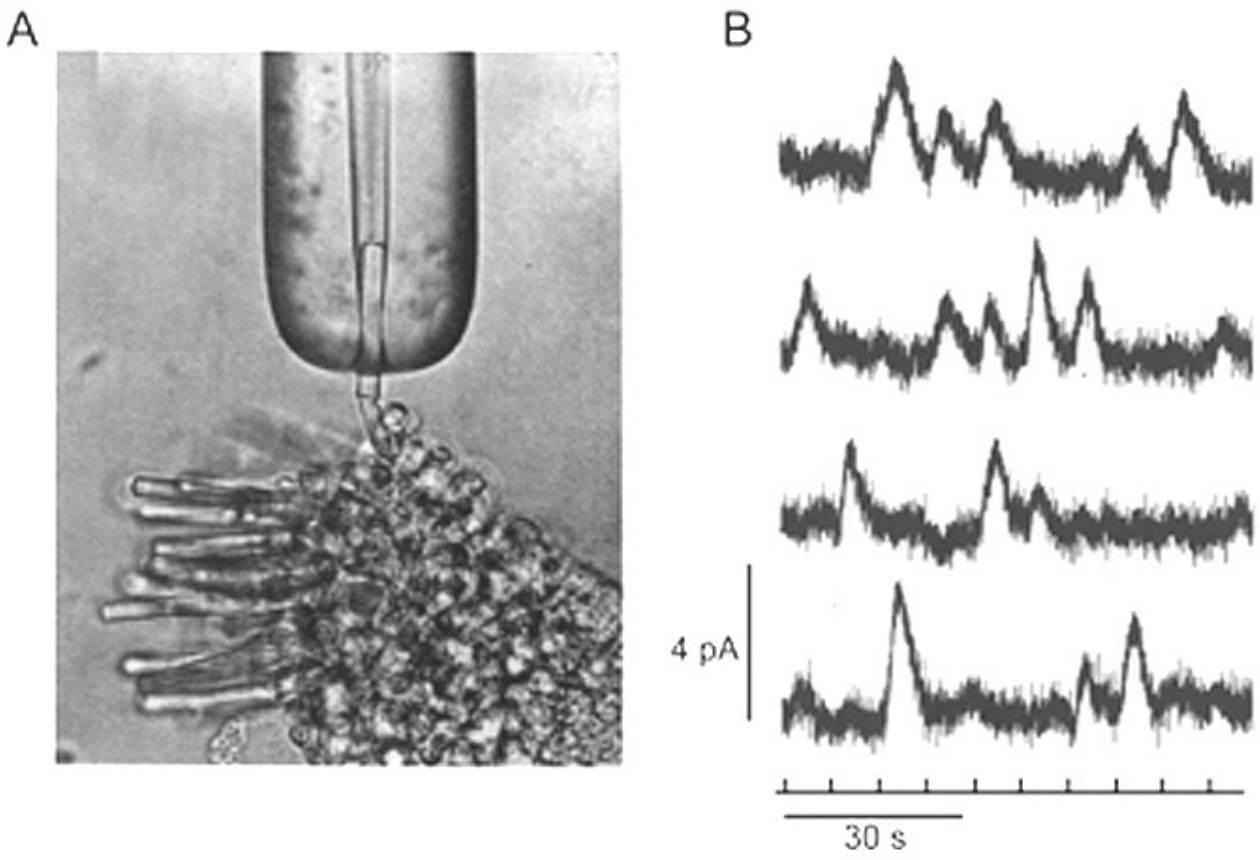

Figure 5. Suction-electrode recording on the membrane current of a single toad rod. (A) The outer segment of a rod projecting from a piece of retina was sucked in position in a suction electrode. Proximal end of cell remains attached to retina. Boundary between inner and outer segments is visible. (B) Response of rod outer segment to a series of 40 consecutive dim flashes. 20 msec flash delivering 0.029 photons μm^{-2} at 500 nm, flash timing monitored below. The rod showed no response to some flashes, or a small response of ~ 1 pA to others, and occasionally a larger response. This suggests that the flash response is quantized, as might be expected when on average very few photons are absorbed. With further analysis, the authors demonstrated that each quantal electrical event resulted from a single photo-isomerization with mean amplitude of ~ 1 pA - the single-photon response. Modified from Baylor et al. (15)

Following light activation, a timely recovery of the photoreceptor is essential so that it can respond to subsequently absorbed photons, and signal rapid changes in illumination (Figure 8). This recovery from light requires the efficient inactivation of each of the activated components: R*, G*, and PDE*, as well as the efficient regeneration of rhodopsin (R) and the rapid restoration of the cGMP concentration. The termination rates of the activation steps set the time course of the photoresponse.

Although rod phototransduction is the best characterized sensory transduction pathway, rods differ from other sensory cells in that light leads to hyperpolarization rather than depolarization. Rods respond to light with graded hyperpolarization whose amplitude increases monotonically as a function of flash intensity until saturation. One hallmark of rod phototransduction is the reproducibility of its single-photon response in both amplitude and kinetics. This is quite remarkable considering the fact that events generated by single molecules are stochastic in nature. The study on the underlying mechanisms has long been a hot topic in the vision field. Recent research pointed to two possible mechanisms: 1. Rhodopsin inactivation is averaged over multiple shutoff steps so that the integrated R* activity varies less than otherwise controlled by a single step. 2. Averaging over the deactivation of multiple G protein molecules is important for the constancy in response decay.

The details of the activation phase of rod phototransduction are now well established. A quantitative description is achieved that reproduces the activation kinetics of the rod response under physiological conditions (16-19).

We shall discuss below the major proteins mediating the activation phase in mouse rods - visual pigment, transducin, the effector PDE, and the cGMP-gated channel. The focus will be on studies with combined approaches from mouse genetics and physiology.

7. Visual Pigments of Mouse Rods and Cones

Mouse has a single rod pigment, rhodopsin, and two cone pigments: S- and M- cone pigments, with maximal spectral sensitivity at 360 nm and 508 nm, respectively. Mouse is unusual in that individual cones express both S- and M-cone pigments, with the M-pigment level decreasing in a gradient from dorsal to ventral retina (20).

Mouse rhodopsin and cone pigments belong to the super family of G-protein coupled receptors (GPCRs). A high-resolution (2.8 Å), three-dimensional structure of the ground state of bovine rhodopsin was determined in 2000 by Palczewski et al. (Figure 9a) (21, 22). The future challenge is to solve the structure of cone pigments, which is much more unstable than rhodopsin.

Visual pigments from most vertebrate species, including mammals, use 11-cis-retinal (denoted A1), while those from many water-based animals use 11-cis-3,4-dehydroretinal (denoted A2), as their natural ligand (23-25). George Wald first identified vitamin A in the retina (26) and later showed how it functions with light, which forms the molecular basis of vision (Nobel Prize 1967). The chromophore is covalently bound via a Schiff-base linkage to a conserved lysine residue (K296 in mammalian rhodopsin) in the seventh transmembrane helix (Figure 9a and 9b). In darkness, the 11-cis-retinal acts as an inverse agonist to lock rhodopsin in an inactive state by preventing free opsin from activating the transduction cascade. The "locking" role of 11-cis-retinal as was clearly demonstrated in RPE65-null mice. RPE65 functions as an isomerase in the RPE visual cycle, which is important for regenerating rod and cone pigments. $Rpe65^{-/-}$ retina has virtually no 11-cis-retinal (27). Rod photoreceptors degenerate slowly due to the constant activation of phototransduction by the large amount of free rod opsin. This degeneration can be prevented by deleting the transducin α-subunit, which blocks the activation of the downstream cascade (28). In a separate experiment, K296 is mutated to glutamic acid, producing an opsin with no chromophore-binding site (29). Although the K296E opsin constitutively activates transducin in vitro, the constitutive activity of the mutant opsin in vivo was turned off due to phosphorylation by rhodopsin kinase followed by arrestin binding (see R* termination).

Even with 11-cis-retinal attached, rhodopsin occasionally undergoes spontaneous (thermal) activation in the dark, producing responses identical to those triggered by photons (30). Spontaneous activation of visual pigment molecules sets an ultimate limit on visual sensitivity (31-34). In a toad rod, the rate of thermal activation of rhodopsin was measured to be 0.031 $s^{-1}rod^{-1}$ at 22 (C, corresponding to an average wait of 2000 years for the spontaneous activation of a given rhodopsin molecule to occur, based on a total of $2x10^9$ rhodopsin molecules per cell (35). This great stability makes it possible for rods to pack many rhodopsin molecules to the rod discs to increase their photon-capture ability while keeping the dark noise low. In wild-type mouse rods, it is rather difficult to measure the discrete noise arising from the thermal activation of rhodopsin because of the relatively small amplitude of the single-photon response. However, the measurement has been achieved with $GCAPs^{-/-}$ rods (36), the single-photon response of which is nearly five times that of wild type as a result of the elimination of the Ca^{2+}-mediated negative feedback on guanylate cyclase (see later). The rate is ~0.012 $s^{-1}rod^{-1}$ at 36°C.

It should be mentioned that the question of dark noise in vision has had a long intellectual history from the point of view of psychophysics and system neuroscience. As early as 1940s and 1950s, Hecht and Barlow have estimated the amount of "dark light" in human rods based on psychophysical experiments (7, 37). More than 30 years later, Baylor and colleagues used suction-pipette recording technique on primate rods to demonstrate that the very low quantal noise from rhodopsin, corresponding to ~ 0.01 event s^{-1} rod^{-1} in darkness), indeed matches the human psychophysical scotopic threshold. The quantitative agreement between the quantal noise measured from single rods and that measured in human psychophysics was considered a breakthrough in the

vision field and a wonderful convergence between cell physiology and human psychophysics/systems neuroscience - the goal of modern neuroscience after all!

Red cone pigment is much more prone to spontaneous isomerization than rhodopsin (38, 39), but it is difficult to measure the rate from native cones (38). By expressing human red cone pigment transgenically in GCAPs$^{-/-}$ rods, the rate of human red cone pigment was found to be surprisingly low at ~10 $s^{-1}cone^{-1}$ (molecular rate constant ~1.35 x 10^{-7} sec^{-1}) (40), almost 1000-fold lower than the overall dark transduction noise previously reported in primate cones (41, 42). Thus, the overwhelming amount of dark noise in the primate red cone originates not from spontaneous isomerization of the pigment, but most probably from constitutive activity in the downstream phototransduction steps, such as the phosphodiesterase (43).

The molecular rate constant for thermal isomerization of A2 human red cone pigment was determined to be ~5.6 x 10^{-6} sec^{-1} by expressing human red cone pigment in Xenopus rods (38). Since mammals use A1 chromophore, A1 red cone pigment is perhaps 40-fold less prone to spontaneous isomerization than the A2 form (40). This is likely due to the fact that the A2 chromophore has an additional double bond in the β-ionone ring, which has been suggested to lower the energy barrier for isomerization (44). Consequently, this introduces

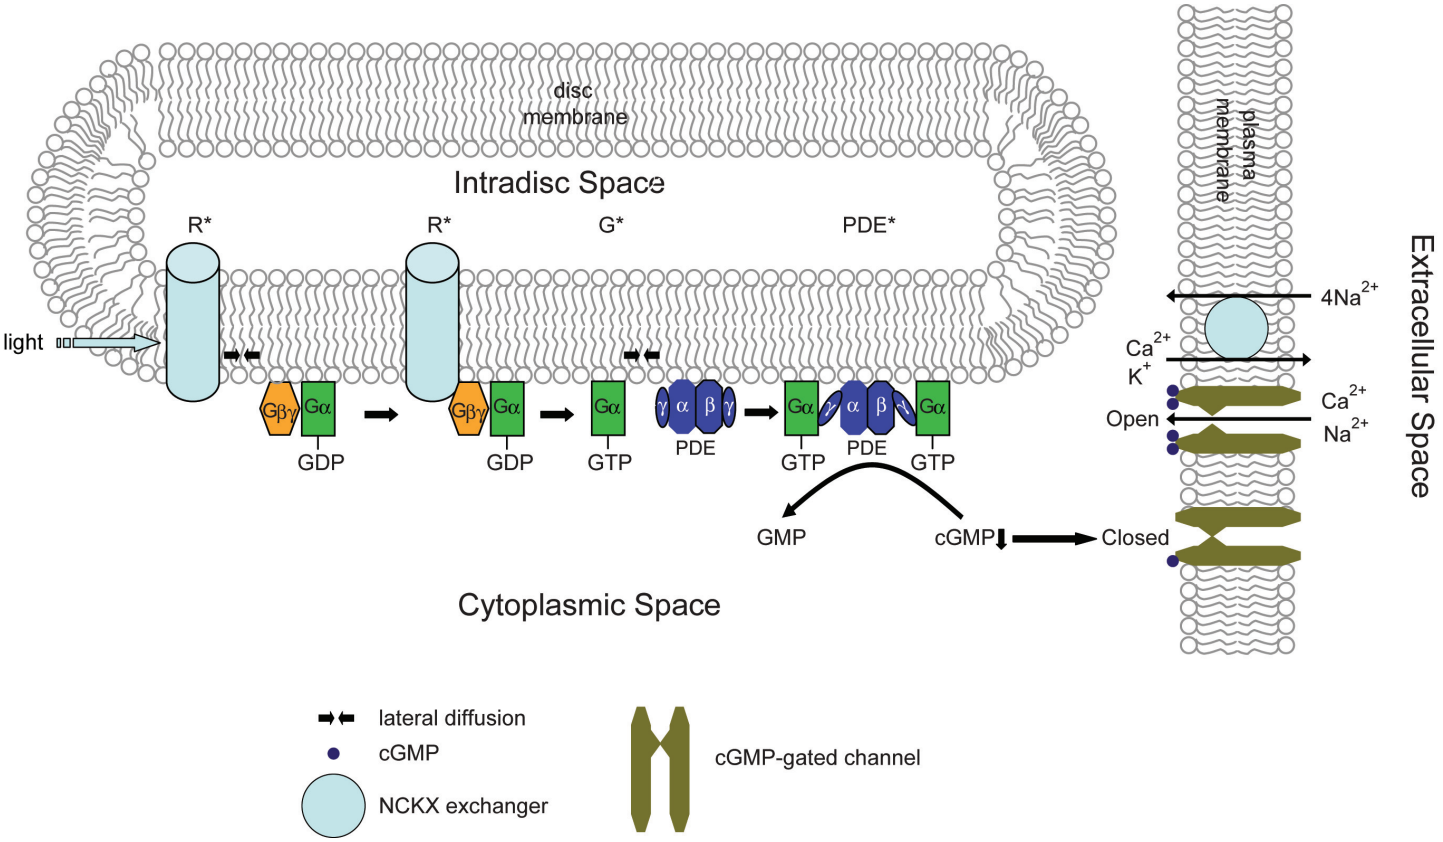

Figure 7. Schematic representation on the activation of vertebrate rod phototransduction. Following photon absorption, the activated rhodopsin (R*) activates the heterotrimeric G protein, catalyzing the exchange of GDP for GTP, producing the active Gα*-GTP. Two Gα*-GTP bind to the two inhibitory (subunits of PDE, thereby releasing the inhibition on the catalytic α and β subunits, forming PDE*, which in turn catalyzes the hydrolysis of cGMP. The consequent decrease in the cytoplasmic free cGMP concentration leads to the closure of the cGMP-gated channels on the plasma membrane and blockage of the influx of cations into the outer segment, which results in the reduction of the circulating dark current.

a red shift in absorption (45) and decreases the thermal stability of the A2 pigment. Incidentally, A1 rhodopsin was found to be 30 times more stable than A2 rhodopsin, rather similar to the finding for red cone pigment (46). More importantly, unlike in lower vertebrates such as salamander where A2 red cone pigment is sufficiently noisy as to impose a potential adaptational influence on cones even in darkness (38, 39, 47), A1 red cone pigment (and likewise for green and blue cone pigments) in primates and presumably other mammals should be quiet enough to have hardly any adaptational influence on cone sensitivity. In other words, the much lower absolute sensitivity of mammalian cones compared to mammalian rods appears to arise not from quantal noise in the pigments themselves, but from other phototransduction steps (48-50). This may explain why primate red, green and blue cones, unlike their amphibian counterparts (51, 52), all have similar sensitivities irrespective of their difference in visual pigments (41).

Photon absorption by 11-cis-retinal triggers the cis-to-trans isomerization of the retinoid chromophore (53, 54). As early as in the 1930s-1950s, vision scientists knew that rhodopsin bleaches in stages over intermediates that were short-lived at room temperature, yet stable at low temperatures (55-57), (Figure 10). Hubbard and Kropf measured the "bleaching intermediates (a mixture of lumirhodopsin and metarhodopsin) " by spectrophotometry at -17 °C (58). Photo-isomerization rapidly converts the ligand from a powerful inverse agonist to a powerful agonist, leading to the formation of a series of spectrally distinct intermediates of rhodopsin in the order of bathorhodopsin, lumirhodopsin, metarhodopsin I (Meta I), and metarhodopsin II (Meta II) within a few millisecond (Figure 10) (reviewed in Okada and Palczewski, 2001 (59)). Meta II is the active form of rhodopsin (R*), which in turn decays to the inactive Meta III. The Meta-II state of cone pigment

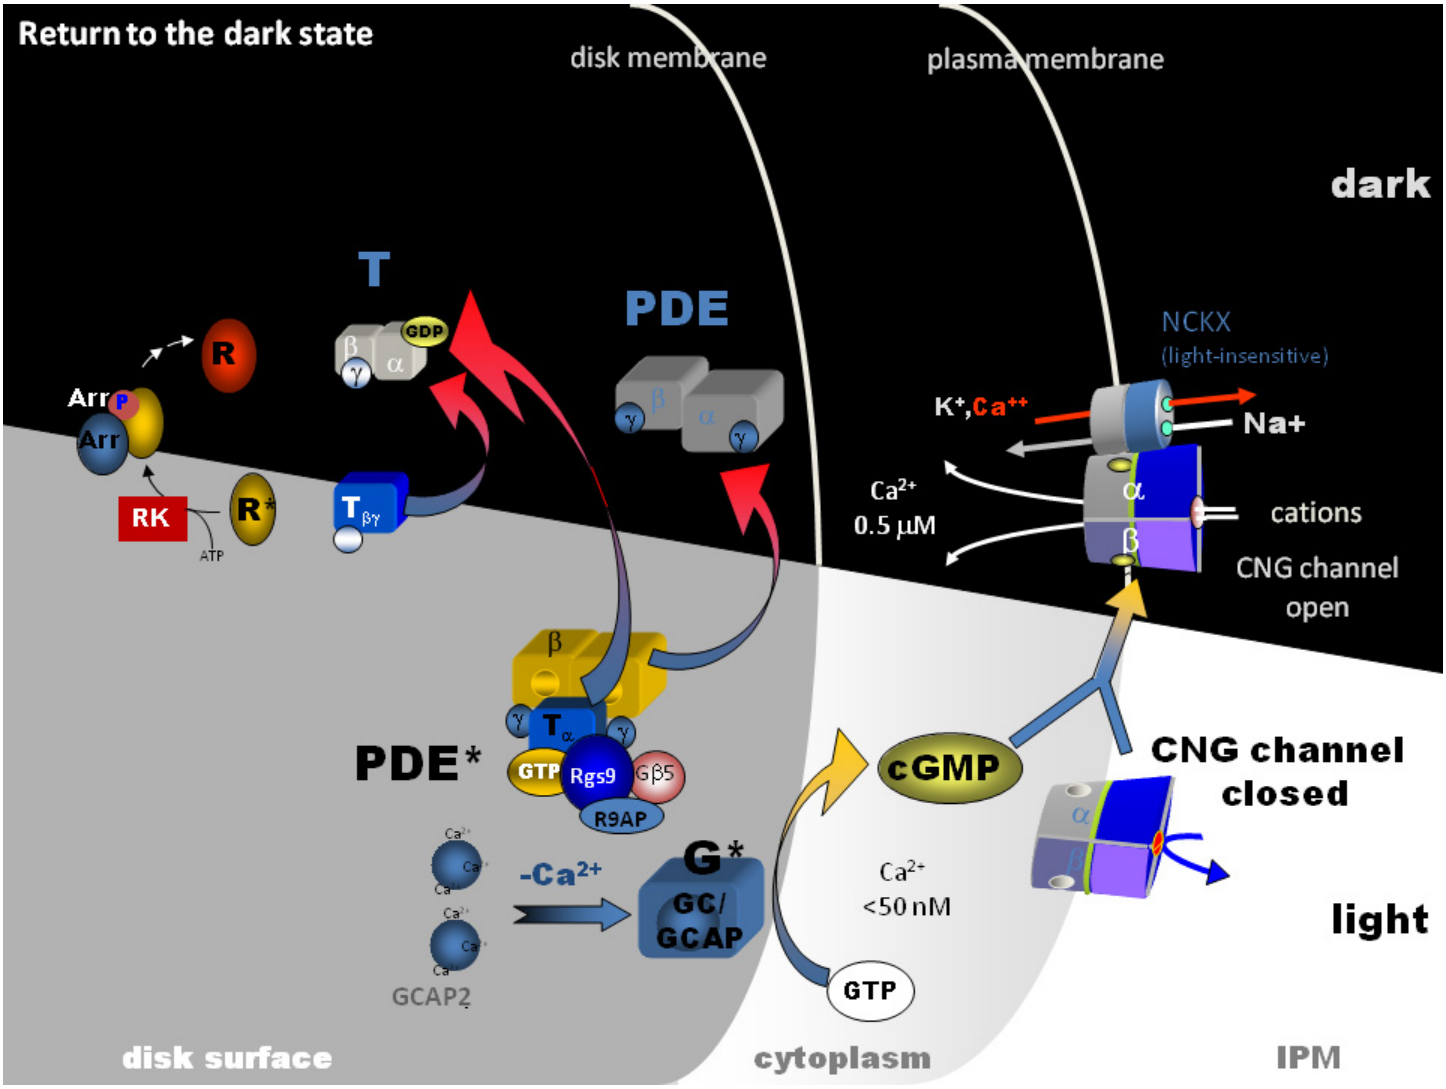

Figure 8. Recovery of rod phototransduction cascade that results in the re-openning of cGMP-gated channels on the plasma membrane (from light to dark state). decays 50 times more rapidly than that of rhodopsin (60-62). Despite this difference, rhodopsin and transgenic red cone cone pigment, and vice versa, signal identically downstream when compared side-by-side in the same Xenopus rod or cone (38). The same was found for rhodopsin and transgenic red cone pigment in mouse rod (40). Thus, not only do rod and cone pigments interact with a given transducin, pigment kinase and arrestin in quantitatively identical ways, but the shutoff mediated by pigment kinase and arrestin also precedes the Meta-II decay of rod and cone pigments, rendering the decay of Meta II non-rate-limiting under normal conditions (see R* termination).

Retinal absorbs maximally in the UV-range (max ~380 nm) when in solution or bound to opsin in the unprotonated form. The absorption shifts into the visible region when the Schiff-base (SB) is protonated. Like other vertebrate pigments, mouse rhodopsin and M-cone pigment are protonated. On the other hand, mouse S-cone pigment is unprotonated, explaining its absorption in the UV-region (63). The positively charged Schiff-base is stabilized by the counterion E113 (residue number according to mouse rhodopsin) in rhodopsin and M-cone pigment (21, 64-66). Rhodopsin activation involves a "counterion switch" mechanism in which E181

located in the extracellular loop II transfers a proton via a hydrogen-bonded network to the primary counterion, E113, during the formation of Meta I. Therefore, E181 replaces E113 as the counterion to stabilize the protonated Schiff-base in the transition stage before its eventual deprotonation ((67), Figure 11).

Because the mouse S-cone pigment is not protonated and the nearby E113 is neutral, the interesting questions are: does a protonation event occur during light activation, and does it involve a "counterion switch" mechanism? Remarkably, after the 11-cis isomerization, the Schiff-base picked up a proton in the Lumi state from E108 to become transiently protonated (68) and a counterion switch occurs from E108 (E113 in rhodopsin) to E176 (E181 in rhodopsin) during the Lumi to Meta I transition, in close analogy to rhodopsin ((69), Figure 12). The photoactivation mechanism of S-cone pigment, SB → PSB (protonated Schiff-base) (+):E108(-) → PSB(+):E176(-) → SB, makes vision possible in the UV region. Thus, the counterion switch appears to be a general mechanism for the activation of all visual pigments.

The decay of R* eventually leads to the departure of all-trans-retinal from the protein. The all-trans chromophore is converted back to 11-cis-retinal through a cascade of enzymatic reactions called the visual cycle in the adjacent RPE, before being used again for the regeneration of visual pigments (for example, see review McBee et al., 2001 (70)).

Visual pigment is a major structural component of rods and cones. It is not surprising that genetic deletion of mouse rhodopsin results in rods without proper outer-segment formation (3, 4). Is half the amount of normal rhodopsin enough for maintaining a healthy ROS? In rho$^{+/-}$ mouse, rods are properly formed despite only half of the normal level of rhodopsin being present. However, a progressive mild degeneration of the rods does occur. Interestingly, the activation rate of the photoresponse of rho$^{+/-}$ rods is twice that of normal (71). The explanation for this observation was originally proposed that a lower rhodopsin concentration reduces protein crowding on the disc membrane, thereby increasing rhodopsin's diffusion coefficient and its rate of encounter with transducin. This finding thus would point to the diffusional encounter of transducin by photoexcited rhodopsin as the rate-limiting step in the activation of the rod photoresponse. However, Liang et al. subsequently reported that rods in rho$^{+/-}$ mouse are not completely normal in that rhodopsin exists in small raft-like structures as well as in large and organized para-crystals (72). In addition, there is an approximate 40% reduction in the ROS volume, in the rhodopsin content and in the 11-cis-retinal level in these cells. These authors suggested that the observed acceleration of phototransduction in rho$^{+/-}$ rods was not due to a lower density of rhodopsin on the disc surface but to the structural changes in the whole ROS.

8. High quantum efficiency of photoactivation

The quantum efficiency of photoactivation measures the probability that the adsorption of a photon initiates photoactivation. This probability is defined as the ratio between the number of photoactivated molecules and the number of molecules that absorbed a photon. Quantum efficiency of visual pigments is wavelength-independent at ~ 0.7 in the spectrum of visible light whereas it falls to about 0.25 for wavelengths shorter than 300 nm (73). This suggests that every absorbed photon in the visible range can activate rhodopsin equally well. The quantum efficiency of 0.7 is very similar across all visual pigments. This high efficiency seems to be a common feature of most vertebrate visual pigments.

9. The activation of transducin constitutes the first amplification step

Photoactivated pigment binds the transducin heterotrimer and catalyzes the exchange of GTP for GDP on the α-subunit. Gα-GTP (G*) dissociates from R* as well as its native partners, Gβν and interacts with the cGMP phosphodiesterase (PDE) to carry the signal forward. Released R* is free to activate additional transducin molecules. Transducin activation by R* represents the first amplification step in the phototransduction cascade.

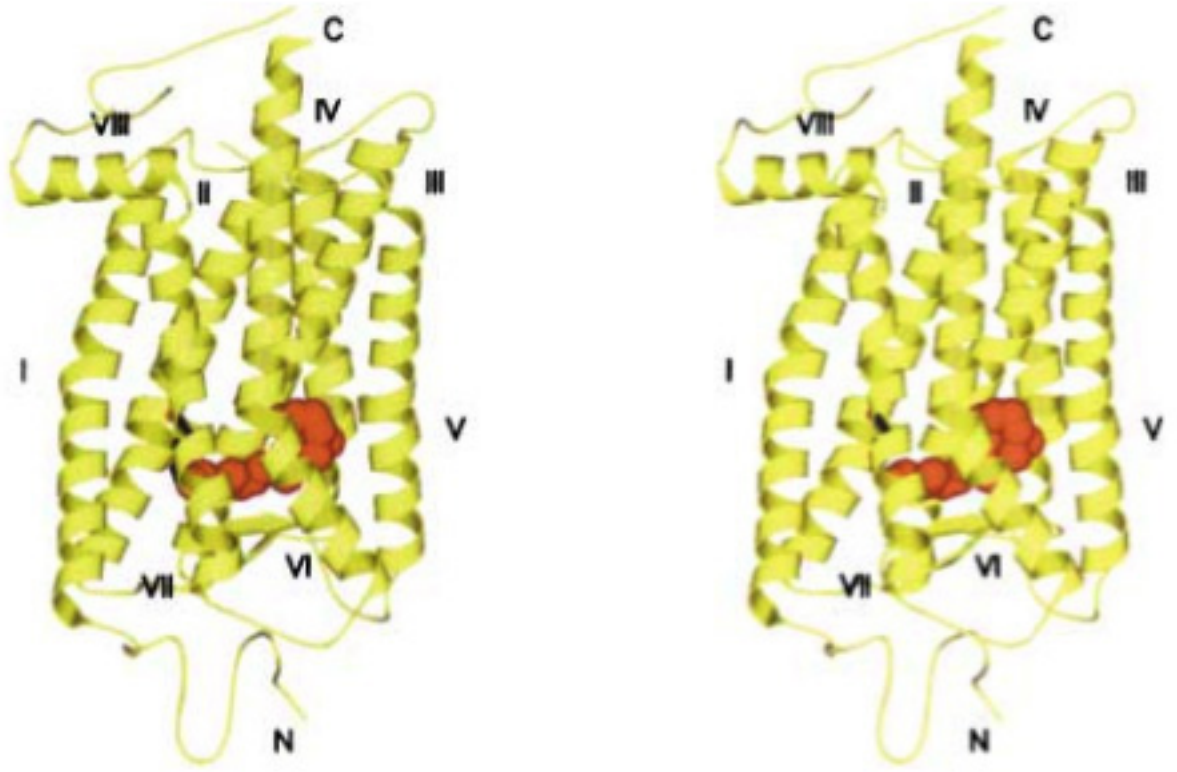

Figure 9a Stereo pair of the crystal structure of rhodopsin. From Stenkamp et al. 2002 (209).

The estimated rate of transducin activation by a single R* has ranged from 10 to over 3000 s^{-1} at room temperature (for review see Pugh and Lamb, 1993). More recently, a rate of ~ 120 s^{-1} was reported to be more consistent with biochemical, light-scattering, and electrophysiological measurements ((74), but see (75)). The rate is roughly doubled in mammalian rods due to a difference in body temperature. Until recently, it was believed that over a hundred transducins are activated during the lifetime of a single R* in mammalian rods (76). This number is now revised to be ~ 20 in mouse rods, based on the shorter life time of R* (80 msec) and 240 s^{-1} activation rate of transducin by R* (77).

Transducin is present at 10% the amount of pigment. Rods and cones have different isoforms of transducin, being $G\alpha t_1 G\beta_1\gamma_1$ in rods and $G\alpha t_2 G\beta_3\gamma_8$ in cones (78-81). The C-terminal of the γ subunit is farnesylated and the N-terminal of the α subunit is acylated (82-84). These lipid modifications help anchor the holo-transducin to the disc membrane. The importance of transducin for conveying the signal from R* to PDE was confirmed by gene-targeting experiments, in which rods of Gαt1-null mice (gnat1$-/-$) were found to lose all light sensitivity (85). The gnat1$^{-/-}$ mouse line has proven to be a valuable tool for blocking rod phototransduction in many studies (86-88). It was also used successfully to delineate two apoptotic pathways in light-induced retinal degeneration (89). Bright light triggers apoptosis of photoreceptors through a mechanism requiring the activation of rhodopsin but not transducin signaling. In contrast, low-intensity light induces apoptosis that is predominantly dependent on transducin signaling.

Almost two decades ago, rod transducin was found to undergo light-dependent redistribution (164, 219). Great progress has been made in the past few years by using mouse (or rat) models for study. Both Gαt2 and $G\beta_1\gamma_1$ subunits are present predominantly in the ROS in darkness, but translocate in bright light, with slightly different time courses, to the inner segment and the inner nuclear layer (90). This phenomenon has been suggested to contribute to light adaptation of rods (91), but others argue that the main function of transducin translocation is to provide protection for rods in bright light when rods contribute little to vision (92). In contrast, Gαt2 has been

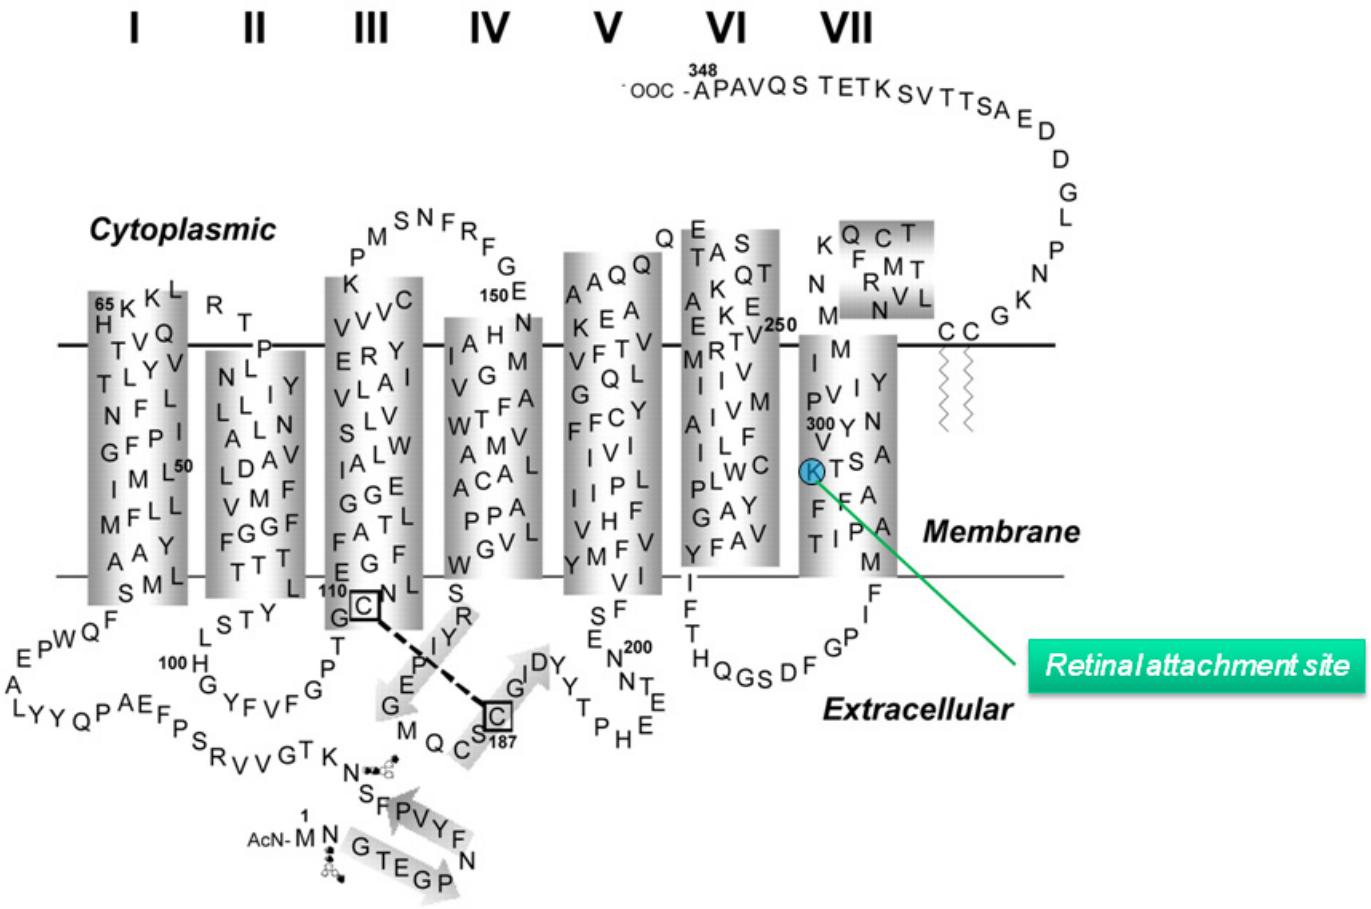

Figure 9b. Structural model of bovine rhodopsin showing seven transmembrane components and the attachment site for retinal. The seven-TM helices are shown by numbered gray boxes, and β-strands are shown by arrows. The respective residue ranges of these TM helices are as follows: I, 35-60; II, 71-100; III, 107-137; IV, 151-173; V, 200-225; VI, 247-277; VII, 286-306; VIII, 310-324. The dashed line indicates the C110-C187 disulfide bond located at the interface between the TM and EC domains. Reprinted from (208)

found not to translocate from the cone outer segment (COS) in light under physiological conditions (92-94) and only translocates away from the cone outer segment under very high-intensity light (95). This might be consistent with the need for cones to function in bright light (92).

$G_{\gamma 1}$ in rods and $G_{\gamma 8}$ in cones are farnesylated with a 15-carbon chain, but all other G_{γ} subunits are geranylgeranylated with a 20-carbon chain. What is the significance of this difference? Knock-in mice expressing geranylgeranylated instead of farnesylated $G_{\gamma 1}$ exhibited impaired properties in light adaptation because the stronger attachment by geranylgeranylation attenuated the light-dependent translocation of $G_{\gamma 1}$ from ROS to the inner region (90). It thus appears that the selective farnesylation is important for the regulation of visual sensitivity by providing sufficient but not excessive anchoring of $G\beta_{1\gamma 1}$ to the membrane.

10. The high catalytic power of PDE accounts for the second amplification step

PDE is the third component of vertebrate phototransduction. It is a tetrameric protein consisting of two equally active catalytic subunits, α and β, and two identical ν subunits (96-98). PDE is anchored to the disc membrane by isoprenylation of the C-termini of the two catalytic subunits (99, 100). The density of PDE is ~1-2% of rhodopsin. Thus, the first three components of phototransduction are present in the ratio of 100R:10G:1PDE.

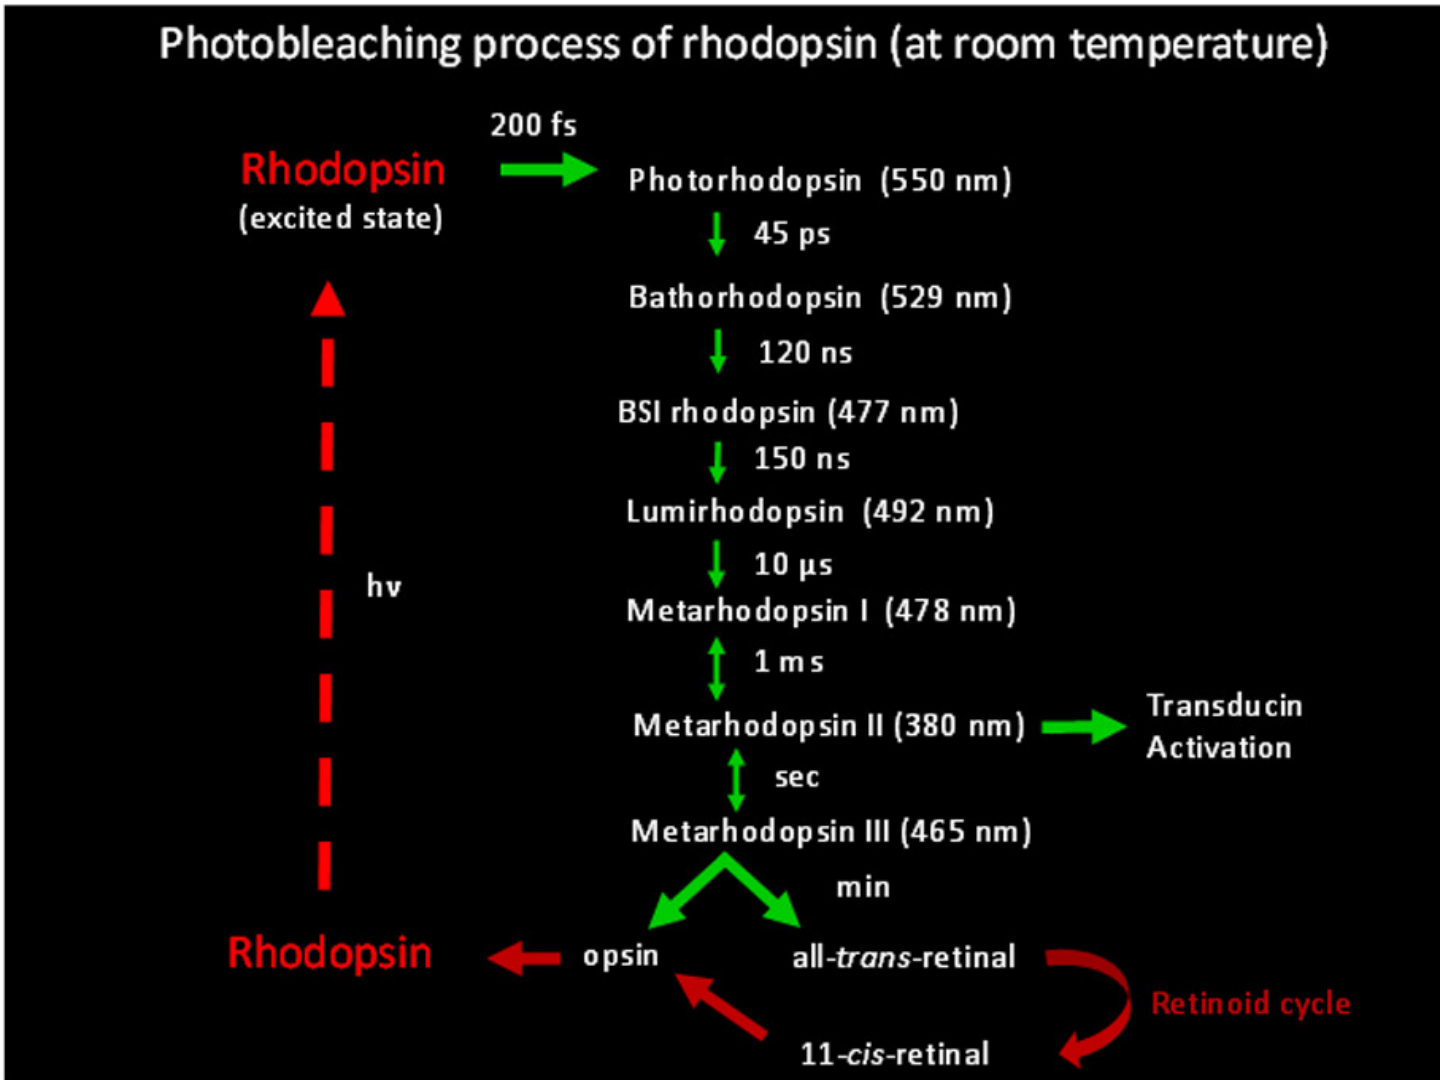

Figure 10. Photobleaching process of bovine rhodopsin. After photon absorption and electronic excitation, fast isomerization of the chromophore leads to the formation of a series of intermediate states of rhodopsin. This is called the "bleaching process" because rhodopsin loses its color. The intermediate states were identified by both low-temperature and time-resolved spectroscopy. The peak spectral sensitivity of each state was indicated. BSI, blue-shifted intermediate. Modified from Wolfgang Baehr.

In the dark, the two γ subunits act as inhibitory subunits by binding to the two catalytic subunits. In the light, Gα-GTP encounters PDEγ and sterically displaces the latter (still associated with PDEαβ, therefore relieving its inhibitory effect on the catalytic subunits and permitting the hydrolysis of cGMP to proceed.

In contrast to the amplification achieved during transducin activation by R*, the activation of PDE by G* constitutes no gain, i.e. with an efficiency approaching at most unity. It is the catalytic power of PDE* that provides the second amplification step. It was reported that PDE* hydrolyzes cGMP at a rate close to the limit set by aqueous diffusion, with a Km of ~ 10 µM and a Kcat of 2200 s^{-1} (74, 96). The combined amplification provided by rhodopsin and PDE are very high (~ 10^5-10^6), ensuring the high sensitivity of rods, including the ability of rods to detect single photons (for review see (19, 101)).

One might have expected that the deletion of PDEγ from mouse rods would unleash the full catalytic power of PDEαβ. However, Tsang et al. found that, in the absence of PDEγ, the PDEαβ dimer actually lacked hydrolytic activity, and the photoreceptors of the mutant mouse rapidly degenerated (102). Thus, the inhibitory PDEγ subunit appears to be necessary for the integrity of the catalytic PDEαβ subunits. The degeneration might be caused by an abnormally high cGMP concentration due to the lack of hydrolysis. A related example is the rd

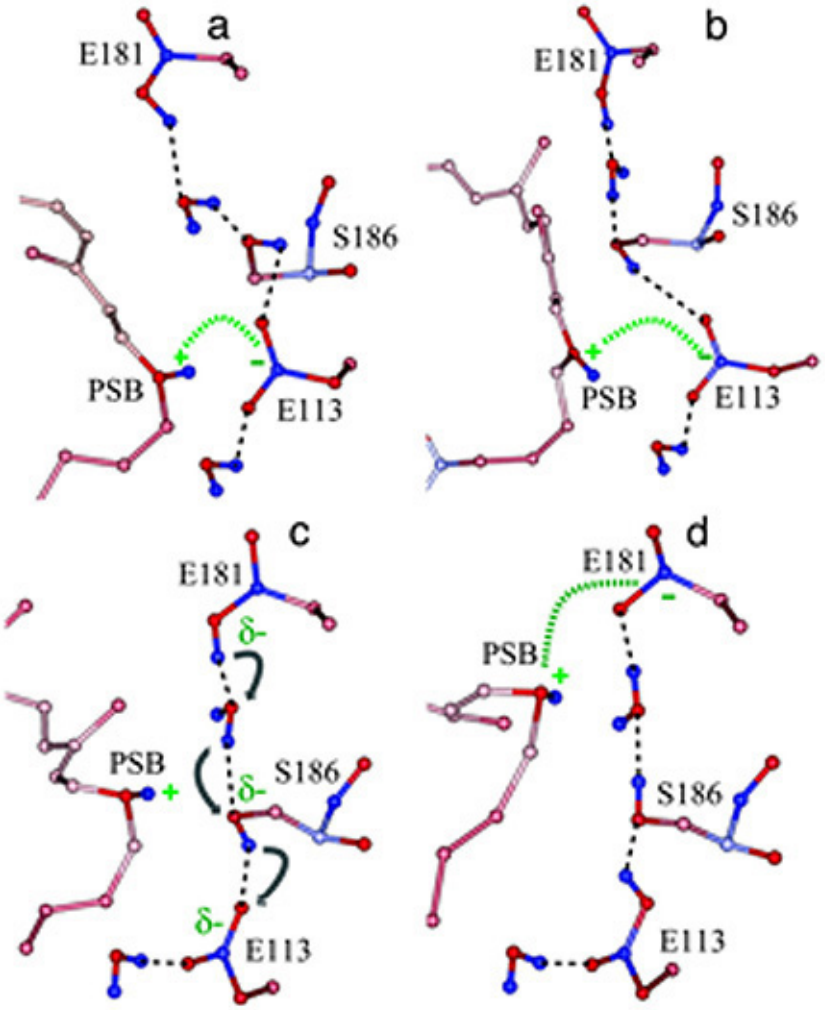

Figure 11. Schematic of the proposed proton transfer mechanism for switching the protonated Schiff-base (PSB) counterion in rhodopsin. (a) Rhodopsin: two water molecules and Ser-186 form a H-bond chain between Glu-113 and Glu-181. Electrostatic interaction between the PSB and Glu-113 is indicated by the green dashed line. (b) Blue-shifted intermediate: after photoisomerization, the H-bond chain evolves so that the two water molecules and Ser-186 are lined up to prepare for the proton transfer and the PSB has shifted relative to Glu-113. (c) Lumirhodopsin: the PSB shifts further away from Glu-113 toward Glu-181. The gray arrows indicate a possible proton transfer pathway. (d) Metarhodopsin I: proton transfer is completed. The PSB group is now close to Glu-181 to establish the electrostatic interaction (green dashed line) with the new counterion. Reprinted from Yan et al., 2003 (67).

mouse, which is one of the best-known models for retinal degeneration. The rod cells in the rd mouse begin to degenerate at about P8, followed by cones; by 4 weeks, virtually no photoreceptors are left (103, 104). Degeneration in this mouse model is preceded by the accumulation of cGMP in the retina, correlated with deficient activity of the rod PDE due to a mutation in the β subunit (105, 106). It is worth noting that the rd mouse was instrumental in suggesting that inner retinal neurons could mediate non-image-forming vision (107, 108).

In addition to its inhibitory function, PDEγ accelerates the GAP (GTPase Activating Protein) activity of G* for self-shutoff (see G*-PDE* termination). Mouse rods carrying the W70A point mutation of PDEγ which impairs the $G\alpha t_1$-PDEγ interaction, showed a greatly reduced sensitivity to light and a slower recovery from the flash response than wild type (109).

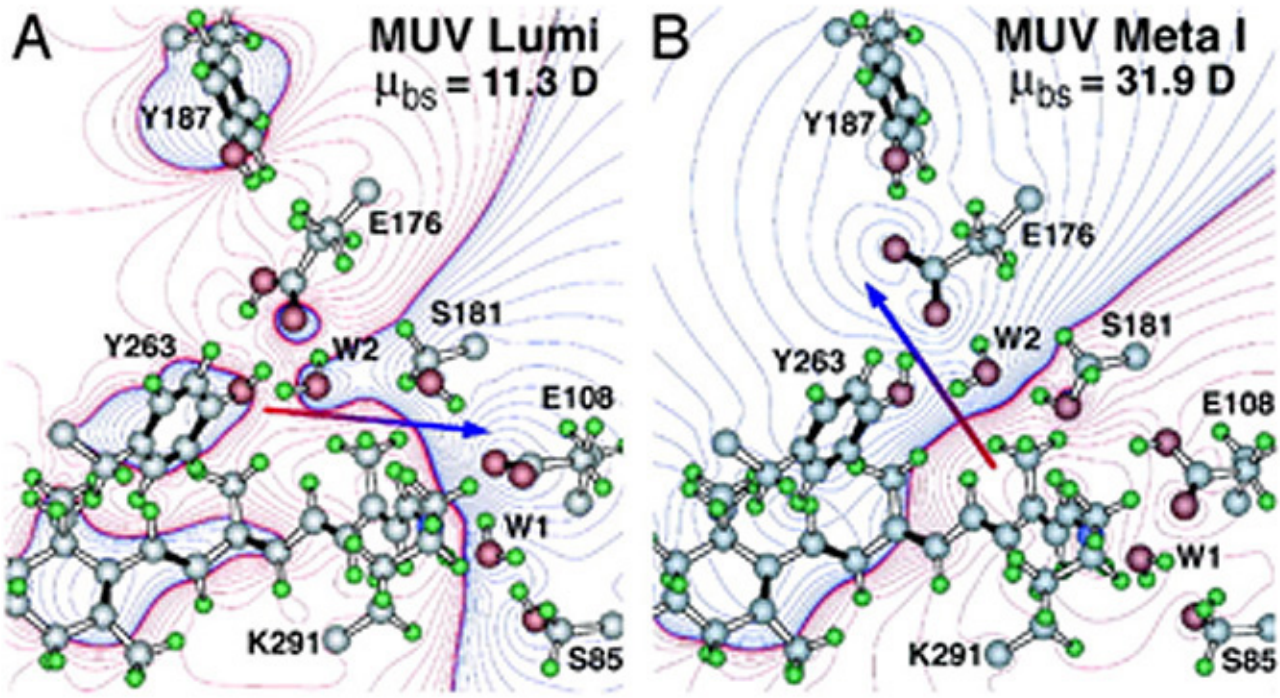

Figure 12. Molecular models of the lumi (A) and meta I (B) intermediates of mouse S-cone (UV) pigment based on the assumption that a counterion switch occurs during the lumi (E108 counterion) to meta I (E176 counterion) transformation. The dipole moments of the binding site residues, μ_{bs}, are given in the upper right of A and B and the dipole moment vector is shown by using red-to-blue arrows. 11. cGMP is the second messenger mediating rod phototransduction

By 1970, scientists generally believed that a second messenger was required to mediate the rod photoresponse based on several lines of evidence. First, light absorption occurs on the rod disc membrane, whereas the light sensitive conductance is in the plasma membrane. Since rod discs are separate from the plasma membrane, a second messenger is required to connect the two. Second, the dim-flash response of rods lasts a few seconds, which is too long to be accounted by the open time of known membrane conductance. However, it took more than a decade before the identity of the second messenger was finally determined to be cGMP (reviewed in (110). The "fierce battle was fought" on the validity between two competing candidates, Ca^{2+} and cGMP. According to the Ca^{2+} hypothesis, which was first proposed by Hagins (6), the concentration of intracellular free Ca^{2+} is low in the dark and rises in the light to block light-sensitive current. The main supporting evidence was that reducing the concentration of external Ca^{2+} dramatically increases the dark current, suggesting internal Ca^{2+} inhibits the dark current. On the other hand, the cGMP hypothesis proposed that the concentration of cGMP was high in the dark to maintain a cGMP-dependent conductance. Light led to the hydrolysis of cGMP and the subsequent closing of the conductance. The supporting evidence is that intracellular injection of cGMP increases the amplitude and latency of the photoresponse. Adding to the complexity is the finding that the free cGMP concentration varies inversely with the free Ca^{2+} concentration in rods, making it difficult to separate the effect of the two.

This debate was finally settled with the discovery of cGMP-gated channels in rods by Fesenko and colleagues in 1985 (111). By using the patch-clamp technique, they showed that cGMP increased a cation conductance of

inside-out patches of outer-segment plasma membrane without the need of ATP. The direct channel gating by cGMP is surprising because cyclic nucleotides were generally believed to act through cyclic-nucleotide dependent kinases and protein phosphorylation on target proteins at that time. This dogma partially explained scientists' reluctance to embrace the cGMP hypothesis because protein phosphorylation was too slow. Another monumental work by Yau and Nakatani was published at the same year that helped the anointment of cGMP as the right candidate (112). An identical cGMP-gated cation conductance was found on a truncated rod outer segment with an intact plasma membrane. Most importantly, this conductance could be suppressed by light, suggesting that the long-sought light-sensitive conductance is the cGMP-gated conductance. The publications by Fesenko and Yau marked the end of the Ca^{2+} hypothesis.

12. The cGMP-gated channel provides the final step of photo-activation

The cGMP-gated channel belongs to the family of cyclic-nucleotide-gated (CNG) channels, which are non-selective cation channels (reviewed in (113, 114)). The channel is located on the plasma membrane and is the last component in the activation phase of phototransduction. In the dark, a basal concentration of one to several μM cGMP keeps a small percentage of the CNG channels open (115). The decline in cGMP concentration upon illumination leads to rapid closure of the channels with a sub-millisecond delay (116). The gating of the rod channel by cGMP is cooperative with a Hill coefficient of ~ 3; therefore, the light-triggered suppression of the dark current is 3 times larger than the decrease in the intracellular cGMP concentration.

For a long time, the rod channel was believed to be a hetero-tetramer consisting of 2 CNGA1 and 2 CNGB1 subunits. In 2002, a number of laboratories made the surprising discovery that the rod channel actually has a 3CNGA1:1CNGB1 subunit composition (117-119), whereas the cone channel supposedly exhibits a 2CNGA3: 2CNGB3 stoichiometry (120). CNGA1 and CNGA3 subunits form functional homomeric channels by themselves when heterologously expressed. Although CNGB1 and CNGB3 do not form functional channels by themselves, they confer several properties typical of native channels when co-expressed with A subunits: flickery opening behavior, increased sensitivity to L-cis-diltiazem (a CNG channel-specific inhibitor), and weaker block by extracellular calcium (113, 121-123).

In humans, mutations in CNGA1 causes retinitis pigmentosa (124), while mutations in both CNGA3 (125) and CNGB3 (126) cause achromatopsia. Mouse models carrying null mutations of CNGB1 (127) and CNGA3 (121) are available. CNGB1 was found to be crucial for the targeting of the native CNG channel in rods. Thus, only trace amounts of the CNGA1 subunit were found on the ROS in CNGB1-null mice and the majority of rod photoreceptors failed to respond to light (127). CNGA3-deficient mice selectively lost their cone photoresponse with the rod pathway intact. Analogous to the case of rod transducin, CNGA3-null mice were used to block cone phototransduction in studying the intrinsically photosensitive retinal ganglion cells (86, 87).

In the dark, the concentration of free cGMP in the rod outer segment was estimated to be several μM, which is lower than the K1/2 (~ 10-40 μM depending on Ca^{2+} concentration), the concentration of cGMP necessary to half-maximally activate the channel. As a result, only ~ 1% of the CNG channels are open! In other words, 99% of the channels are already closed in the dark and light can only suppress the remaining 1% channels. This explains why current induced by cGMP injection is more than 10 times larger than the dark current.

The inward current through the cGMP-gated channel is composed of ~85% Na^+ because Na^+ is the predominant external cation and the channel is non-selective to monovalent cations. The remaining current is mainly carried by Ca^{2+} with a minor contribution from Mg^{2+} (115, 128). Extracellular Ca^{2+} actually partially blocks the channel to reduce its conductance under physiological conditions. The inward current is balanced by an outward current flowing across the inner-segment membrane, which is mainly carried by potassium ions. This "circulating current" is also called "dark current" in both rods and cones (6). Unlike other ligand-gated

channels, the CNG channel does not desensitize to cGMP, which is important for rods to maintain a steady dark current ranging between 20 and 70 pA in vertebrate rods. The rod photoresponse is essentially a transient suppression of the circulating current. It was estimated that the dark current was carried by ~ 10, 000 channels. The participation of large numbers of "micro" channels averages out the channels noise, i.e. reduce an otherwise substantial stochastic channel noise if the dark current were carried out by a few "macro" channels. This feature improves the sensitivity of rods.

Two extrusion mechanisms are critical to maintain ionic balance in rods. An energy-dependent Na-K ATPase at the inner segment pumped Na^+ out and K^+ into the cells. A Na/Ca,K exchanger (NCKX) in the outer-segment plasma membrane extrudes one Ca^{2+} and one K^+ outward in exchange for four Na^+ inward producing the net entry of one positive charge. The exchanger and the CNG channel were found to form a stable complex on the plasma membrane, likely as a way to control the stoichiometry between the two, which is critical for regulating Ca^{2+} concentration in the rod outer segment. During the light response, the influx of Ca^{2+} is reduced due to the closure of some CNG channels while the efflux of Ca^{2+} through the exchanger is maintained. The resulting Ca^{2+} decline triggers negative feedback to produce light adaptation.

13. Phototransduction termination

Following light activation, a timely recovery of the photoreceptor is essential so that it can respond to subsequently absorbed photons, and signal rapid changes in illumination. This recovery from light requires the efficient inactivation of each of the activated components: R*, G*, and PDE*, as well as a rapid restoration of the cGMP concentration. The termination rates of the activation steps set the time course of the photoresponse.

In the past decade, knowledge gained from genetically engineered mouse lines has provided major advances in understanding the termination of the rod photoresponse. In the following sections, we shall discuss separately the events responsible for the inactivations of R*, G* and PDE*, followed by the restoration of cGMP.

14. R* termination

Activated rhodopsin (R*) is inactivated by a two-step process. First, R* is phosphorylated by rhodopsin kinase (GRK1), which lowers the activity of R*. Second, the protein arrestin (Arr1) binds to phosphorylated R*, capping its residual activity (129, 130).

Multiple serine/threonine residues at the C-terminal of rhodopsin (six in mice and seven in humans) provide the phosphorylation sites for GRK1. Cone pigments have more potential phosphorylation sites at the C-terminal than rhodopsin. For example, human red cone pigment has 10 such sites. Even though biochemical experiments originally suggested that rhodopsin is predominantly phosphorylated at only one serine residue following light exposure (131), subsequent recordings from transgenic mouse rods carrying phosphorylation-site mutations suggested that the reproducible deactivation of R* requires at least three phosphorylation events (132). In addition, all six sites need to be phosphorylated in order for the normal decline of the response to proceed.

Multiple phosphorylation events are also proposed to underlie the reproducibility of rod responses to single-photons (132-134). Despite the fact that events generated by single molecules are stochastic in nature, the single-photon response of rods shows remarkable reproducibility in amplitude and shape (15, 135, 136). By averaging over multiple shutoff steps, the integrated R* activity varies less than otherwise controlled by a single step. This hypothesis is supported by experiments using transgenic mouse rods carrying phosphorylation-site mutations (137). The authors showed that the reproducibility of the single-photon response varies in a graded and systematic manner with the number, but not the identity, of the phosphorylation sites. Each phosphorylation site provides an independent step in rhodopsin deactivation and that, collectively, these steps tightly control the lifetime of R*.

Much less is known about the role of the phosphorylation sites in cone pigments. The only in vivo experiment was done by Kefalov et al. (38), showing that transgenic frog rods expressing a human red cone pigment with all 10 putative phosphorylation sites mutated gave a prolonged response. It suggests that activated cone pigment is quenched by a similar two-step shutoff mechanism even though its active lifetime is much shorter than that of rhodopsin.

In addition to mutations of all of the C-terminal serine and threonine residues to alanine (132), rhodopsin phosphorylation can also be prevented by deleting the C-terminal region of the pigment (138) or ablating GRK1 (139). As expected, rods from all three transgenic mouse lines showed similar properties of the single-photon response, with an amplitude reaching a plateau about twice that of wild-type and decaying stochastically to baseline after a long interval of 3 to 5 seconds. GRK1-mediated phosphorylation begins to reduce the activity of R* at ~100 msec after the flash, because this is the time point at which the transgenic response starts to deviate from the WT response (Figure 13). As mentioned earlier, it was estimated in a recent study that the lifetime of R* is ~80 msec (77), suggesting that arrestin binding occurs rapidly after phosphorylation of the pigment. Therefore, GRK1/arrestin mediated shutoff occurs in rods even earlier than the fast Meta-II decay of cone pigment (38), which is of the order of 1 s after flash (60, 62, 140). The GRK1-mediated shutoff likely happens even faster in cones (see below).

Mouse and rat are unusual in that the same GRK1 is present in both rods and cones. In all other species studied, another pigment kinase (the so called "cone pigment kinase"), GRK7, is present in cone photoreceptors (141-144). Indeed, many animal species, including human, have both GRK1 and GRK7 in cones. This explains why Oguchi patients with a defective GRK1 gene have normal daytime vision whereas GRK1-null mice have prolonged cone photoresponses (145, 146). Interestingly, GRK7 was shown to have considerably higher specific activity than GRK1 and, in fish, is present at a much higher concentration in cones than GRK1 is in rods (142, 147). This difference has been proposed as a potential mechanism underlying the faster shutoff and lower sensitivity of cones than rods (reviewed in (148)).

Biochemical experiments suggest that GRK1-mediated phosphorylation of R* is regulated by recoverin (Rec) (149-152), which belongs to a family of calcium-binding proteins. The hypothesis is that, when intracellular free Ca^{2+} concentration is high in the dark, Rec-Ca^{2+} binds to GRK1 and inhibits R* phosphorylation. When Ca^{2+} concentration decreases in the light, Ca^{2+} dissociates from recoverin; consequently, the resulting affinity between recoverin and GRK1 is reduced, and its inhibition on R* phosphorylation is released. However, this hypothesis was challenged by in vitro measurements suggesting that the extent of R* phosphorylation was unaffected by light adaptation and by changes in intracellular Ca^{2+} (153). This controversy was finally settled by recordings from Rec$^{-/-}$ mouse rods (154), which showed that Rec-Ca^{2+} prolongs the dark-adapted flash response and increases the rod's sensitivity to dim steady light, probably by inhibiting the phosphorylation of R* by GRK1. Furthermore, Rec$^{-/-}$ rods had faster Ca^{2+} dynamics, indicating that recoverin is a significant Ca^{2+} buffer in the ROS.

In the second step for the deactivation of R*, arrestin binds to phosphorylated R* (R*-P) to cap its catalytic activity. In mouse, the dim-flash responses from rods of arrestin-knockout (Arr$^{-/-}$) mice do not differ greatly from the wild-type response until in its falling phase, when recovery reaches approximately halfway back to baseline (155). Therefore, phosphorylation alone can reduce R*'s activity significantly. The response of Arr$^{-/-}$ rods on average recovers ~10 times more slowly than the response of rods lacking rhodopsin phosphorylation (Figure 13), presumably reflecting the continuous activity of the phosphorylated meta-II state of R* until it decays to inactive meta III. In rods lacking both GRK1 and arrestin (GRK1$^{-/-}$Arr$^{-/-}$), the activation phase and peak amplitude of the dim-flash response resemble those of GRK1$^{-/-}$ rods but then decay slowly with a time constant similar to that of the Arr$^{-/-}$ response (156), reflecting the decay of non-phosphorylated R. It thus appears that phosphorylation does not influence the decay of R*.

At least two splice variants exist for rod arrestin: a full-length (p48) and a C-terminal truncated form (p44) (157). P44 has a faster on-rate than p48 for binding R* and R*-P (158, 159). In addition, p44 is more efficient than p48 in turning off R* in vitro (158, 160). Although p48 is ~10 times more abundant than p44, it translocates from ROS to the rest of the cell in the dark, therefore largely absent in dark-adapted ROS (161-164). This raises an interesting question about the roles of individual isoforms of arrestin in the intact rods. By selectively expressing the two isoforms in mouse rods lacking endogenous arrestin, it was found that both isoforms could quench the activity of phosphorylated R* rapidly. However, only p48 was able to quench the activity of non-phosphorylated R* (156).

Cones express their own arrestin called cone arrestin or X-arrestin (Arr4) (165, 166). Surprisingly, both the rod and cone forms of arrestin exist in mouse cones (167). Arr1 in cones is ~50-fold higher than that of Arr4 (168). Single cell recordings from cones of mice with one or both arrestins knocked out shows that arrestin is required for normal cone inactivation although removal of one arrestin has negligible effect (168).

15. G*-PDE* termination

Earlier, genetically engineered mouse lines were designed to disrupt R* termination. More recent studies have centered on G*-PDE* termination. G* is inactivated when its bound GTP is hydrolyzed to GDP. Although transducin has a slow intrinsic GTPase activity, the hydrolysis is greatly accelerated by the GAP complex. The complex is composed of a member of the family of regulator-of-G-protein-signaling proteins (RGS9-1 (169),), the long form of Gβ5 subunit (Gβ5-L (170),), and a membrane-anchor protein (R9AP (171),). RGS9-1 has a G protein γ-like (GGL) domain that binds to Gβ5-L, and has an N-terminal DEP (Dishevell/Eg110/Pleckstrin) domain that interacts with R9AP. After hydrolysis, Gα-GDP dissociates from PDEγ which allows the latter to re-exert its inhibition on the catalytic PDEαβ subunits (reviewed in (76)). The molecular reactions underlying this step are shown schematically in Figure 14.

Even though only RGS9-1 has GAP activity, all three components of the GAP complex are obligatory partners because genetic ablation of any one of them in mouse resulted in an increased instability of the other two through a posttranscriptional mechanism (172-174). This is why transgenic mouse rods lacking RGS9-1, Gβ5-L, or R9AP display a similar delay in the recovery phase of the flash response without much noticeable differences in the activation phase (172, 174, 175). In addition, the GAP activity on transducin is enhanced by PDEγ (109, 169, 176, 177) see PDE section). This provides an elegant mechanism for ensuring that excitation does not normally decay until G* has bound to the effector, PDE. The same GAP complex is present in both rods and cones; however, its concentration is much higher in cones than in rods (178, 179). This has been suggested to contribute to the faster response kinetics of cones than rods.

Overexpression of PDEγ in mouse rods can accelerate the shutoff of light response independent of the GAP complex, suggesting that the inhibitory sites on PDE α and β are accessible to excess PDEγ after endogenous PDEγ has been displaced by G* upon illumination (109). Overexpression also reduces the gain of transduction apparently through the "dominant negative effect" of interfering with the binding of G* to endogenous PDEγ.

Termination of phototransduction requires the shutoff of both R* and G*-PDE*, with the slower step determining the overall rate of response recovery. The identity of the rate-limiting step for rod recovery has been a long-standing question until recently (135, 180-183). By overexpressing the GAP complex in mouse rods, Krispel et al showed that the recovery of rod response was dramatically accelerated whereas overexpression of GRK1 had no effect (77). This experiment unequivocally demonstrated that the termination of G*-PDE* is the rate-limiting step. It is worthwhile to note that the same step is not necessarily the rate-limiting step in cone recovery because there is a much higher concentration of the GAP complex in cones. The same "overexpression" technique can be used in cones to answer this question.

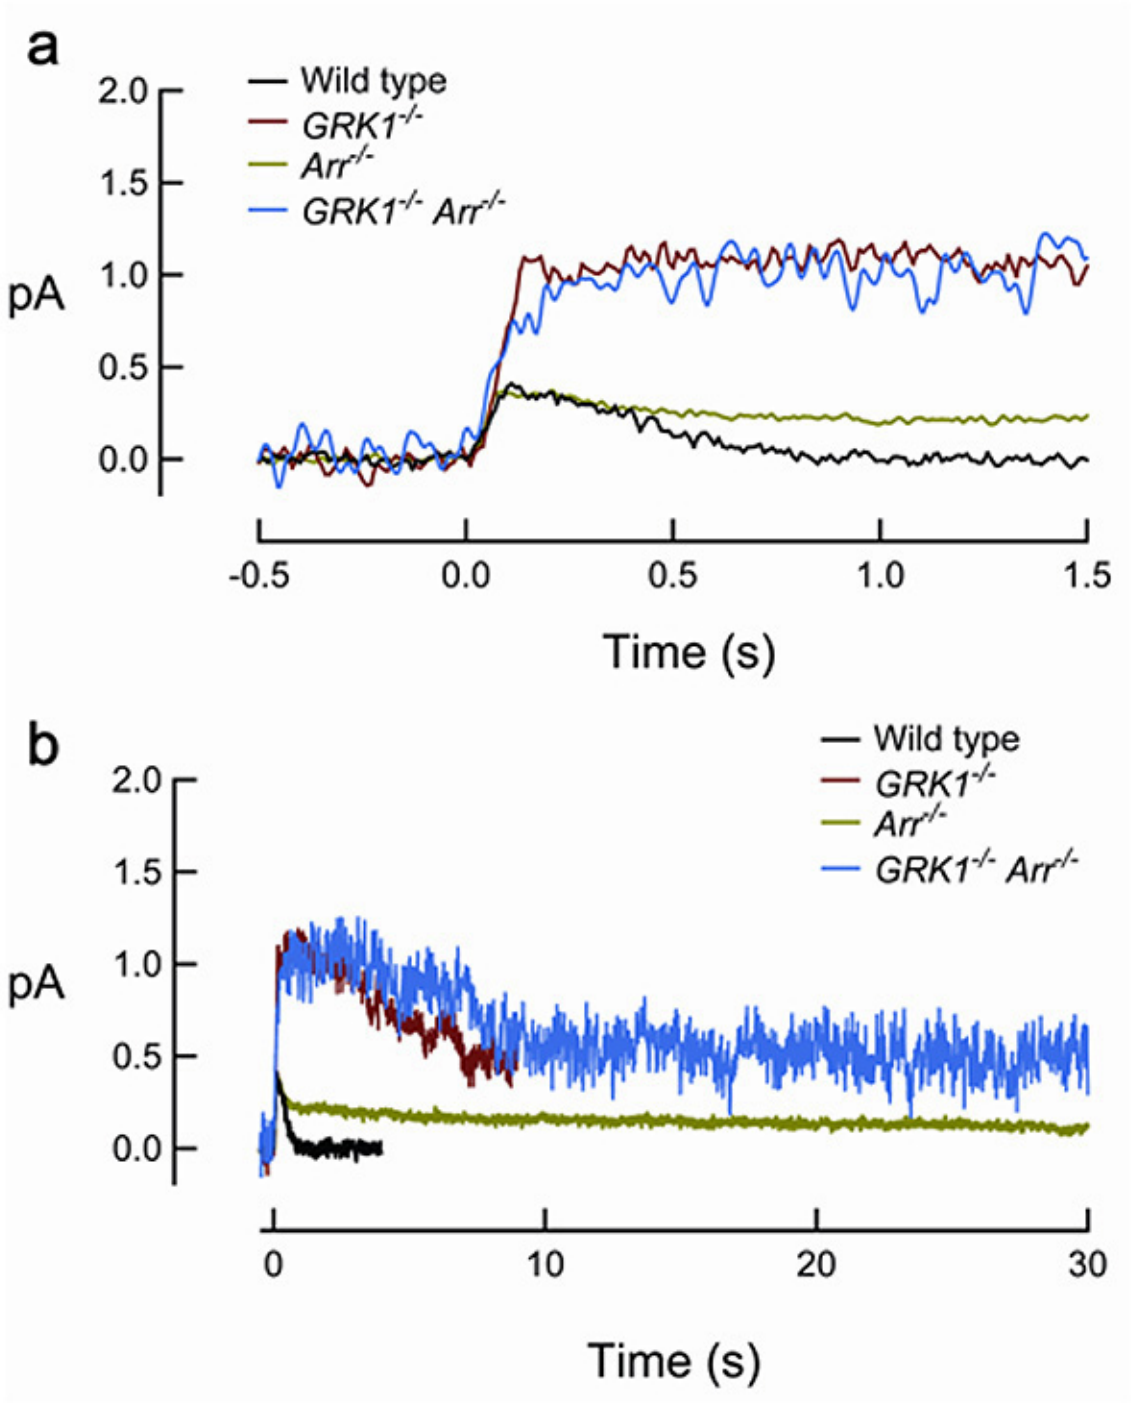

Figure 13. Form of the single-photon response from knockout mouse rods with deficient R* termination on fast (a) and slow (b) time scales. Flashes were delivered at t = 0. Courtesy of Marie E. Burns.

Another implication of the above finding has to do with the question of the reproducibility of the single-photon response (see R* Termination). Because G* deactivation is 2.5 times slower than R* deactivation (77), the slower G* termination dictates the recovery kinetics of the single-photon response of rods. In addition to the multi-step involved in the shutoff of R*, the activation of ~20 transducin by one R* can provide the necessary averaging for an otherwise stochastic process.

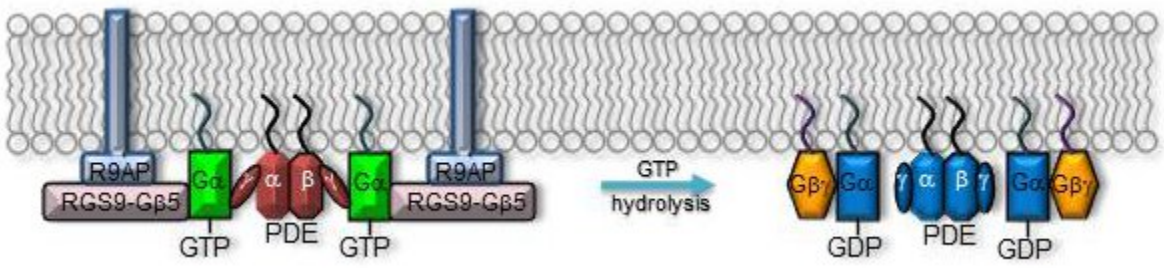

Figure 14. Schematic on the termination G*-PDE*. Gα*-GTP binds to PDEγ and activates PDE. The deactivation of Gα*-GTP is accelerated by the GAP complex, R9AP-RGS9-1-Gβ5L, in which RGS9-1 facilitates the hydrolysis of the bound GTP to GDP, leading to the re-formation of the inactive heterotrimeric Gα-GDP-Gβγ and inactive PDE. This step was found to be the rate-limiting step of rod recovery (77).

16. Restoration of cGMP

The free concentration of cGMP is determined by the PDE-mediated hydrolysis and guanylate-cyclase (GC)-mediated synthesis. For the photoreceptor to recover, not only is the light-stimulated cGMP hydrolysis by PDE required to terminate as discussed in the previous sections, but the dark level of cGMP also has to be restored. There are two GCs in mouse photoreceptors: GC1 (GC-E) and GC2 (GC-F). GC1 is present in both rods and cones (184, 185), and GC2 is present only in rods (186). It seems that the basal activity of either GC1 or GC2 is sufficient to maintain dark current in rods (187, 188). Deletion of either GC has no significant impact on rod sensitivity. GC1 is important for cone function because cones degenerate in its absence. Deletion of both GC1 and GC2 rendered rod and cone photoreceptors nonfunctional and unstable (187).

GC activity is regulated by Ca^{2+}, mediated by the guanylate-cyclase-activating proteins (GCAPs). This regulation is the most important negative-feedback mechanism triggered by Ca^{2+} in the light. For topics on other Ca^{2+}-feedback effects and light adaptation, readers can refer to the following publications (101, 115, 189, 190).

GCAPs belong to a large family of calmodulin-like Ca^{2+}-binding proteins. Two GCAPs are present in mouse retinas, GCAP1 and GCAP2. Both GCAPs are expressed in mouse rods, but GCAP1 is primarily expressed in cones (191, 192). In darkness, the relatively high Ca2+ concentration promotes the formation of the Ca^{2+}-bound form of GCAPs, which inhibits GCs. When the Ca^{2+} concentration declines during the light response, the dissociation of Ca^{2+} allows GCAP to activate GC, thereby quickly restoring the basal cGMP concentration (Figure 15).

The two GCAP genes were knocked out in mouse simultaneously by taking advantage of their tail-to-tail arrangement on chromosome 17 (193). The flash response of GCAPs$^{-/-}$ rods showed a larger amplitude and delayed decline compared to wild type, consistent with a delay in cGMP synthesis during recovery when the associated Ca^{2+}-feedback was removed. The power of Ca^{2+}-mediated regulation through GCAP can be appreciated from the fact that the single-photon response of GCAPs$^{-/-}$ rods is nearly 5 times that of wild type, versus the 2-fold increase when pigment phosphorylation is prevented. By comparing the light response of GCAPs$^{-/-}$ rods with that of wild-type rods, Burns et al. found that the activation of GC resulting from a change in Ca^{2+}-dependent GCAP activity occurs within ~40 ms after the flash and in a highly cooperative manner, with a Hill coefficient of 4 (189). Therefore, the effect occurs much earlier than pigment phosphorylation, which is 80-100 msec after the flash (see R* termination). The rapid feedback to GC has dual effects on photoreceptors, decreasing the dark-adapted flash sensitivity (132) and speeding the restoration of the dark current (36).

What are the functional differences between the two GCAPs? In vitro, GCAP1 activates GC1 more efficiently than GC2 (194, 195), whereas GCAP2 activates both GC1 and GC2 with similar efficiency (186, 196, 197). In vivo, transgenic GCAP1 can rescue the GCAPs$^{-/-}$ phenotype in rods and cones, as tested by single rod cell recordings and electroretinography, even in the absence of GCAP2 (198, 199). Expression of bovine GCAP2 in GCAPs$^{-/-}$ rods restored the recovery of rods to saturating flashes but failed to restore the recovery kinetics of responses initiated by sub-saturating flashes and, in particular, failed to rescue the fast initial phase of recovery (193), suggesting that GCAP1 is responsible for the initial rapid phase of response recovery. GCAP2 speeds up the recovery of flash responses and adjusts the operating range of rods to higher intensities of ambient illumination (200).

17. Mouse model of cone phototransduction

Recently, there have been substantial advances in the understanding of cone transduction with fish as the model (142, 143, 147, 201, 202). On the other hand, despite the enormous success in studying rod phototransduction by a combination of mouse genetics and suction-electrode recording in recent years, the usage of mouse as a model system for studying cone phototransduction has until recently been limited to ERG studies. This is mainly due to the rarity of cones (~3%) and the fragility of the cone outer segment (COS).

This hurdle was finally overcome by Pugh and colleagues (146, 203). The conventional suction-pipette recording, which involves drawing the ROS into the suction pipette ("OS in"), is not tolerated well by the more fragile COS. Instead, Pugh and colleagues drew a portion of the inner segment ("OS out") of a cone photoreceptor in a retinal slice into the suction pipette, allowing long, stable recordings. Previously, it was shown that the same information could be obtained by recording from either outer or inner segment of amphibian rods and cones (204) as expected from the nature of the circulating current.

To overcome the difficulty of identifying the ~3% cones in mouse retina, Pugh and colleagues used three different mouse lines. The first lacks the neural leucine zipper transcription factor (Nrl) (205), which drastically alters the cell fate of rod photoreceptors by turning them into cone-like photoreceptors (146, 206). The second expresses EGFP in mouse cones, which facilitates/verifies their identification (207). The third lacks the rod transducin α-subunit (gnat1$^{-/-}$), which blocks rod phototransduction (85).

In the case of the EGFP mouse line, background light is required in order to suppress the rod response so that the cone response can be isolated. As a result, the cone response is slightly light-adapted, therefore slightly faster and smaller for a given test-flash intensity than that from gnat1$^{-/-}$ or Nrl$^{-/-}$ cones. When this factor is taken into consideration, the light response properties of mouse cones recorded from the three mouse lines are very similar and are as expected from mammalian cones (Figure 16, Table 3) (203). Prominent among these features is that mouse cones are far more tolerant than mouse rods to bleached pigment. The dark current recovers substantially in both S- and M-type cones following strong flashes that bleach a substantial fraction of the pigment. One surprising finding, however, is that the inactivation of M pigment is more retarded than that of S pigment in the absence of GRK1, suggesting the existence of a GRK1-independent inactivation mechanism for the S pigment. Nrl$^{-/-}$ cones differ from wild type in certain respects. Their outer segments are shorter, more disordered and undergo a slow degeneration (206). In addition, in contrast to wild type, Nrl$^{-/-}$ cones express a much higher percentage of S-opsin. Thus, transgenic mice expressing EGFP in their cones and gnat1$^{-/-}$ mice are better than Nrl$^{-/-}$ mice for studying cone physiology.

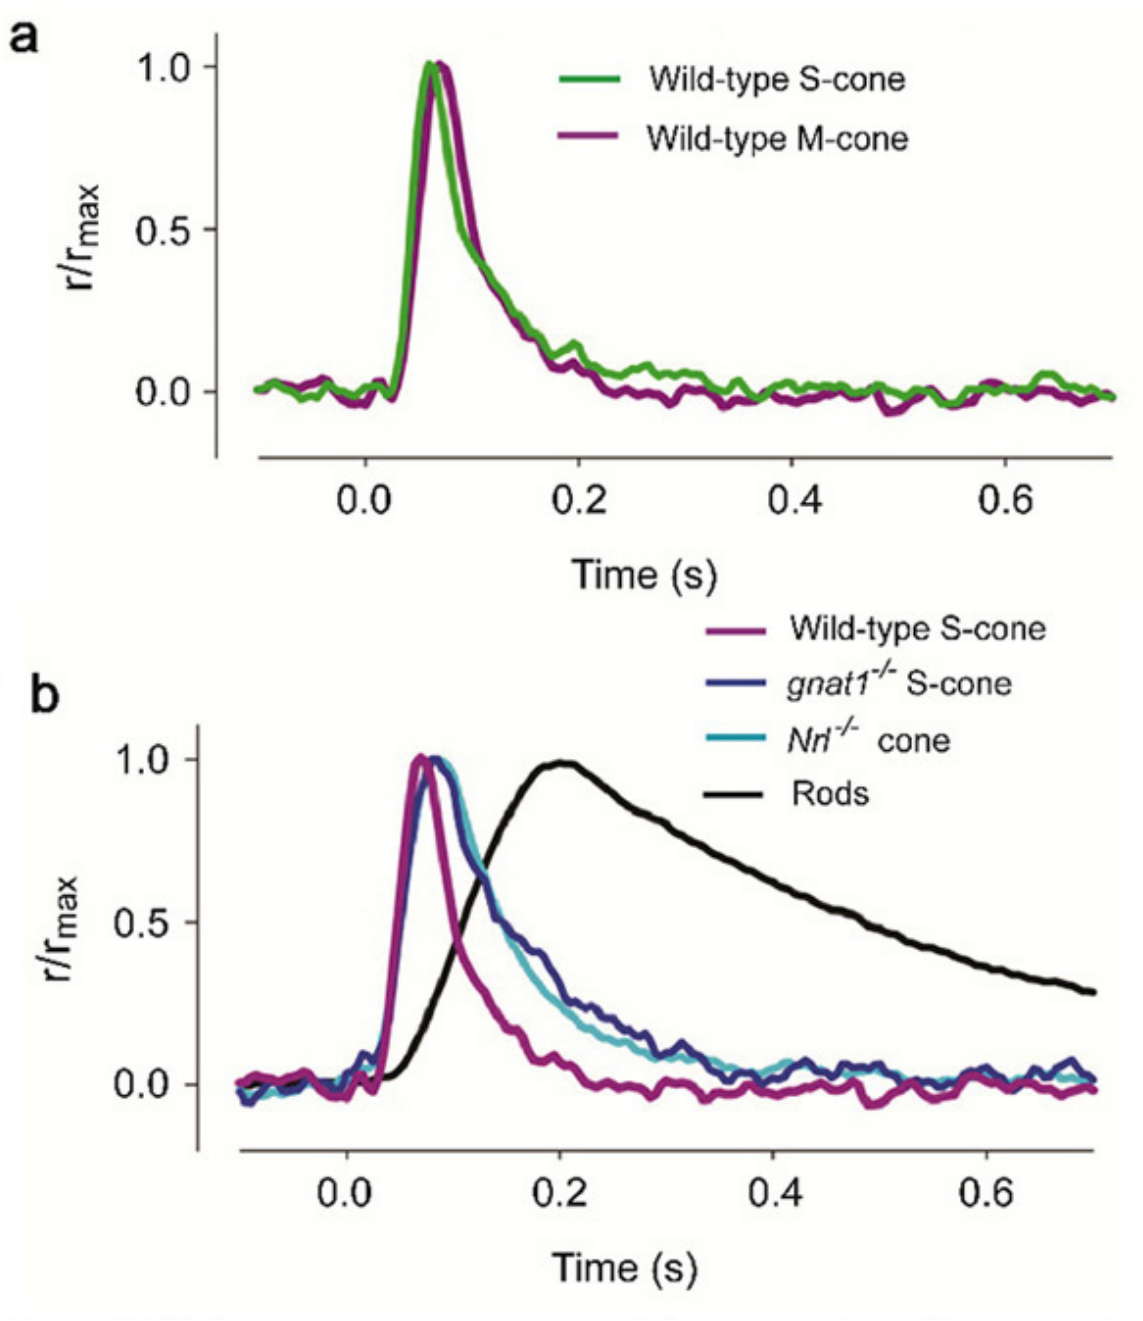

Figure 16. Flash responses of mouse cone photoreceptors from different genotypes. a. Comparison of the average response of S-cones to 361-nm flashes and M-cones to 510-nm flashes. b. Comparison of the average flash responses to 361-nm flashes of wild-type S-cones, gnat1$^{-/-}$ S-cones, Nrl$^{-/-}$ cones, and rods recorded under the same "OS out" conditions. Each trace is scaled to unity at its peak. Data from Fig. 4E & F of Nikonov et al., 2006 (203) with permission from the Rockefeller University Press.

Table 3. Kinetic and Sensitivity Parameters of mouse rods and cones. I_d, dark current. t_p, the time to peak of the dim-flash response. τ_D, the dominant recovery time constant. $I_{1/2}$, Flash strength that elicited a half-maximal response, uncorrected for pigment bleaching for cones. Data from Table 1 of Nikanov, 2006 (203)

	I_d (pA)	t_p (ms)	τ_D (ms)	$I_{1/2}$ (photons μm^{-2} s^{-1})
S-cone (n = 21)	6 ± 1	73 ± 5	73 ± 10	$(1.8 \pm 0.6) \times 10^5$
M-cone (n = 8)	8 ± 2	63 ± 5	68 ± 18	$(2.5 \pm 0.9) \times 10^5$
Rods (n = 26)	20 ±6	205 ± 10	235 ± 20	350

18. Concluding remarks

In the past decade, great progress has been made in using mouse models to elucidate the mechanisms of activation and termination of the rod phototransduction pathway. Although there are still questions to be answered about the rod pathway such as the reproducibility of the single-photon response, the current frontier of phototransduction research lies in cones, which, for human vision, are far more important than rods. The recent success in recording from single mouse cones ushers in a new era in research on vertebrate cone phototransduction. Many long standing questions, e.g., the mechanisms for the enormous ability of cones to adapt to light, and the differences between rods and cones in sensitivity and kinetics, can now be addressed with a combination of mouse genetics and electrophysiology.

About the Author

Dr. Yingbin Fu is presently an Assistant Professor in the Department of Ophthalmology and Visual Science, John Moran Eye Center, University of Utah. He received his B.S in Biochemistry at Peking University, Beijing, China. After receiving his Ph.D. in Biochemistry at Michigan State University, East Lansing, Michigan, Dr. Fu's interests turned into retina and he joined Dr. King-Wai Yau's lab as a postdoc fellow at the Johns Hopkins University School of Medicine in Baltimore, Maryland. His postdoc experience turned out to be quite fruitful after he successfully brought his expertise in Xenopus and mouse genetics to the Yau lab, a world-class electrophysiology lab. Dr. Fu made significant discoveries on the role of visual pigments in rod and cone phototransduction, and the role of melanopsin in intrinsically photosensitive retinal ganglion cells. After moving to Utah to establish his own lab, Dr. Fu's research primarily focuses on two objectives: 1. To understand the mechanisms governing the assembly/trafficking of key photoreceptor proteins and its role in photoreceptor survival; 2. To perform functional characterization on genetic variants that are associated with age-related macular degeneration (AMD) with animal models. Email: yingbin.fu@hsc.utah.edu

S-Potentials and Horizontal Cells

Ido Perlman, PhD,[1] Helga Kolb, PhD,[2] and Ralph Nelson, PhD[3]

Created: May 1, 2007; Updated: December 30, 2011.

1. Introduction

Horizontal cells are the interneurons of distal vertebrate retina. They provide the pathways for both local and long range interactions between photoreceptors. These interactions are called feedback signals. Feedback signals adjust the gain of photoreceptor synaptic output, both as seen in the horizontal cells themselves and in the adjacent, proximally projecting bipolar cells. In forming a distal, lateral synaptic network, horizontal cells enrich not only their own physiology but that of presynaptic and postsynaptic partners. They generate spatial opponency in both cones and bipolar cells. They also generate color opponency in cones, bipolar cells, and chromatic horizontal-cell subtypes. The actions of horizontal cells propagate forward in the retina, can be identified in the physiology of retinal ganglion cells, and in visual perception. Horizontal cell actions are in turn tuned by neuromodulators released by other retinal neurons.

2. History

The first intracellular, light-evoked responses recorded in the vertebrate retina were slow, negative going changes in membrane potential that lasted for as long as the light stimulus was present (Fig. 1). Before the morphological source of these responses became clear, they were called simply S-potentials (1). As shown in figure 1, S-potentials are membrane hyperpolarizations that last for as long as the light stimulus is present. The graded character of the S-potential is evident in figure 1A. The brighter the stimulus, the larger the amplitude of the S-potential until a saturation level is reached. In figure 1B, the duration of a light stimulus of fixed intensity is altered in order to examine the temporal properties of S-potentials. For long stimuli, the S-potential only changes in duration but the amplitude remains constant (2 leftmost responses in Fig. 1B). Further reduction in the stimulus duration causes a decrease in amplitude (Fig. 1B). This illustrates the temporal summation of the S-potential, following Bloch's law. Up to certain stimulus durations, in this case about 10 msec, the amplitude is directly related to the quantal content of the stimulus (quantal flux multiplied by duration), while for stimuli of longer duration, the amplitude is related to the quantal flux, that is, the rate of quantal absorption by photoreceptors (1). In S-potentials this 'critical duration' varies considerably with stimulus conditions (2). It is likely that S-potentials were named in honor of their discoverer, Gunnar Svaetichin, although 'slow potential' is another common interpretation.

S-potentials puzzled neurophysiologists of the 1950s when they were first described. At that time, neurons were thought only to be depolarized by synaptic inputs (inside becoming more positive relative to outside), thus having their inside-negative resting membrane potentials become reduced. This depolarization was thought of as excitation, and if the excitation was large enough, action potentials, or nerve spikes, were generated to transfer signals down the length of the nerve-cell axon. S-potentials, however, were not depolarized by light, but rather hyperpolarized, and did not fire action potentials, even with the brightest light stimuli.

At first, the cell type of origin for S-potentials was not really known other than that microelectrode tips were somewhere in the outer retina. In fact, initially Svaetichin thought S-potentials arose from cones (1). However, later intracellular marking techniques, in which dyes were injected from the electrode tips into the cytoplasm of

Corresponding author.

the recorded neuron, revealed that horizontal cells, second order neurons postsynaptic to cones, were the source of the S-potentials (3, 4). Since being first described in fish retinas, S-potentials have been recorded from retinal horizontal cells in all vertebrate classes. These include both cold-blooded vertebrates (4-13), household mammals (14-20) and primates (21-26). Horizontal cells have now been studied by numerous investigators using anatomical, biochemical, pharmacological and electrophysiological techniques. In this chapter, we shall try to summarize our current knowledge of horizontal cells in the vertebrate retina.

3. Morphology and Circuitry

Horizontal cells are second order neurons contacting photoreceptors directly all across the plane of the retina's outer plexiform layer. These cell types were first described as huge brick-like structures occupying much of the inner nuclear layer in the fish retina (27, 28). Early interpretations assumed these cells to be glial cells, mainly because they gave rise to hyperpolarizing slow responses to light (S-potentials) rather than true depolarizing spikes like 'real neurons'. Now we know horizontal cells to be true neurons that make true, if unique, synapses and exhibit most of the structural and ultrastructural characteristics of neurons. Through Golgi staining, intracellular marking and immunostaining techniques we have learned that horizontal cells can adapt various morphologies in the retinas of different vertebrate species (6, 29-44).

Selective rod and cone contacts of horizontal cells

There are two morphological types of horizontal cell in the majority of terrestrial vertebrate retinas, B-type cells with axons and A-type cells that are axonless (Fig. 2a). In mammals the dendrites of both B- and A-types contact cones, while the axon terminals of B-type cells contact rods (gray area, Fig. 1A). In birds and reptiles, horizontal cells come in further axonless subtypes with color specific cone connections (Fig. 2a, axonless). Figure 2a shows the morphologies of these different types of horizontal cells in different species as indicated. Also shown are the spectral types of cone (red, blue and green dots) that connect with each type.

In fish retinas, short-axon or axonless horizontal cells (type H4) contact only rods (45, 46), while the dendrites of all axon bearing cells contact only cones (Fig. 2b). The axons of fish horizontal cells do not contact photoreceptors. There are multiple types of axon bearing, cone-contacting, horizontal cells in fish (H1, H2, H3), each with different patterns of cone selectivity. In the zebrafish example (Fig. 2b), most are excited by 2 of the 4 cone types and avoid excitatory input from other types. The exception is the H3 UV triphasic type that appears to be selectively excited by either UV or blue cones. H2 and H3 types are color opponent in wavelength physiology, but H1 is not.

Mammalian and reptilian B-type horizontal cells code changes in brightness but do not discriminate color. They regulate adaptational and spatial responses of cones and bipolar cells. These are luminosity type horizontal cells whose physiology will be discussed later. These B-Type cells can often be identified with antibodies against calcium binding proteins (47-49) and some contain the neurotransmitter GABA (47, 50, 51). In turtle retina, acetylcholine has been located in H1 type horizontal cell dendrites where they invaginate the cone pedicles (47). H1 type cells of turtles are morphologically analogous to mammalian B-type cells. The dendrites of B-type horizontal cells in mammalian retinas are bushy and contact all cones within the dendritic field. The axon emerges from one of these dendrites. At its distal end, an axon terminal sprouts to collect signals from large numbers of rods at some distance from the cone-contacting dendritic field. The length and thinness of the axon is believed to electrically isolate one portion of the cell from the other, thereby, separating a cone-photoreceptor-involved compartment of the cell from a rod-photoreceptor-involved compartment (17). In species where there are few rods (Fig. 2a, turtle) the B-type axon terminal makes sparse contacts with both red cones and the few rods present in this retina (36, 52). Nonetheless soma-dendritic and axon terminal compartments maintain physiological separation, as evidenced by different summation areas (53). The type I horizontal cell of pigeon

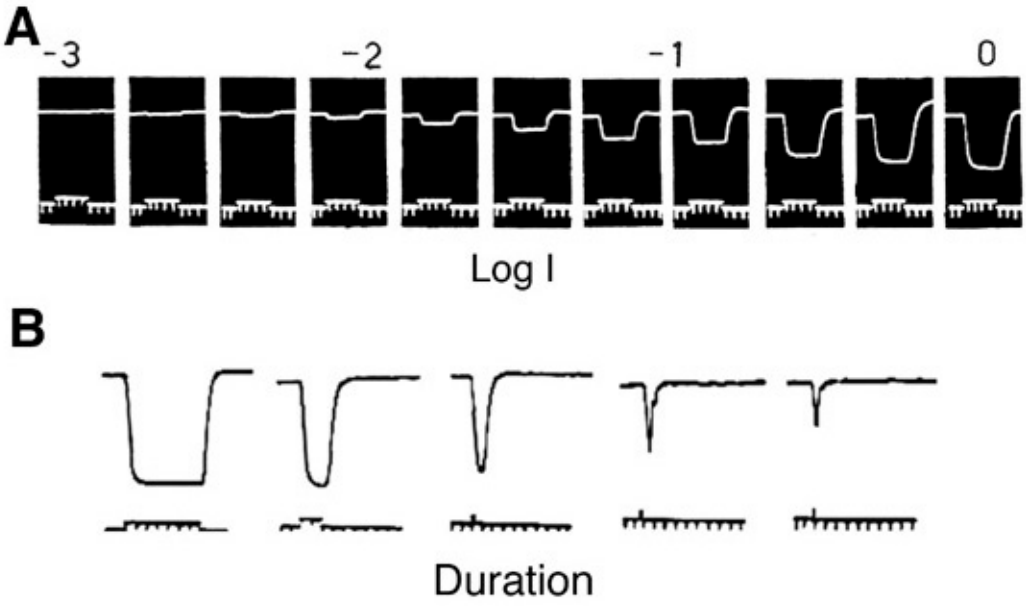

Figure 1. The S-potential of the fish retina. Light stimuli of fixed duration and different irradiances (A) and light stimuli of fixed irradiance but different durations (B) were used to elicit these potentials. Lower traces in A and B record light-stimulus duration and provide 100 msec 'tick-marks'. The illustrations are from Svaetichin,1953 (1).

retina is axon bearing and also appears analogous to mammalian B-type cells. Similar to turtle, the axon terminal contacts a mixture of rods and cones, while the dendrites contact cones (35).

A-type horizontal cells in mammals are purely cone connecting (most species have only green and blue cones). They have no connections with rod photoreceptors at all. The H2 cell of the trichromatic primate retina (humans and old world monkeys) is a kind of A-type cell. Even the H2 cell, where one or more dendrites are elongated and axon-like, contacts only cones. Interestingly enough, these longer dendrites contact principally blue cones. This may be a general theme for mammalian axonless horizontal cells that is only now being realized. In certain big cats (not yet confirmed in domestic cat), the elongated dendritic tips of A-type cells contact blue cones, while the dendrites closer to the cell body are in contact with both red cones and blue cones (54). In horses the A-type cell is apparently only connected to blue cones (Fig. 2a) (38, 40).

In reptiles, and birds with well developed color vision, typically there are two axonless horizontal cell types. Each of these connects selectively with a cone type. In turtles, birds, and fish, species with excellent color vision, type H2 and type H3 horizontal cells are large, stellate cells. In birds and turtles these cells lack axons, but in fish H2 and H3 are axon-bearing. These cells contact cones selectively and sense color (Fig. 2a, axonless, color-opponent types of birds and reptiles; Fig. 2b, H2 and H3 axon bearing types of fish). H2 and H3 respond to some wavelengths with hyperpolarization, and to other wavelengths with depolarization. Thus, in turtle (pentachromats) and fish (trichromats or tetrachromats), H2 horizontal cells connect to green and blue cones and H3 to blue cones (Fig. 2a, Fig. 2b), or to blue cones and ultraviolet cones (6, 7, 36, 37, 41, 43, 52, 55, 56). In the turtle and zebrafish, ultraviolet-sensitive cones appear to connect only with H3 type horizontal cells, sharing this type with blue cones. Some chromatic horizontal cells can be recognized in immunohistochemistry. The C-type horizontal cells of the turtle can be labeled with antibodies to nitric oxide synthase and calcium binding proteins (47); the former suggests a role for NO in their functioning (see section on Neuromodulation).

Gunnar Svaetichin (1915-1981) mastered high impedance microelectrode techniques while studying neurophysiology in the Karolinska Institute with Ragnar Granit (nobel prize, 1967). These enabled intracellular recording of light responses from retinal interneurons, a field that he founded. It was an imaginative area to pursue in the 1940's. He is the discoverer of S-potentials, now known to be retinal horizontal cell responses, and discovered both color opponent and non opponent types. The discovery of neural color opponency ranks with the most significant findings in color vision in the 20th century (292). The later decades of his career were spent at the Venezuelan Institute for Scientific Research.

Lateral elements and spinules

Horizontal cells always interact with photoreceptor terminals at what are known as 'lateral elements' post-synaptic to photoreceptor ribbons (Fig. 3a, le, arrow). In fish retinas, the horizontal cell connections with cones at the lateral elements are characterized by minute projections called spinules (Fig. 3b). Spinules are dynamic and change shape with the level of illumination. Spinule formation is stimulated by background illumination, while darkness causes retraction (57, 58). These plastic spinules are known to contain the calcium binding proteins caldendrin and CaMKII (59). Spinules are under an endogenous circadian control but need centrifugal control from the brain via FMR-amide-like and GnRH-like hormone releasing hormones (60, 61) acting upon the dopaminergic interplexiform cell system in the retina (62, 63). These spinules appear also to be under the local control of the visual-cycle byproduct retinoic acid (64, 65).

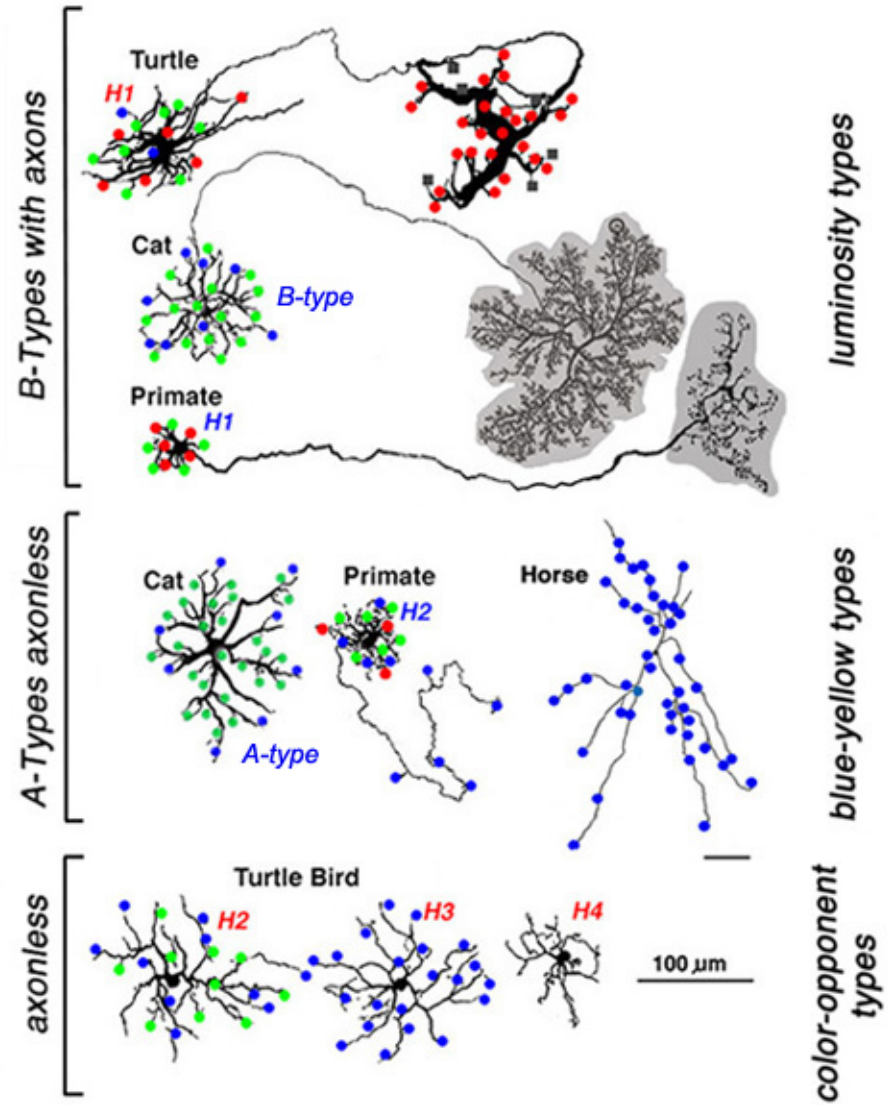

Figure 2a. The morphologies of different types of horizontal cell and their known connectivities with rod and cone photoreceptors. The cells are drawn from Golgi stained or Neurobiotin filled retinal cells and viewed in flat whole-mounted preparations. B-type cells with axons, and A-type axonless cells exist in most vertebrate retinas. The physiological type that is associated with each morphological type is indicated to the right of the figure, i.e luminosity, blue-yellow and color-opponent types. Red-, green- and blue-dots represent inputs from red-, green-, and blue cones respectively. Black squares or shaded gray areas represent rod inputs. The turtle H1 cell is from Ammermüller and Kolb, 1995 (84); H2-H4 are from Kolb et al., 1988 (293). The cat B-type is from Nelson et al., 1975 (17); the A-type is from Kolb, 1974 (294). Primate H1 and H2 types are from Helga Kolb not elsewhere published. The horse axonless horizontal cell is from Sandmann et al., 1996 (40).

Gap-junction contacts and connexins

Retinal horizontal cells in all species are interconnected to homologous neighbors, by areas of gap junctions. These occur between dendrites, between axon terminals, and occasionally between dendrites and cell bodies. Gap junctions are very selective, occurring only between cells of the same type (that is H1 to H1 etc). This exclusivity even extends to axon terminal regions and dendritic regions of B-type horizontal cells, that is, gap junctions connect dendrite to dendrite, and axon terminal to axon terminal, but not axon terminal to dendrite (66, 67). The gap junctions can be extremely large, appearing as plaques (Fig. 3c). First described in fish retinas by Yamada and Ishikawa (28), gap junctions were considered “fused membrane structures” specialized for electrical transmission. Procion Yellow dye diffusion between morphologically similar horizontal cells was noted

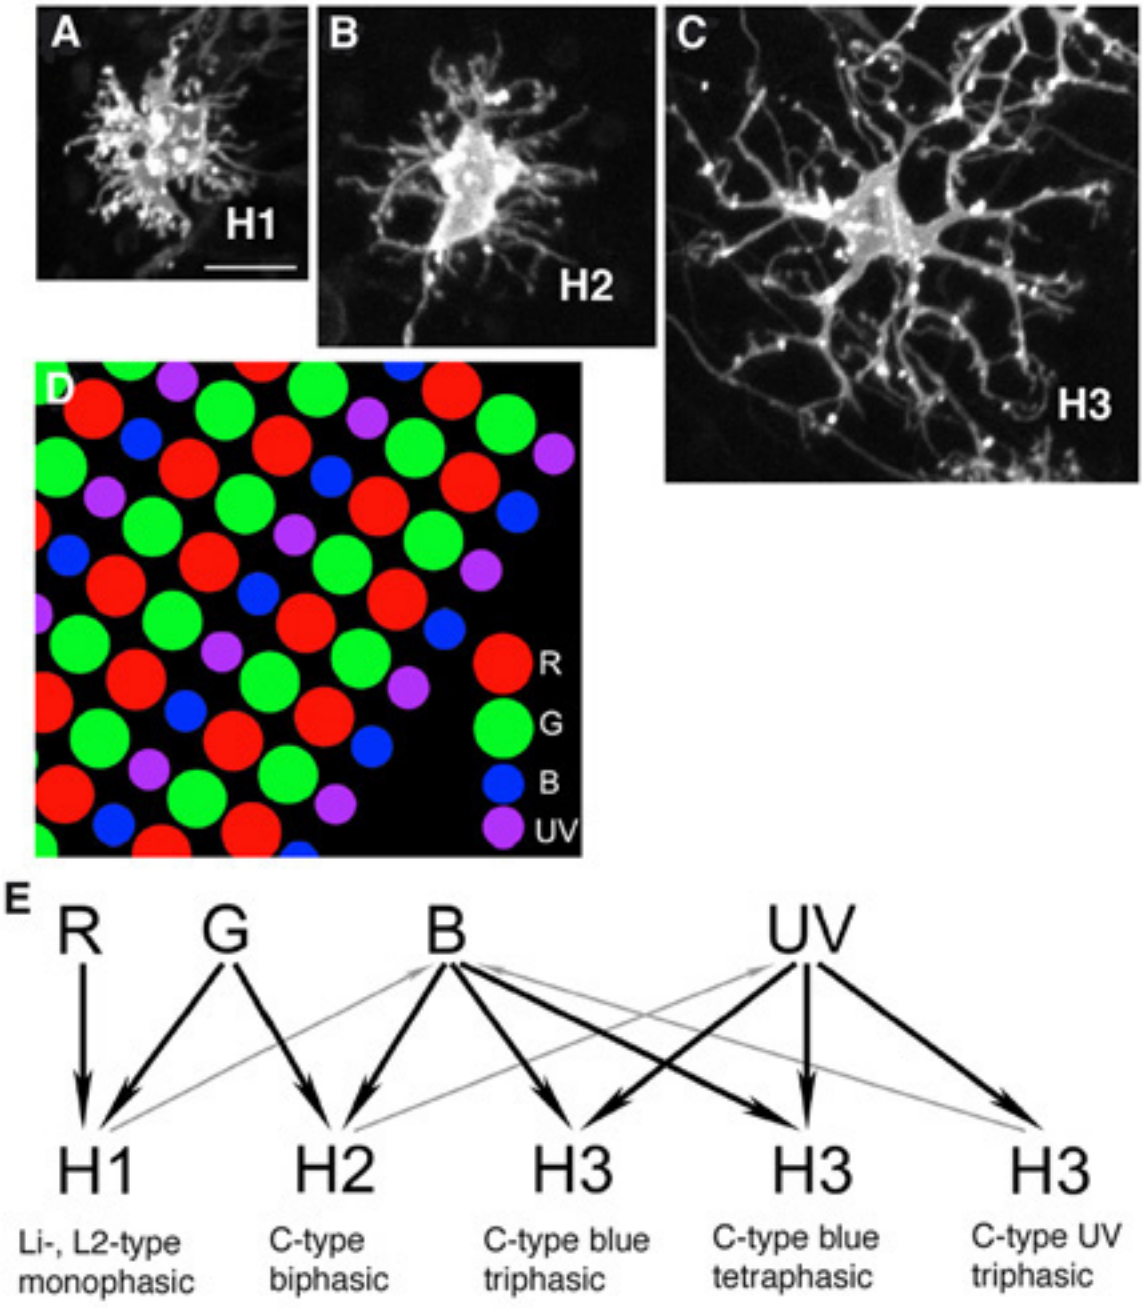

Figure 2b. Cone contacts of H1, H2 and H3 horizontal cell types in zebrafish retina (*A*, *B*, *C* respectively). These neurons were back-labeled with DiI through crystals placed on their axons. Dendritic tips and spines contact cones, sometimes in clusters called 'rosettes'. *D*. Zebrafish cones form a regular mosaic of red (R), green (G), blue (B) and ultraviolet (UV) types. The position of horizontal-cell contacts within the mosaic identifies the cone color type that is contacted. *E*. Summary of cone contacts for H1, H2 and H3 types. Black arrows are contacts proposed for feed-forward excitation, while gray arrows are contacts proposed for feedback inhibition. Except for the UV triphasic H3 cell, all horizontal cells are excited by 2 cone types. The figure is from Li, et al, 2009 (37), with physiological identifications based on Connaughton and Nelson, 2010 (6).

by Kaneko (66) and indicated that the electrical junctions could pass small molecules freely through the so-called S-space of horizontal cells (10).

Gap junctions are formed at closely opposed plasma membranes (2-4 nm gap) from two horizontal cell processes (Fig. 3c). Each of the interacting cells supplies connexons or hemichannels to complete the gap

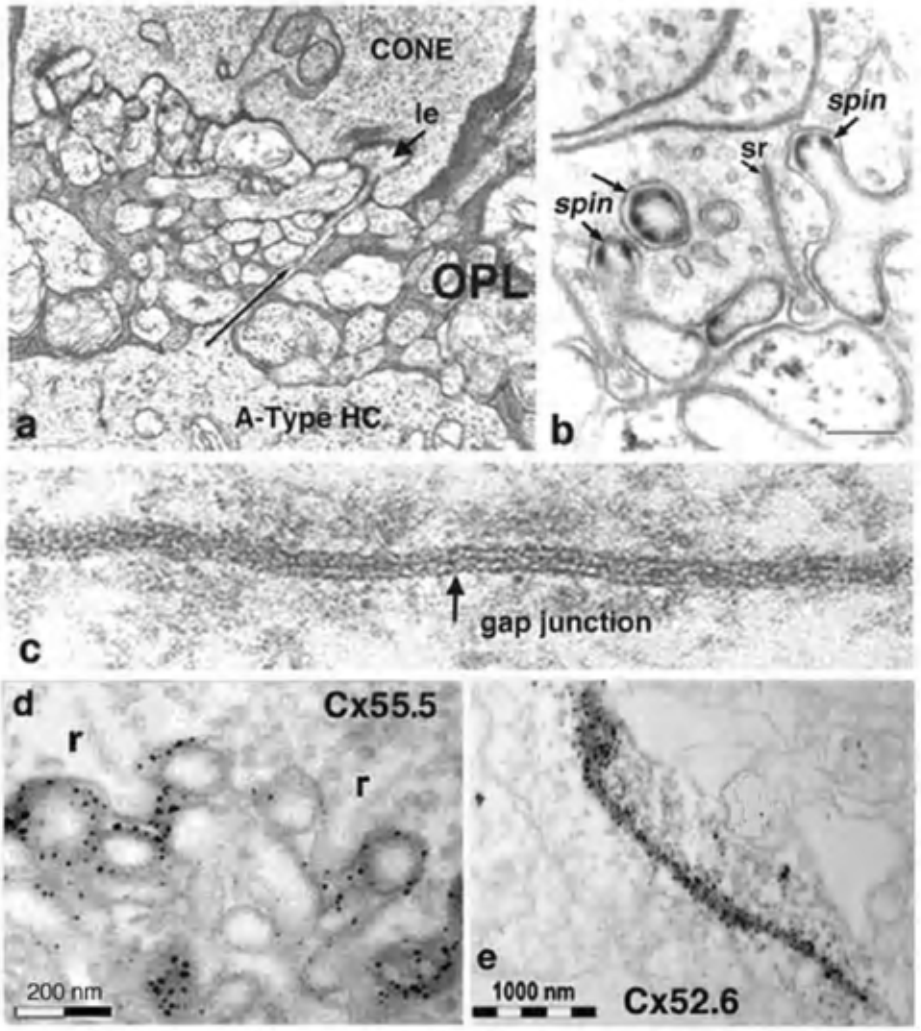

Figure 3. *a*) Electron micrograph of cat outer plexiform layer (OPL) shows an A-type horizontal cell dendritic terminal entering an overlying cone pedicle to form a lateral element (le) at a ribbon triad. *b*) Light adapted fish retina exhibits spinules (spin) on horizontal cell lateral elements in cone pedicles at synaptic ribbon (31) synapses. *c*) High magnification electron micrograph of a gap junction between two A-type horizontal cell dendrites in the cat retina. The latest information concerning gap junction connexins in zebrafish retina shows that *d*) Cx 55.5 forms a hemi- gap junction between HC dendrites and cone pedicles at the ribbon synapse (arrow), while *e*) complete gap junctions between HC dendrites are made by Cx 52.6. The illustrations in *a* and *c* are from Kolb (1977) (103). The illustration in *b* is from From DeJuan and Garcia, (2001) (62). Both *d* and *e* are taken from Shields et al., (2007) (72).

junction contact. These channels can consist of homomeric or heteromeric connexin subunits, thus, potentially allowing a huge variety of gap junctions with slightly different properties to exist between various neurons. Each connexon channel contains six connexins (Cx) surrounding the channel pore. In fish and turtle retinas Cx43 and Cx26 were originally thought to comprise the horizontal cell gap junction connexins (68, 69). However more recently connexin 57 has been demonstrated to be expressed at the protein level and to mediate dendritic gap junctions between mouse B-type horizontal cells. The number of junctions appears to increase with light adaptation (70). In a study on rabbit retina where, unlike mouse, both A- and B-type horizontal cells occur, O'Brien and colleagues have found that Cx50 is the connexin between A-type horizontal-cell dendrites (71). In zebrafish multiple connexins are expressed, in particular Cx52.6 that participates in dendro-dendritic junctions (Fig. 3e) and Cx55.5 that forms hemi-gap-junction channels with cones at lateral elements (Fig. 3d) (72). In zebrafish with Cx55.5 knockout, horizontal-cell color opponency is reduced (73). This connexin is important for feedback modulation of cone synapses. In addition to Cx55.5, another connexin (52.9) is also expressed in zebrafish horizontal cells. It is found both in lateral elements where it may participate in feedback, and in gap

junctions between horizontal cell dendrites within the outer plexiform layer (73). Horizontal cell gap junctions pass not only ions but small cytoplasmic molecules and tracer dyes of less than 500 Dalton size (74). Gap junctions enlarge horizontal cell receptive fields (see section on gap junction physiology), and are modulated by retinal neurotransmitters or humoral factors (see section on neuromodulation).

4. Physiological Types

The vertebrate retina contains a mosaic of rod- and cone-photoreceptors that serve for dark- and light-adapted vision respectively. Multiple cone types, each selectively expressing a visual pigment tuned to a specific region of the visible spectrum, provide vertebrates with the opportunity to discriminate colors. Cone types are defined by the spectral preference of their visual pigment; e.g. short-wavelength (SW) cones, medium-wavelength (MW) cones and long-wavelength (LW) cones, also referred to as blue/UV cones, green cones and red cones respectively. Most mammals are dichromats (2 cone types); however, old world monkeys and humans are trichromats (3 different cone types), and many non-mammalian species are also trichromats or even tetrachromats (4 different cone types). In the retinas of birds, fish and reptiles, a class of SW cones that are sensitive to ultraviolet light (UV cones) can be found (27, 75-79), in addition to the LW, MW, and typical SW cones (red, green and blue cones respectively). Since rods and cones of different spectral types are directly connected to horizontal cells, it is of interest to explore how horizontal cells integrate and process this richness of spectral information.

Physiologists recognize two major types of horizontal cell, luminosity and chromaticity. These can be distinguished by photoresponses to lights of different wavelength. The luminosity (L-type) horizontal cells always respond with hyperpolarization to light stimuli of any wavelength within the visible range of the spectrum, while the chromaticity (C-type) horizontal cells respond with different polarity to light stimuli of different wavelengths (80).

L-type horizontal cells

Luminosity (L-type) horizontal cells are found in every retina that has been studied, non-mammalian vertebrates, mammals and primates. Figure 4 shows the photoresponses of luminosity-type horizontal cells from toad (A), rabbit (B) and monkey (C) retinas. Regardless of the wavelength, these cells respond with membrane hyperpolarization that depends only on the brightness and duration of the stimulus. In some species, two classes of L-type horizontal cells can be distinguished both by anatomical structure and physiological properties. In the turtle retina, the L1 and L2 types are similar in spectral sensitivity but differ in receptive field size and in photoresponse kinetics to red and green light (53, 81). Anatomically, these two L-type horizontal cell physiologies are respectively the axon terminal and the soma of the turtle H1 horizontal cell (Fig. 2a).

In cat and rabbit retinas, A-type and B-type cells (Fig. 2a) are both luminosity types. They differ in morphology and in connectivity with rods and cones but respond only with hyperpolarizations to light stimuli (14, 15, 17). Differences in A- and B-type spectral properties have not yet been reported. Like turtle retinas, the retinas of cyprinids and old world monkeys have both red and green cones. In these species some L-type horizontal cells favor green cone signals, while others favor red cone signals. In cyprinids, the former is called an L1 type, and the latter an L2 type (82). In old world primates both red and green favoring L-type signals arise from the H1 morphological type. Rather than two discrete types, there is a distribution in the balance of red cone and green cone signals for H1 cells (21, 24). In zebrafish also, there is a distribution in red-green balance on the H1 cell, yielding at the extremes L1 green-peaking types, and L2 red-peaking types (6).

C-type horizontal cells

In 1959, Svaetichin and MacNichol (80) first reported on extreme wavelength-dependency of some S-potentials (Fig. 5). As shown in the figure, the photoresponses of this S-unit reversed in polarity at a wavelength of about

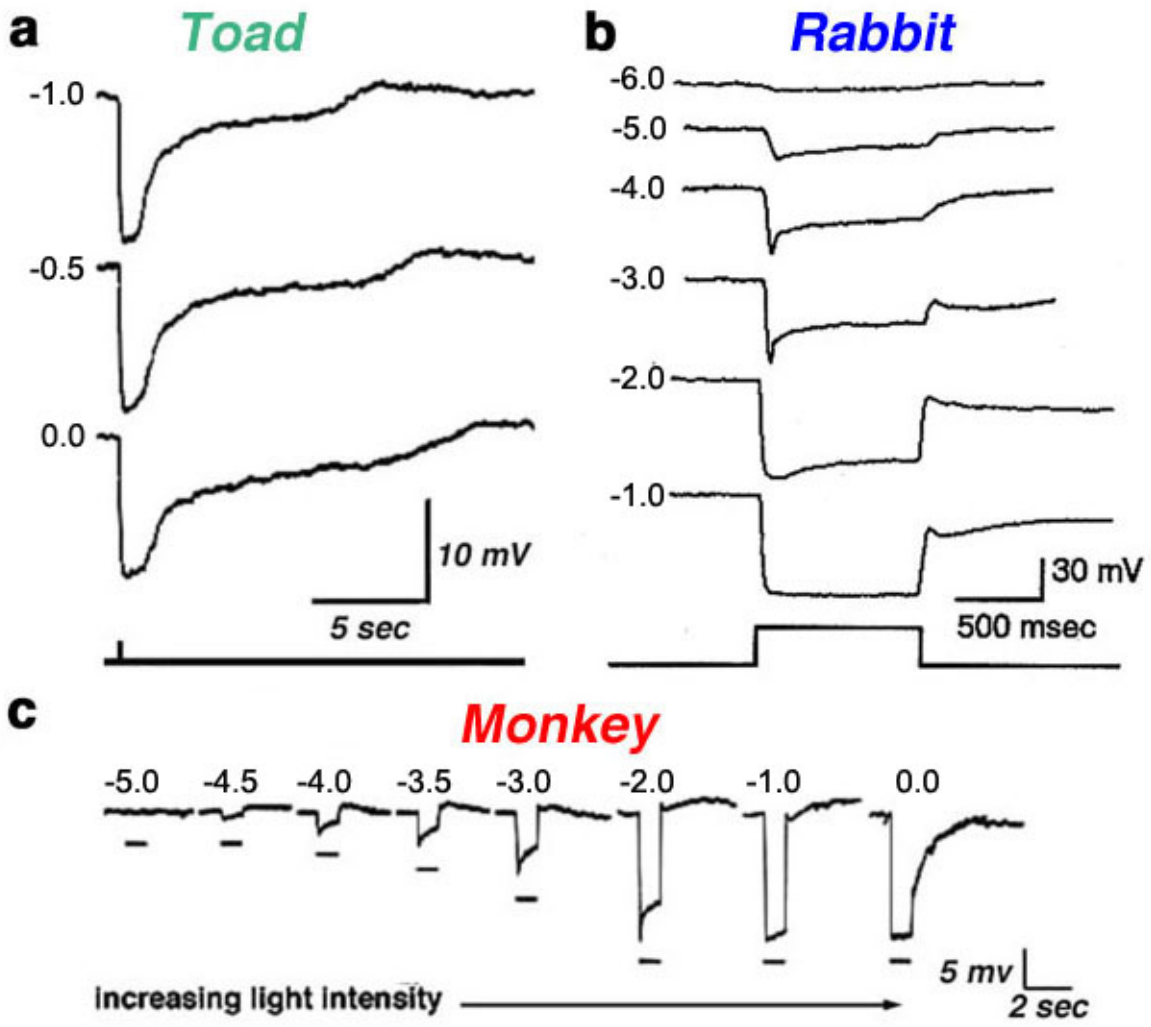

Figure 4. Photoresponses recorded from luminosity-type horizontal cells of toad, rabbit and monkey retinas. In each case, photoresponses were elicited by light stimuli of different intensities. Stimulus intensity is given in log units relative to the most intense stimulus available for the particular recording system. The illustration in *a* is from Normann and Pochobradsky, 1976 (295); in *b* from Bloomfield, 1992 (296), and in *c* from Dacheux and Raviola, 1990 (23).

560 nm. Photoresponses to light stimuli of longer wavelength depolarized the cell membrane, while stimuli of shorter wavelengths hyperpolarized the cell membrane. Svaetichin and MacNichol called these 'color opponent' S-units chromaticity or C-type horizontal cells. C-type horizontal cells have been extensively studied in turtle, amphibian and fish retinas (7, 9, 55, 83-94). Horizontal cells are named by the number of wavelengths at which response polarity reverses; no reversal – monophasic (or L-type) cells, one reversal – biphasic C-type cells, two reversals – triphasic C-type cells, three reversals – tetraphasic C-type cells. Wavelengths at which response polarity reverses are called 'null wavelengths'. In fish retinas, three types of chromaticity horizontal cells have been described; biphasic, triphasic and tetraphasic (6, 86, 95, 96). In the bowfin retina, the null wavelength for the biphasic cells is around 640 nm, while null wavelengths of the triphasic cells are; in the regions of 500-530 nm and 650-670 nm respectively (95). The biphasic and triphasic C-type horizontal cells of the fish retina are identified morphologically as H2 and H3 types respectively (Fig. 2b). In zebrafish the H3 morphological type has taken on as many as 3 physiological identities: the blue triphasic, analogous to previous findings in fish, a UV triphasic type, and a tetraphasic type (6).

In the turtle retina, two classes of biphasic C-type horizontal cells have been identified (7, 85, 91). Typical photoresponses of L-type and C-type horizontal cells in the turtle Mauremys caspica to light stimuli of different wavelength and intensity are shown in figure 6. For each wavelength, a series of photoresponses to different intensities is shown. The L-type horizontal cell (1st row in Fig. 6) responds to all stimuli with graded hyperpolarizations regardless of wavelength. The red/green biphasic C-type horizontal cell (2nd row, Fig 6) responds with graded depolarizations to red light stimuli and with graded hyperpolarizations to yellow, green and blue stimuli. The yellow/blue biphasic horizontal cell (3rd row, Fig. 6), responds with depolarizations to red and yellow light stimuli and with hyperpolarizations to blue light stimuli.

In order to define the spectral properties of the horizontal cells, monochromatic light stimuli of dim intensities are used to elicit small amplitude (<1mV) photoresponses. These photoresponses are within the linear range of the cells and can be used to calculate light sensitivities. Sensitivity is defined as the volts of evoked response per quantum of light and is calculated by dividing the voltage response by the number of quanta in the stimulus. The relationship between light sensitivity and wavelength is the action spectrum of the cell and describes the threshold spectral properties. Figure 7 shows the mean action spectra of 8 L-types, 7 red/green types and 6 yellow/blue types of horizontal cell (*A*, *B* and *C* respectively) from the turtle Mauremys caspica. These spectra clearly demonstrate that the L-type horizontal cells are most sensitive to long-wavelength stimuli, with the major excitatory input coming from red cones (7, 85). These cells receive additional excitatory input from green cones and to a lesser extent from blue cones (85). The red/green C-type horizontal cells are characterized by reversal of response polarity around 600 nm (Fig. 7*B*). These cells are excited by green and blue cones and inhibited by red cones (7, 85). The yellow/blue C-type horizontal cells are inhibited by green and red cones and excited by blue cones (7, 85) and interestingly, also by UV cones (27, 97). Their photoresponses reverse in polarity around 540 nm (Fig. 7C).

Triphasic color responses are only rarely reported in turtle horizontal cells (94), but they are common to some cyprinid retinas, where even tetraphasic responses occur (6, 86, 95, 96). The processing of spectral information at just this first post-photoreceptor synapse in these species is quite amazing. Six spectral configurations occur in zebrafish retina (6). The most elaborate of these is the tetraphasic response, with three null points across the spectrum. It is depolarized by UV light, hyperpolarized by blue, depolarized by blue-green, and hyperpolarized by yellow and red (Fig. 8A). Spectral analysis shows that tetraphasic types are depolarized by both green and UV cones, and hyperpolarized by red and blue cones (6). Like other fish (95), zebrafish has triphasic responses, but there are two types, one hyperpolarized primarily by UV cones (Fig. 8B) and the other hyperpolarized primarily by blue cones (Fig. 8C). Both these triphasic cells depolarize with middle-wavelength (green cone) stimulation, and hyperpolarize with long-wavelength (red cone) stimulation. The biphasic cells of zebrafish (Fig. 8D) are depolarized by long wavelengths (red cones) and hyperpolarized by short and medium wavelengths (both blue and green cones) (6). The zebrafish L-type horizontal cells (Fig. 8E, 8F) are hyperpolarized by input from both red and green cones, but are little influenced by blue cone and UV cone signals. When response amplitudes at different wavelengths are fit by a spectral model that takes into account the shapes of zebrafish cone pigments (6, 98), L-type responses to blue and UV stimuli (Figs. 8E, 8F) are shown to result from stimulation of the short-wavelength absorbance limbs of red and green cones. L1 types show a balance of red and green cone signals and L2 cells hyperpolarize predominantly in response to red cone stimulation (6).

Mammals lack C-type horizontal cells

Given the diversity of horizontal-cell physiology in lower vertebrates, where dendritic contacts with cones containing different visual pigments frequently produce chromatically opponent responses, it is surprising that in mammalian retinas, whose horizontal-cell dendrites also contact cones with different visual pigments, only luminosity-type horizontal cell responses can be recorded (18, 19, 22, 99, 100). For example, both cat A- and B-horizontal cells are luminosity types (Fig. 9), that are dominated by red-cone input, although low-level

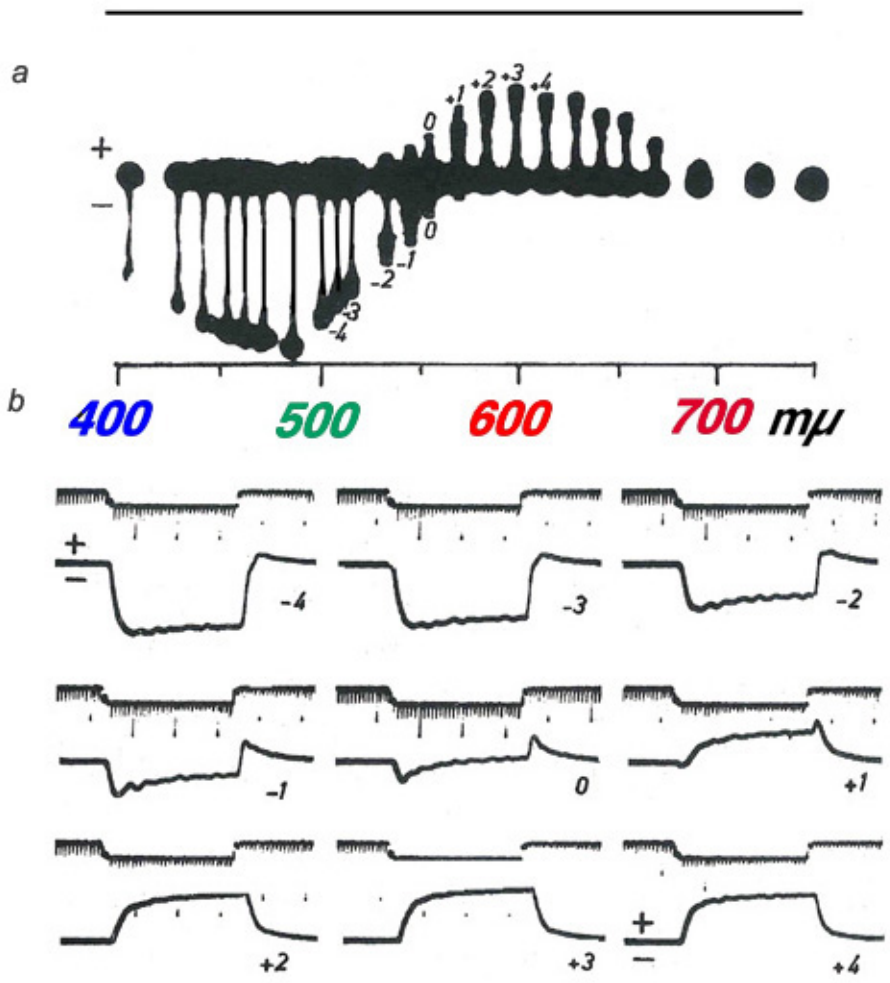

Figure 5. Color opponency of S-potentials in the fish retina. *a*. Responses were recorded as a function of wavelength covering the entire visible spectrum using light stimuli of different wavelength but similar quantal content. *b*. The responses that were elicited by selected light stimuli, numbered in *a* from -4 to +4, are shown at greater time resolution. The longer time marks on the rectangular stimulus traces (upper traces in *b*) are 100 msec, the shorter, 10 msec. The illustration is from Svaetichin and MacNichol, 1959 (80).

synergistic input from blue cones can be detected using specific spectral stimulating and adapting conditions (100). In both A- and B- type cells, rod signals (Fig. 9) are intermixed with cone signals (16, 17).

The failure of mammalian horizontal cells to be color opponent may correlate with the absence of a horizontal cell that avoids contact with long-wavelength cones. The biphasic responses in zebrafish retinas are thought to arise from an H2 type horizontal cell that avoids contact with red cones, while selectively contacting green, blue, and UV cones. Excitatory input arises from the blue and green cone contacts, and the red inhibitory input arises from feedback contacts from red-cone dominated H1, L-type horizontal cells, onto blue cones (Fig.2b, panel E). In the H2 cell there is no red hyperpolarizing signal to mask the H1 red-inhibitory feedback onto the blue cones. This allows the H2 cell to show the color opponent feedback signal (37).

In primate retina, despite a full complement of red, green and blue cone types, horizontal cells also only occur as luminosity types (22, 23). H1 cells receive synergistic signals from long- and medium-wavelength cones (red and green cones), while H2 cells receive synergistic input from all three spectral types of cones; long- medium- and short-wavelength (red, green and blue cones) as shown in figure 10. Anatomically H1 type horizontal cells tend to avoid the pedicles of blue cones (Fig. 10, Neurobiotin-injected H1 cell) (22, 101) and are therefore not responsive to blue-cone isolating stimuli (Fig. 10E). On the other hand, large numbers of H2 dendrites contact

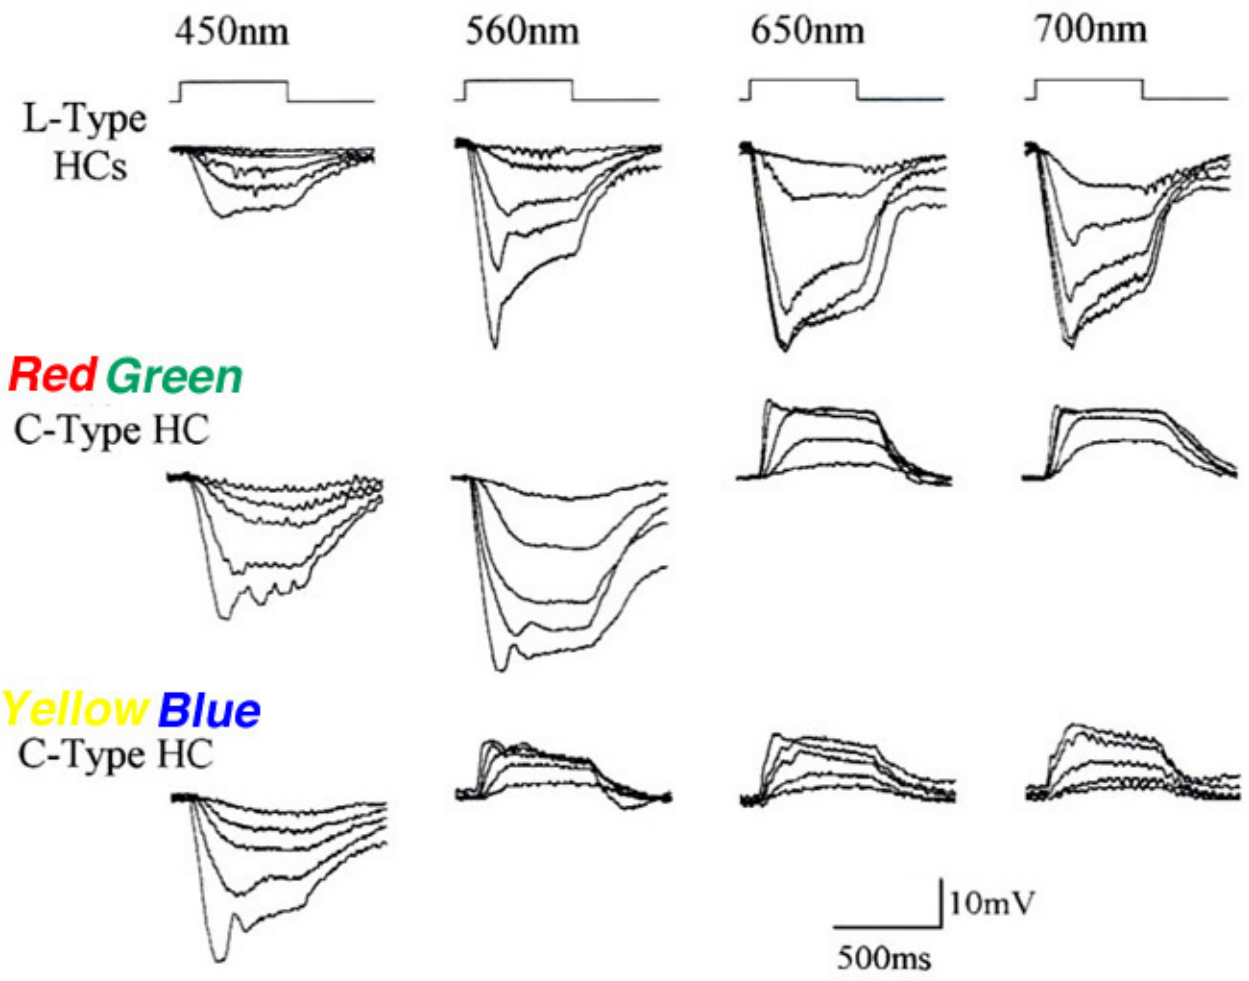

Figure 6. Wavelength dependency of the photoresponses from an L-type horizontal cell, a red/green C-type horizontal cell, and a yellow/blue C-type horizontal cell in the retina of the turtle Mauremys caspica. For each wavelength, several intensities are nested. The illustration is from Twig et al., 2003 (92).

blue cone pedicles (Fig. 10, Neurobiotin-injected H2 cells, outlined clusters) (22, 101, 102). The H2 cell is indeed very sensitive to the blue end of the spectrum (Fig. 10J). Yet, the responses of both horizontal cell types are only of hyperpolarizing polarity to all wavelengths (22). Thus, it appears that subsets of mammalian and primate L-type horizontal cells are devoted primarily to processing of either red green and blue signals or red and green signals, but spectral opponency is not part of the processing regime.

5. Rod and cone contributions and passive electrical models

Mixing of rod and cone signals

Steinberg (19, 99) was the first to distinguish separate rod and cone signals in S-potentials from a mammalian retina. He made intracellular recordings from horizontal cells in the cat retina and saw the typical graded hyperpolarizing responses that depended upon the intensity of the light stimulus. However, unlike the responses seen in non-mammalian retinas, Steinberg's S-potential recordings revealed much more distinct rod and cone contributions to the response. A very slow phase of membrane repolarization seen after termination of the light stimulus was identified as the rod contribution. Steinberg called this the 'rod after effect' (Fig. 9). The difference

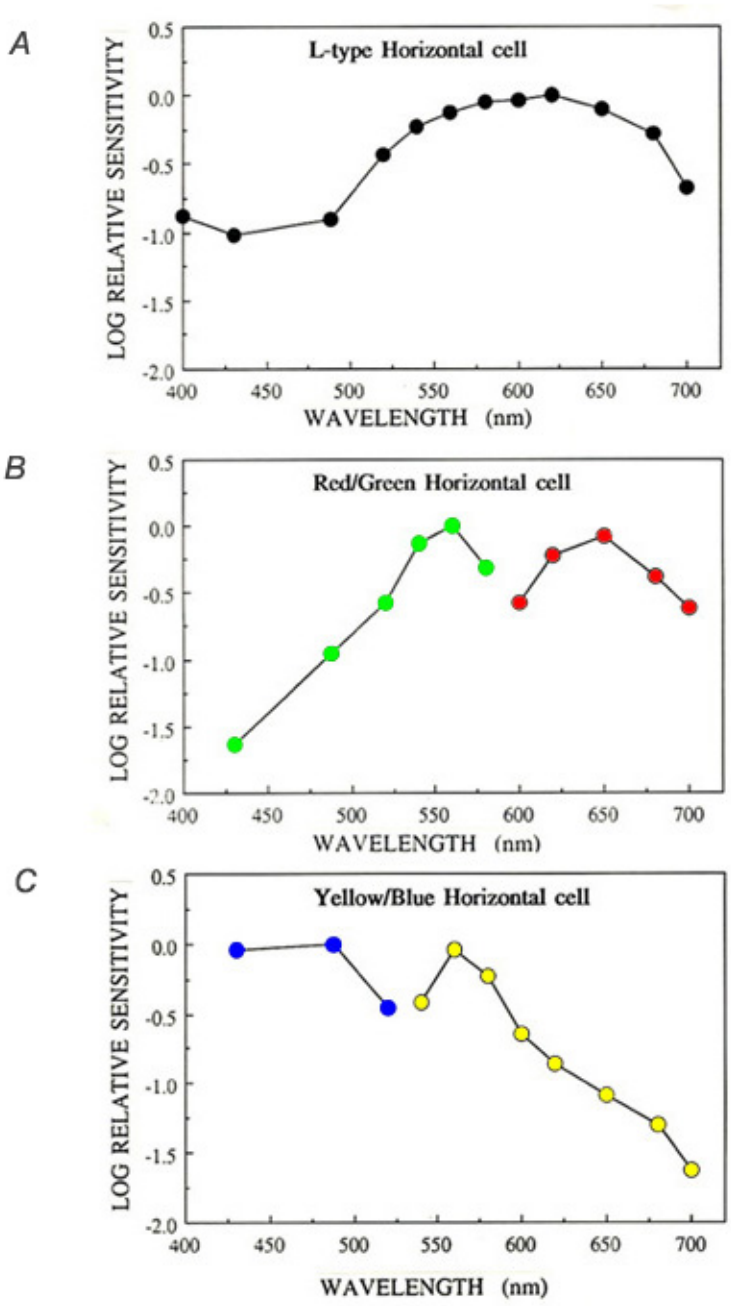

Figure 7. Action spectra of 8 L-type (*A*), 7 red/green C-type (*B*) and 6 yellow/blue C-type (*C*) horizontal cells in the turtle retina (Mauremys caspica). Sensitivity data were calculated from photoresponses of small amplitude (<1 mV) that were elicited by dim light stimuli illuminating the entire receptive field of the studied cells. In order to compare the different action spectra, the spectrum of each cell was normalized to the peak sensitivity. In (*A*), all responses were of hyperpolarizing polarity. In (*B*) and (*C*), depolarizing responses are marked respectively by red and yellow circles, and hyperpolarizing responses by green and blue circles. Reproduced from Asi and Perlman, 1998 (85).

in offset kinetics for rod and cone signal components provides a convenient assay for separating rod and cone inputs to S-potentials in rod-dominated mammalian retinas (16). In Figure 9, typical mixed rod and cone signals of all three horizontal cell structures in cats are shown (17). In A- and B-type horizontal cell bodies, rod and cone signals are about equal in amplitude, whereas in the axon terminal of the B-type cell, the slowly recovering response characteristic of rod signals occurs. This is interpreted to indicate that rod and cone signals are almost

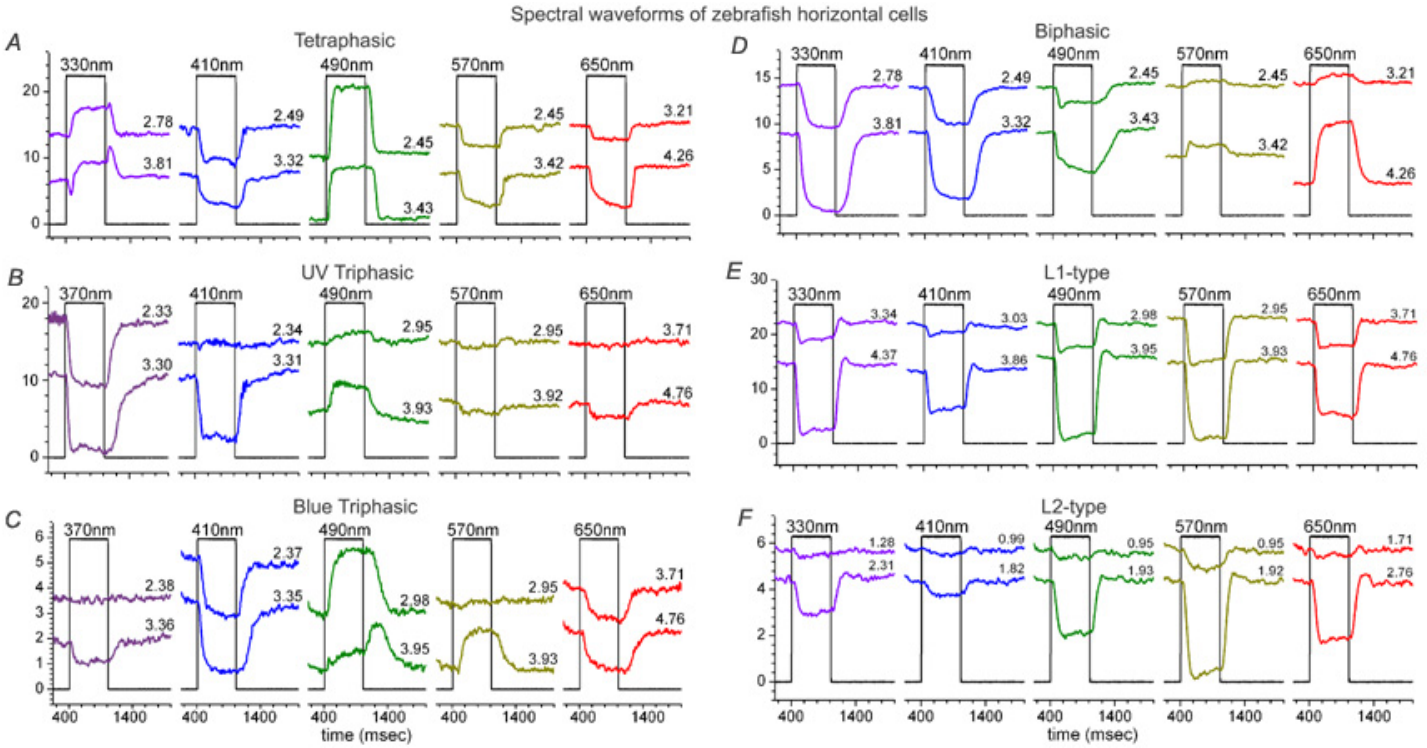

Figure 8. Color physiology of zebrafish horizontal cells. *A*. Tetraphasic type is depolarized by ultraviolet (UV-330nm) hyperpolarized by blue (410nm) depolarized by blue-green (490nm) and hyperpolarized both by yellow (570nm) and red (650nm) wavelengths. *B*. UV triphasic cell hyperpolarizes at full amplitude for both irradiances of the UV 330nm stimuli but is depolarized by the dimmer of the blue 410nm stimuli and hyperpolarized by the brighter 410nm stimulus. For 490nm the cell depolarizes, but at longer wavelengths the cell hyperpolarizes. The blue triphasic cell (*C*) hyperpolarizes fully for both 410nm blue stimuli, but responds only weakly to 330nm UV stimuli. Depolarization occurs in the blue-green (490nm) and yellow (570nm) but the cell hyperpolarizes for red stimuli (650nm). The biphasic cell (*D*) is hyperpolarized for short-wavelengths (330nm, 410nm, and 490nm) but is depolarized by long wavelengths (570nm, 650nm). Two L-type cells, L1 (*E*) and L2 (*F*) hyperpolarize at all wavelengths, but the amplitude ratio at 490nm and 570nm favors 570nm for the L2-type, and is more evenly balanced for the L1-type. All amplitudes are given in mV. Numbers to the right of each trace are stimulus irradiance, given in $\log(h\nu \cdot \mu m^{-2} \cdot s^{-1})$. Illustrations are from Connaughton and Nelson, 2010 (6).

equally mixed in cat horizontal cell bodies, but only rod signals are seen in the axon terminals. The 'rod after effect' grows increasingly prolonged with bright light stimuli (Fig. 9, bottom).

Further evidence for the mixing of rod and cone inputs to cat horizontal cells is seen during light adaptation. When retinas are light adapted by steady background lights, rod signals saturate and rod contributions to the horizontal cell photoresponses, including rod after-effects, vanish. In contrast, the cones adapt to the brighter conditions and their input remains robust. These properties of rod and cone inputs are easily seen in the photoresponses of mammalian horizontal cells such as cats and rabbits (15, 17, 19). The photoresponses of the rod-dominated B-type horizontal cell axon terminals are virtually abolished by light adaptation. In the horizontal cell bodies (A and B types), which receive mixed rod and cone inputs, light adaptation selectively reduces the rod contribution but large cone signals remain and therefore, these horizontal cell elements continue to respond well in the presence of background lights (16).

Axon terminals of the axon-bearing B-type horizontal cells in the cat receive an excitatory feed-forward input only from rods, but the cell bodies of A-type and B-type cells contact only cones. So where does the large rod component of the S-potential in the cell bodies of cat horizontal cell bodies come from? Electron microscope observations show gap junctions linking rod and cone photoreceptors in the mammalian outer plexiform layer (103, 104). These electrical synapses introduce rod signals into cones and thence into horizontal cells. This rod/

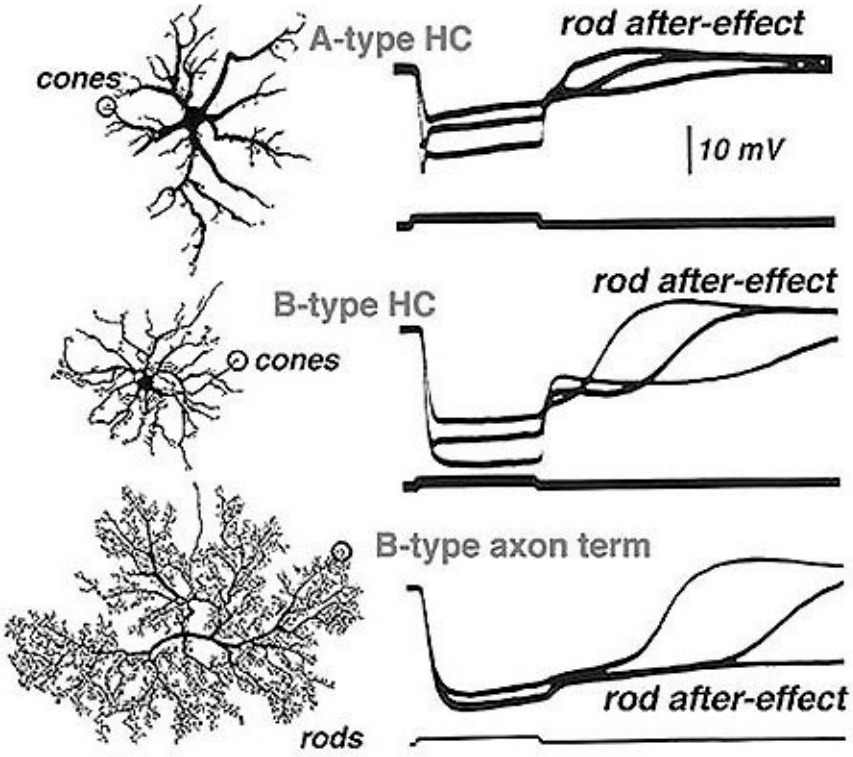

Figure. 9. Rod-cone mixing in horizontal cells of the cat retina. Responses to light stimuli of different intensities were recorded from the cell bodies of A-type and B-type horizontal cells and from the axon terminal of the B-type horizontal cell. Brighter stimuli produce greater amplitudes from the cones, and longer 'rod after-effects' from the saturated rod signals. The illustration is adapted from Nelson et al., 1975 (17).

cone mixing in the photoreceptors is now considered one of the pathways whereby rod driven inputs pass to horizontal cells and to all subsequent second and third order cells in the retina (105-108).

In other species, similar characteristics of rod-cone mixing can be found in horizontal cells. In the rabbit retina, as in the cat retina, rod-dominated input to the axon terminal is identified by waveform, sensitivity and the presence of after-potentials (15, 109). Also in primate retina, the axon terminals of the axon-bearing H1-type horizontal cells produce rod signals while the cell bodies produce cone or mixed rod-cone signals (22, 23, 26). Similar to other mammalian retinas, the somata of primate H1-type horizontal cells receive rod input indirectly via gap junctions between rods and cones (26).

Horizontal cells of reptiles and amphibians, like mammals, mix rod and cone signals. In the retina of the turtle Chelydra serpentina, the photoresponses of H1 axon terminals contain slow, low-amplitude components that are contributed by rod photoreceptors, despite the major excitatory input being from long-wavelength sensitive cones. The cell bodies of the same H1 horizontal cells receive input only from long- and medium-wavelength sensitive cones (110). In Xenopus, horizontal cell dendrites contact both rods and cones (111). Similar to mammals, waveforms characteristic of rods and cones, including rod after-effects are recorded in these cells with light stimulation (112). The amphibian circuitry, with direct rod contacts onto horizontal cell dendrites, differs from mammals, where only cones are contacted, and rod signals enter cones directly through gap junctions. No rod signals have been reported in the purely cone-contacting horizontal cells of fish (Fig. 2b, Fig. 8). In fish rod signals are restricted to H4, a special rod-connected horizontal cell type (45, 46).

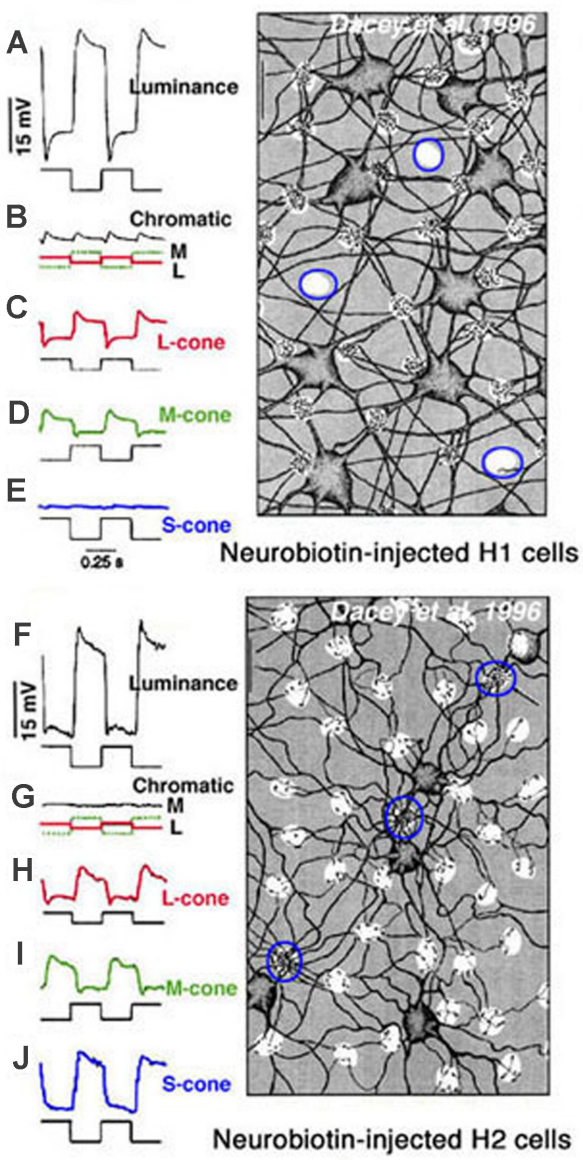

Figure 10. Connectivity and physiology of horizontal cells in the monkey retina. Above: Intracellular staining and chromatic responses of H1 cells. These cells avoid dendritic contact with S-cones (blue outlined white circles). There is no response to S-cone (blue-cone) isolating stimuli (trace *E*). Below: Intracellular staining and chromatic responses of H2 cells. These cells send many dendrites to S-cones (blue outlined cones) as well as to red and green cones. The response to S-cone isolating stimuli is large (*J*). The illustration is from Dacey, 1996 (22).

Passive electrical models

All vertebrate retinas contain at least one horizontal cell type that is an axon-bearing cell (Fig. 2a, *B-types*). The axon terminals and somata of these horizontal cell types are connected by a long thin axon, but in many cases each end behaves as an isolated physiological unit. In the turtle Pseudemys scripta elegans, both axon terminals and somata receive excitatory input mainly from red cones but differ in spatial properties and response kinetics for red and green stimuli (53, 81). In another turtle species, Chelydra serpentina, the axon terminal receives excitatory input from red cones and rods while the cell body dendrites contact red and green cones (110). In domestic mammals (cat, rabbit) and in primates (monkey), the dendrites of the cell body receive input from cones while the terminals of the axon contact thousands of rods. No evidence has been found to indicate any synaptic or electrical interaction between the axon terminal and the soma of the same cell in any of these cases.

Where horizontal cell types have the dendritic portion of the cell much distant from the axonal ending (Fig. 2a, *B-types*), calculations based on the anatomical dimensions and geometry of the neuron, and ohmic linear properties of cell membrane and cytoplasm, indicate that the axons are too long and thin to allow significant passive electrotonic spread of signals from one end of the cell to the other (17, 26, 36, 110). Such models tell us that signals in cell bodies and axon terminals of horizontal cells reflect only the local synaptic inputs. Indeed, the two portions of the same cell act as independent units (17), in clear violation of neuron theory.

The exception to this rule of physiological separation between cell body and axon terminal appears to be the cone-connected horizontal cells in fish. The cone responses of axon terminals in these cells are similar to the cell bodies (3). As there are no cone contacts from/to the axon terminals in fish, it appears likely that signals are passively conducted from the cell body. The high impedance of the simple unbranched axon terminal may be permissive to the passive propagation of signals through the axon.

6. Ionic conductances

Ionotropic glutamate-gated channels

Photoreceptors excite horizontal cells through sign-conserving synapses. In darkness, photoreceptors continuously release an excitatory neurotransmitter that opens horizontal-cell cationic channels with a depolarized reversal potential. Therefore, the horizontal cells are maintained at a relatively depolarized potential in darkness. When the photoreceptors are hyperpolarized by a light stimulus, neurotransmitter release is reduced, the post-synaptic ligand-gated channels close and the horizontal cells hyperpolarize. Neurotransmitter release from photoreceptor terminals is calcium dependent. Exposing the retina to ions that interfere with calcium influx through voltage-dependent calcium channels blocks neurotransmitter release from the photoreceptors, and consequently horizontal cells hyperpolarize (113-115).

Early experiments in intact retinas pointed to the excitatory amino acids L-glutamate and L-aspartate as putative candidates for the photoreceptor neurotransmitter (116-120). Exposing the retina to either L-glutamate or L-aspartate caused depolarization of horizontal cells and loss of photoresponses as shown in figure 11A for horizontal cells in the intact rabbit retina (116). These observations are consistent with the notions that an excitatory amino acid is continuously released by the photoreceptors in the dark, and that light-induced hyperpolarization of horizontal cells reflects the reuptake of the amino acid from the synaptic cleft. Accordingly, exogenously applied neurotransmitter saturates the receptor sites in the horizontal cells causing further depolarization. Since the horizontal cells are saturated with the *ex*ogenously applied neurotransmitter, modulation of *end*ogenous transmitter release by light stimuli has little effect on membrane potential and the photoresponses are eliminated. In the experiment described in figure 11A, solutions containing 15 mM L-aspartate or L-glutamate were needed to induce depolarization of rabbit horizontal cells and loss of photoresponses. These and other studies raised two major questions (1). Why were relatively high concentrations (in the millimolar range) of excitatory amino acids needed to exert the effects shown in figure 11A (78)? Which of the two excitatory amino acids was the photoreceptor neurotransmitter?

The first question was answered by the identification of efficient uptake systems for glutamate and aspartate by excitatory amino acid transporters (EAATs) (121, 122). EAATs efficiently remove excitatory amino acids from extracellular space, thereby greatly reducing the concentration of the exogenously applied aspartate or glutamate reaching the cone-to-horizontal-cell synapses. Retinal glutamate transporters are reviewed elsewhere in Webvision. When non-transportable analogues of excitatory amino acids are applied, considerably lower concentrations are needed to exert effects on horizontal cells (109, 123). This is illustrated in figure 12 where the effect of 10 mM L-glutamate (A) is compared to that of 0.1 mM kainic acid (B). Kainic acid, an agonist for AMPA-kainate-type glutamate receptors in vertebrate horizontal cells, but not a substrate for EAATs, exerts effects similar to L-glutamate at a concentration lower by 100 fold. In both cases horizontal cells are depolarized

and photoresponses lost. In further support of the excitatory amino acid receptor hypothesis, kynurenic acid, a non-selective antagonist of excitatory amino acid receptors (124) hyperpolarizes horizontal cells, also with loss of photoresponse (Fig, 12 C).

The exact identity of the excitatory amino acid was debated for more than a decade. A variety of experiments in intact retinas were designed to decide between L-glutamate and L-aspartate as candidates for photoreceptor neurotransmitter, but with conflicting conclusions. It was not until the development of the isolated cell preparation that a clear answer to this question was obtained. Lasater and Dowling (125), in their pioneering work, isolated horizontal cells from the carp retina and recorded the membrane potentials with sharp microelectrodes. Since these horizontal cells in culture were separated from all other influences of retinal circuitry, including photoreceptor stimulation, they were characterized by hyperpolarized resting potentials (close to the potassium equilibrium potential). Application of low doses of L-glutamate, but not of L-aspartate or D-glutamate, induced depolarization, indicating that selective receptors for L-glutamate existed in the horizontal cell membrane (Fig. 11B). With this experimental approach, a low concentration of L-glutamate was sufficient to induce effects, because in this preparation, removal of extracellular L-glutamate by uptake systems is negligible.

Voltage- and current-clamp techniques have been applied to isolated horizontal cells from a variety of species in order to reveal the properties of the glutamate-gated channels. These channels have a reversal potential around 0 mV, depending upon the composition of the intra-pipette and extracellular solutions (123, 126-128). Pharmacological analysis of the properties of the glutamate-gated channels in horizontal cells, using specific agonists and antagonists, revealed them to be of the AMPA/KA type. They are specifically activated by α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) or kainic acid (KA) and are antagonized by 6-cyano-7-nitroquinoxaline (CNQX) or cis-2, 3-piperidine-dicarboxylic acid (PDA) (129, 130). When AMPA/KA ion channels are activated by the agonist kainic acid, the induced currents are considerably larger than those elicited by L-glutamate, even at higher concentrations (127, 131). This effect has been attributed to fast desensitization of the AMPA/KA type channels by L-glutamate but not by kainic acid (132, 133). Selective blockers of the glutamate-induced desensitization (e.g. cyclothiazide) cause glutamate-induced currents to reach levels similar to those elicited by kainic acid, buttressing the conclusion that horizontal cells express largely AMPA-type glutamate receptors (134-136). Catfish horizontal cells, which express NMDA receptors in addition to AMPA/KA receptors, appear to be an exception to the above general conclusion (131). Further, there is physiological evidence for kainate receptors in addition to AMPA receptors in horizontal cells cultured from human retina (137).

Metabotropic glutamate actions

Glutamate also influences horizontal cells through metabotropic pathways. Unlike ionotropic AMPA-glutamate responses, metabotropic actions do not spread globally through membrane voltage changes within the horizontal cell network, but remain local, influencing only nearby cytoplasmic chemistry. DL-AP4, a glutamate analogue selective for type III metabotropic glutamate receptors, suppresses nearby voltage sensitive potassium channels (138). Similarly, group I and group III metabotropic glutamate receptors increase the amplitudes of nearby voltage-gated calcium currents in horizontal cells (139). Glutamate provides further metabotropic regulation of calcium and potassium channels through modulation of cytoplasmic pH (140). NMDA receptors on catfish horizontal cells have been observed to down-regulate voltage dependent sodium and calcium channel activity through a calmodulin-dependent mechanism, also a type of metabotropic effect (141). Furthermore sodium entry through stimulated AMPA-glutamate channels stimulates local activity of Na^+K^+ ATPase. This in turn appears important in setting membrane potential (142). Thus, in addition to causing the light response itself, photoreceptor glutamate regulates a variety of cellular and membrane functions.

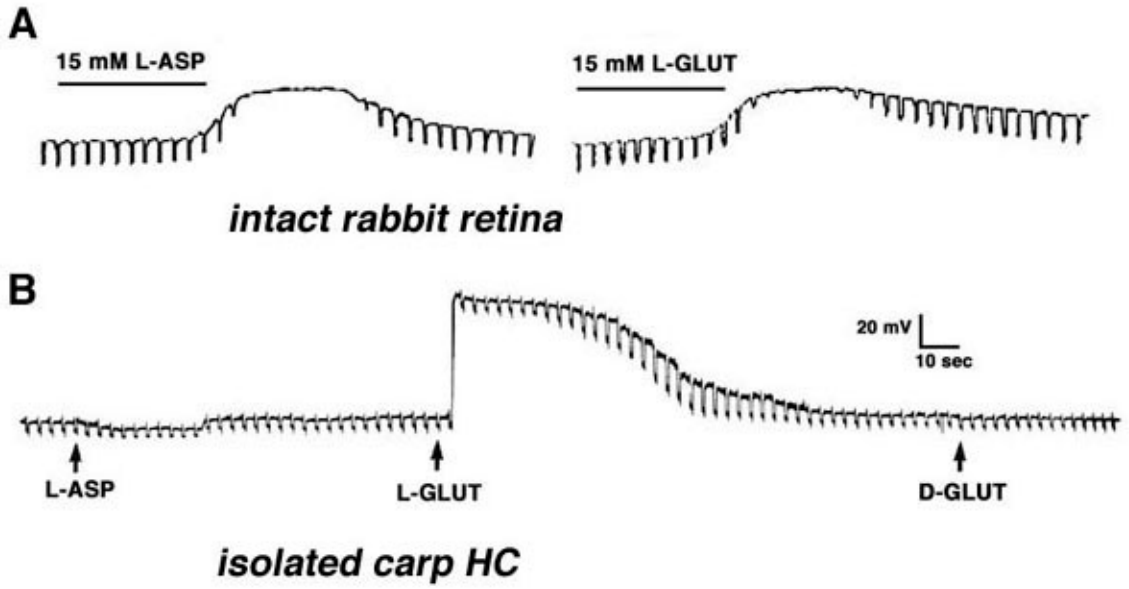

Figure 11. *A*. L-aspartate and L-glutamate depolarize horizontal cell membrane potential and abolish horizontal cell photoresponses in intact rabbit retina. These photoresponses were elicited by diffuse light stimuli. The illustration is from Bloomfield and Dowling, 1985 (116). *B*. L-glutamate depolarizes the membrane potential of a horizontal cell isolated from the carp retina, while L-aspartate and D-glutamate exert no effect. Each application pipette was filled with 500 μM of drug. Current pulses measure changes in membrane resistance. The illustration is from Lasater and Dowling, 1982 (125)

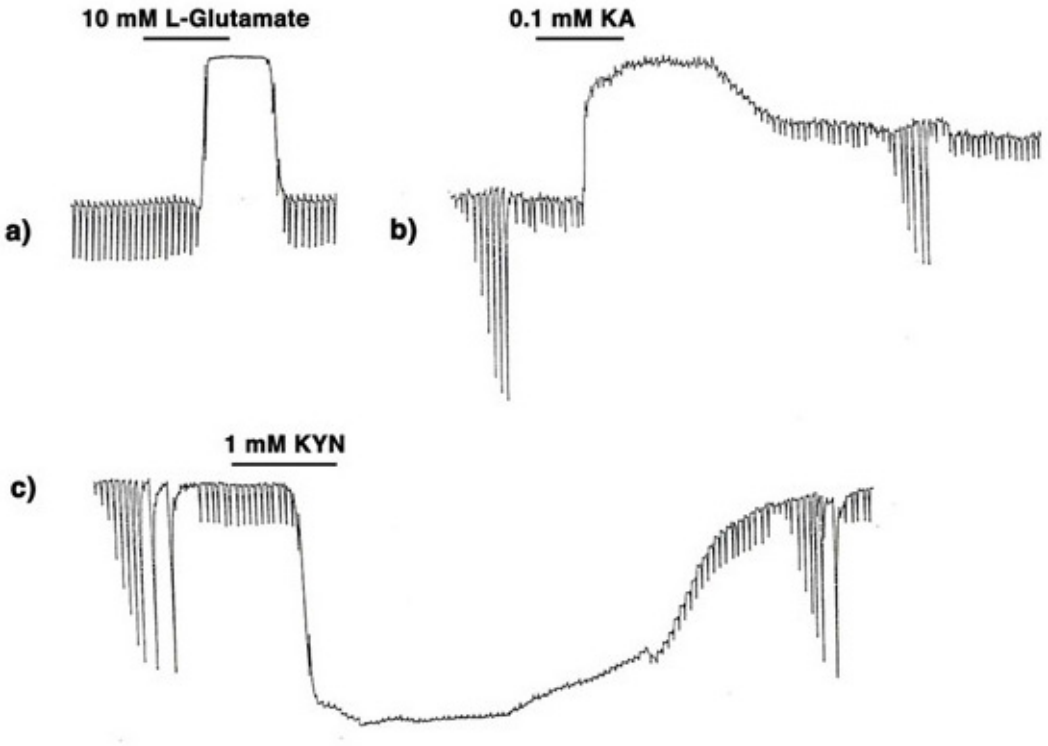

Figure 12. The effects of L-glutamate (*a*), kainic acid (*b*) and kynurenic acid (*c*) upon the membrane potential and photoresponses of L-type horizontal cells in the retina of the turtle Mauremys caspica. The illustrations are from Perlman.

Voltage- and time-dependent membrane channels

The photoresponses of horizontal cells from cold-blooded, as well as warm-blooded mammalian retinas, are shaped by voltage- and time-dependent ionic channels located within the plasma membrane (143-146). Five types of ionic currents; a sodium current, a calcium current and three types of potassium current have been identified in isolated horizontal cells of goldfish (147), catfish (148), white perch (143), skate (149), turtle (150), rabbit (145) and cat (146).

Voltage steps evoke membrane current responses for two types of horizontal cells isolated from the cat retina (Fig. 13A) and four types of horizontal cells isolated from the retina of the white perch (Fig. 13B). In cat horizontal cells, the inward sodium current is clearly evident during the first 10 ms of the current responses while at the steady state, a sustained outward potassium current is seen (Fig. 13A). Fish horizontal cells exhibit a more complex array of currents as evident from the current waveforms and the I-V curves for transient and sustained portions of the response to electrical stimulation (Fig. 13B). Basically all four types of fish horizontal cells exhibit similar ionic currents but they differ in relative magnitude. The sodium current is inward going and is seen during the initial 10ms of the current pulses that are recorded when the horizontal cells are depolarized from a negative holding potential (about -70mV) to around 0mV. It is very similar to the regenerative sodium current typical of spiking neurons. The physiological role of this current in horizontal cells is not known since these cells do not exhibit action potentials. Three types of potassium channel have been identified by their voltage- and time-dependency and by their sensitivity to specific blockers. The inwardly rectifying channels conduct an inward current when the cells are hyperpolarized below potassium equilibrium potential. In some species, extracellular sodium ions influence the reversal potential of these channels making the currents functional at physiological potentials (151). The sustained outward potassium current (delayed rectifier) is activated at potentials more depolarized than the resting, dark potential of the horizontal cells. The outward transient potassium current (I_A), is activated upon fast depolarization from negative potentials. In the intact turtle retina, the outward transient potassium current is activated upon termination of a bright light stimulus, speeding the recovery of the L-type horizontal cell from the depolarizing overshoot at light offset back to the dark level. This effect allows the L-type horizontal cells to follow fast flickering stimuli and thus, improves the frequency response curve of the cells (152).

L-type calcium responses are a prominent feature of isolated horizontal cells. These channels inactivate only slowly resulting in long duration spikes and persistent depolarized states (142, 146, 148, 153). Outward potassium currents appear in themselves too weak to inactivate calcium currents in these cells (154), however glutamate activation of the electrogenic Na/K ATPase appears sufficient to restore hyperpolarized membrane potentials (142). Calcium currents may sometimes contribute to oscillations in the light responses of horizontal cells (155).

GABA receptors and transporters

Some, but not all, horizontal-cell types accumulate GABA (51). A likely target of horizontal-cell GABA is other horizontal cells. Kamermans suggested GABA as mediator of positive feedback between these neurons (156). In many species $GABA_A$ and/or $GABA_C$ receptors are located on horizontal cells. Qian and Dowling discovered retinal $GABA_C$ receptors. They were localized on the membranes of isolated rod horizontal cells of white perch (157). Retinal $GABA_C$ receptors are reviewed elsewhere in Webvision. Currents from $GABA_A$ receptors are found in dissociated rabbit horizontal cells (158). Both $GABA_A$ and $GABA_C$ receptor currents as well as GABA transporter currents occur in isolated catfish horizontal cells (159, 160). Isolated horizontal cells from skate (161) or zebrafish (162) show no evidence of GABA receptor physiology, but do possess GABA transporter physiology. Horizontal-cell GABA circuits are species specific, nonetheless GABA would appear to be an important signaling molecule within the vertebrate outer plexiform layer, and GABA roles include signaling between horizontal cells.

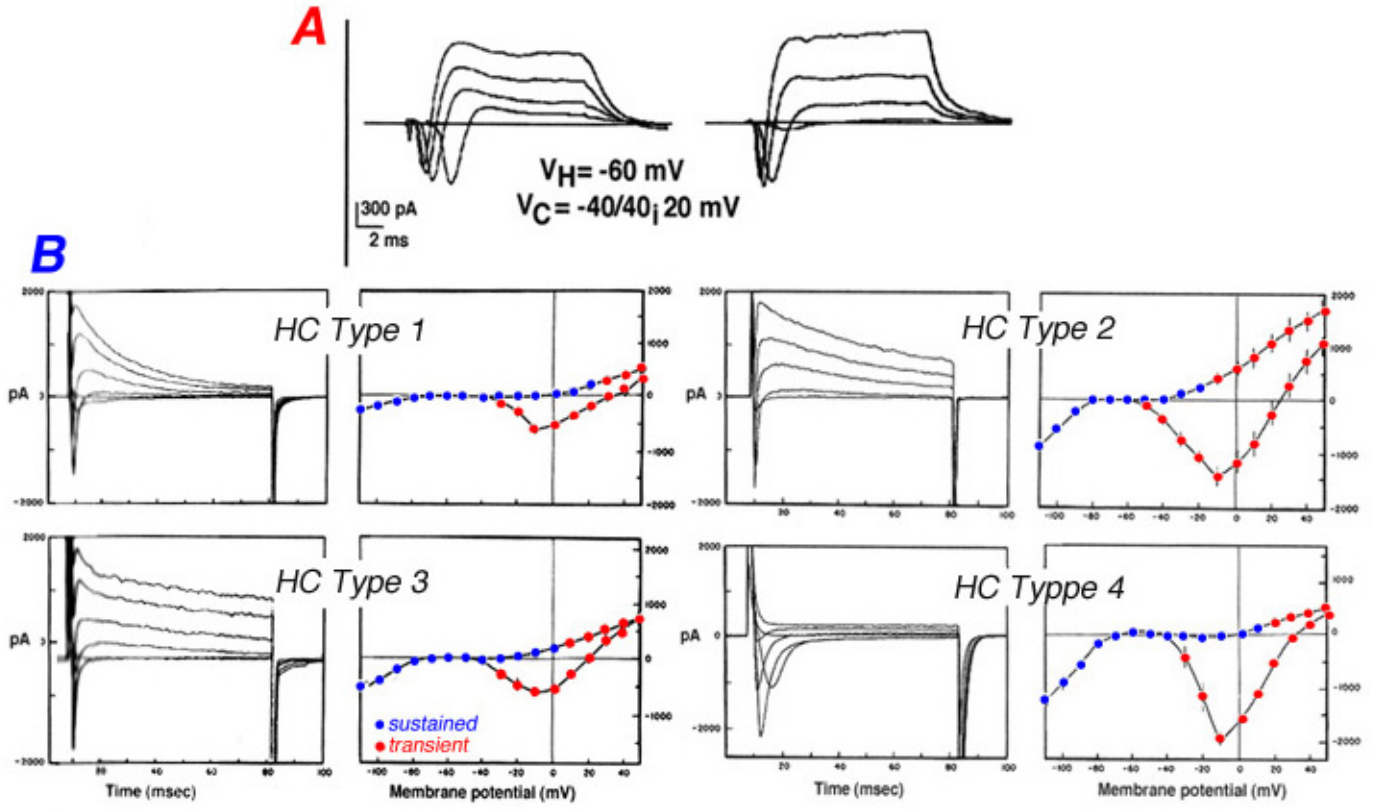

Figure 13. Voltage- and time-dependent ionic conductances in isolated horizontal cells. *A*. Current responses to different voltage steps from a holding potential at -60mV in horizontal cells from the cat retina, from Ueda et al., 1992 (146). *B*. Current responses and I-V curves from 4 types of horizontal cells that were isolated from the retina of the white perch, from Lasater, 1986 (143).

7. Gap junctions and spatial characteristics

Gap junctions

In all vertebrate retinas including mammals, horizontal cells are characterized by large-surface-area gap junctions (Fig. 3c) between each others' dendrites (163, 164). These junctions allow lateral flow of small molecules and ions within the horizontal cell network. Gap-junction-permeant tracers such as Lucifer yellow or Neurobiotin that are injected into one horizontal cell in the layer spread to hundreds of neighboring cells, forming striking images of the interconnected horizontal cell network (Figs. 14, 15A) (14, 66, 67, 84, 165, 166). Gap junctions are formed only between neighboring horizontal cells of the same physiological type as shown in figures 14 and 15A. Networks of turtle H2 cells (Fig. 15A, left panel) and of rabbit A-type cells (Fig. 15A, right panel) are revealed by neurobiotin injection into one cell of the network. Gap-junction connexons between rabbit A-type horizontal cells accommodate molecules as large as 500 Daltons (74). The permeance of the gap junctions between horizontal cells and therefore, dye coupling, is influenced by the intracellular and extracellular milieu and by chemicals such as dopamine, retinoic acid, nitric oxide or hydrogen ions that are released by other retinal cells (see section on neuromodulators).

Receptive field properties

The gap junctions between horizontal cells are highly permeable to small ions and therefore, serve as low-resistance pathways for electrical signals to spread laterally within the horizontal cell layer. Thus, horizontal cells receive excitatory input directly from photoreceptors via chemical synapses and also indirectly via gap junctions

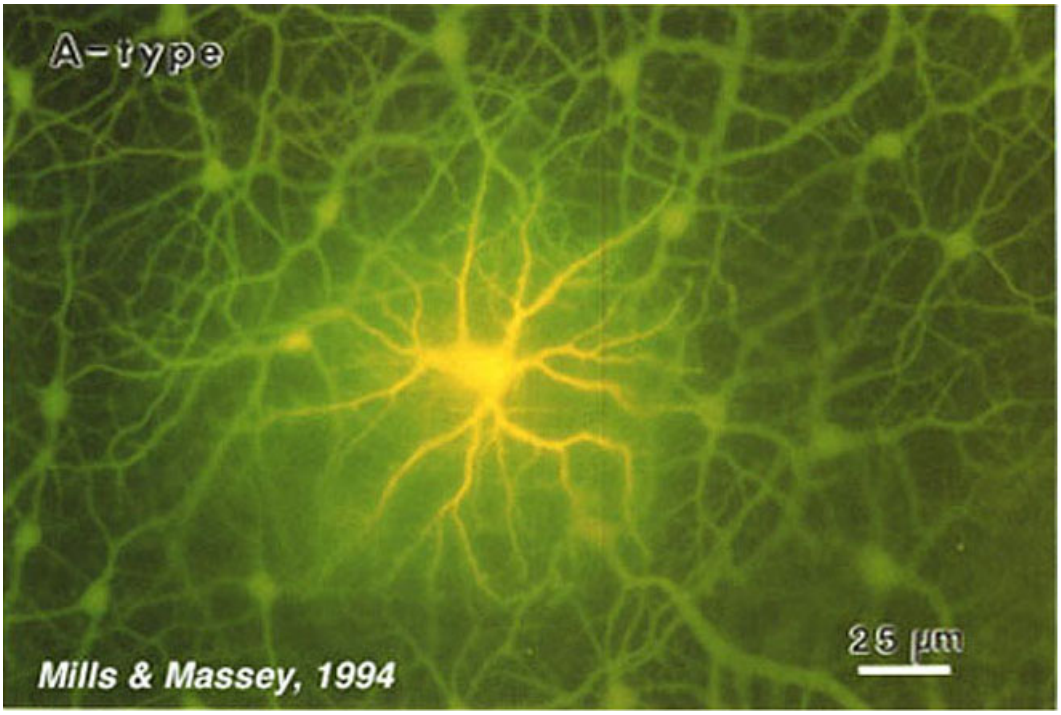

Figure 14. Rabbit horizontal cell network revealed by dye injection. Lucifer dye, injected into one cell, spreads via the gap junctions linking A-Type horizontal cells to reveal the centrally injected cell and hundreds of neighboring cells. The illustration is from Mills and Massey, 1994 (67).

with neighboring horizontal cells. The physiological consequence of the gap junctions between horizontal cells is to create a very large receptive field that spreads out to distant retinal regions, regions beyond the extent of direct dendritic contact with photoreceptors (10, 66).

The receptive fields of horizontal cells are measured by several spatial protocols. The most common are (1) examining responses to a series of concentric spots of increasing diameter but fixed irradiance, or (78) examining responses to long narrow slits of light presented at different positions across the retina. In either case response amplitudes can be modeled, at least to first order, by differential equations describing current flow in a resistive plane (16, 167, 168), or equivalently by discrete passive networks of interconnected resistors (53). An experiment in which an L-type horizontal cell in the retina of the turtle Pseudemys scripta elegans was stimulated with a series of concentric spots of fixed intensity is shown in figure 15B. The first photoresponse to the left was elicited with a stimulus of super-saturating intensity that illuminated the entire receptive field of the cell. This is the maximal photoresponse. A series of 6 photoresponses were then elicited by sub-saturating light stimuli with different stimulus diameters, as illustrated diagrammatically above each response. The photoresponse amplitude gradually decreases as the size of the illuminated retinal area is reduced (Fig. 15B; graph). This reduction of amplitude is not due to diminution of photoreceptor synaptic input to the recorded cell, as even the small spot stimuli are larger than the dendritic extent of the cell. Thus, it is suggested that the low amplitude of the responses to small spot light stimuli are due to shunting of the local photoreceptor input into neighboring horizontal cells through gap junctions. With full-field illumination, all the horizontal cells are evenly illuminated, equipotential, and therefore, no current flows between them. With small spot illumination, the membrane potential of non-illuminated horizontal cells is different from that of illuminated cells causing electrical currents to flow between them and thus, to shunt the responses of the illuminated cells.

The receptive field of a cat A-type horizontal cell, mapped with a narrow slit of light, is shown in figure 16. Exponential decay of response amplitude flanks both sides of the maximal response, which is elicited when the narrow slit is centered on the studied cell. Note that this maximal slit response is always smaller than the one

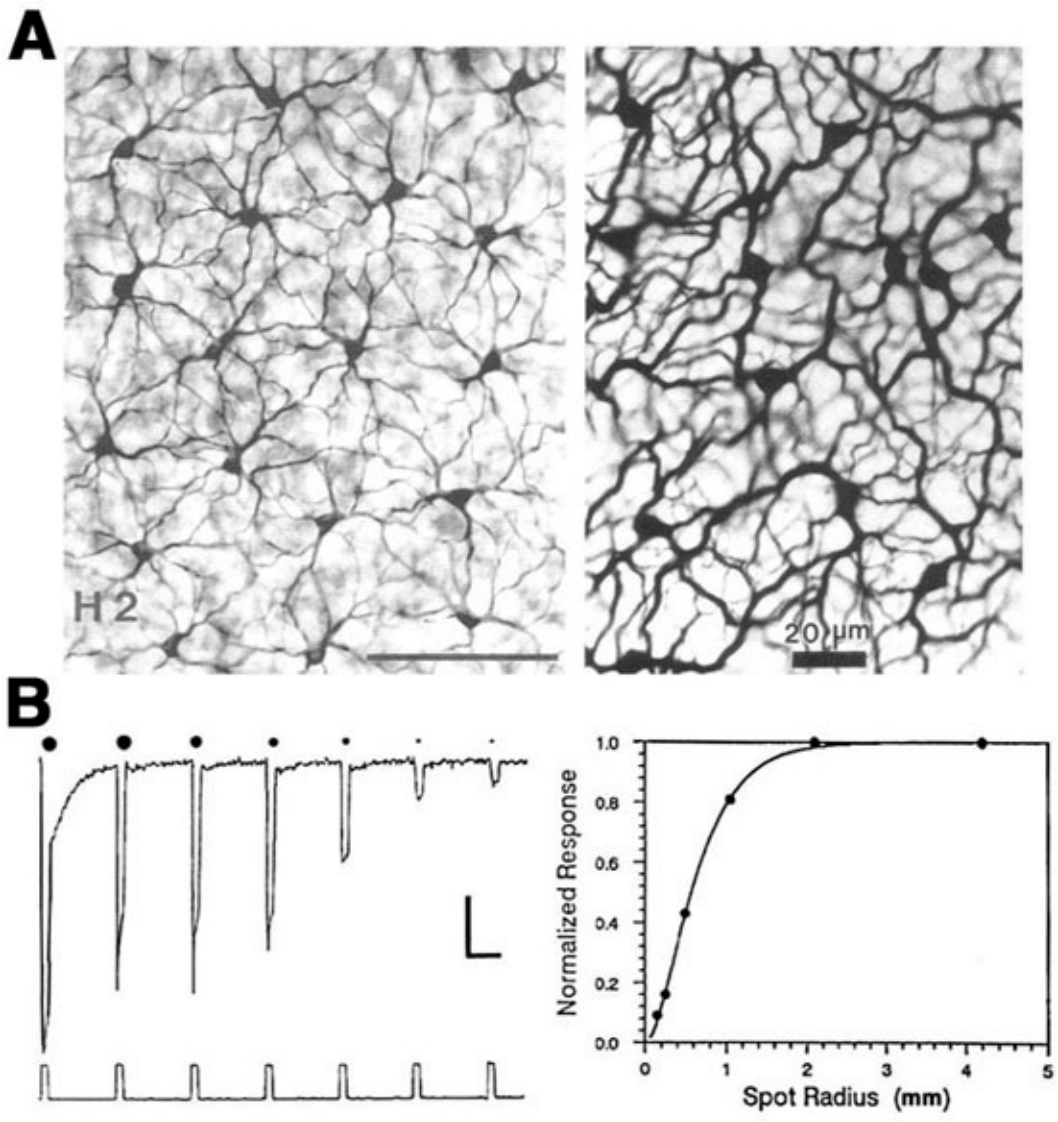

Figure 15. *A*. The syncytia of H2 cells in turtle retina (left) and A-type horizontal cells in the rabbit (right) as revealed by Neurobiotin injection into one cell in each syncytium. The illustration in turtle retina is from Ammermüller et al, 1996 (84); the rabbit retina illustration is from Mills and Massey, 1994 (67). *B*. The size of the receptive field of a turtle L-type horizontal cell as determined from the photoresponses that were elicited by concentric light stimuli of different diameters (left). The peak amplitude, normalized to the response to full field illumination (2^{nd} response from the left), is plotted as a function of spot radius in order to derive the length constant (right). The illustration is from Perlman and Ammermüller, 1994 (176).

elicited by a large light stimulus of the same intensity that covers the entire receptive field of the studied cell (V_{max}). The red receptive field (Fig. 16A) measures the spatial extent of cat red cone signals, while the blue receptive field (Fig. 16B) measures the spatial extent of rod signals, both signal components occur in the same horizontal cell. These signals share a common center, but differ in space constant.

The dimension of the horizontal cell receptive field can be quantified. Using variable diameter spots, one common procedure is to find the minimum spot diameter that elicits a maximal response. Another measure is the receptive-field length constant lambda (λ). For models based on electrical current flow in the horizontal cell layer, lambda is defined as the slit displacement required to reduce response amplitude by 1/e (16, 167, 169, 170). Some other definitions of lambda based on empirical curve fitting of data have also been suggested (10, 171). For models based on electrical current flow in the horizontal-cell syncytium, receptive field size is directly related to lambda, and lambda is directly related to the membrane resistance of the horizontal cell, and inversely related to

the coupling resistance between the horizontal cells. The space constant of the cone signal components in a cat A-type horizontal cell (Fig. 16A) is 250 μm. The space constant for the rod signal component in the same cell is 200 μm (Fig. 16B). This illustrates the point that even in the same cell, depending on what is being measured; somewhat different receptive fields can be inferred. The concept of field size is not monolithic.

The exceptional width of horizontal-cell receptive fields finds several uses. First, horizontal-cell actions on photoreceptors and bipolar cells, both of which are much narrower in receptive field centers than horizontal cells, can be seen in the distal limbs of area functions in these narrower-field neurons. Second, horizontal cell types can be distinguished by the size and properties of receptive fields. In the turtle retina, two types of luminosity horizontal cells were early recognized; L1 and L2 (53) or respectively, large receptive field (LRF) and small receptive field (SRF) horizontal cells (81). The L1 (LRF) cells are characterized by receptive fields of large diameter (>3 mm) while the L2 (SRF) cells have a receptive field diameter of about 2 mm. These two L-type horizontal cells also differ with regards to spectral properties (172) and responsiveness to surround illumination (173). The anatomical stains of LRF and SRF cells actually reveals that they are two, electrically isolated, parts of the same cell. LRF is the axon terminal of H1, and SRF is the cell body (Fig. 2a) (53). Thus receptive field measurements add further evidence that a single horizontal cell may have 2 independent area summation regions.

The horizontal cell syncytium cannot be fully described by static passive electrical models. The resistances within the horizontal cell layer change with illumination and time and therefore, the size of the receptive field (magnitude of lambda, or the length constant) changes also (169, 174, 175). In general, the size of the receptive-field length constant is related to the intensity of the light stimulus used to measure it (16, 167, 172, 176, 177). When the irradiance of the ambient illumination is increased, the length constant first increases to a peak value and then decreases (16, 169, 175). The spatial properties of C-type horizontal cells in the turtle retina depend upon the color of the light stimuli (91, 178). The waveform of the photoresponses of C-type horizontal cells may change dramatically when the spatial pattern of the light stimulus is changed, especially when the wavelength of the light is close to the zone where response polarity reverses (91). This is because depolarizing and hyperpolarizing mechanisms may differ in size. In isolated pairs of horizontal cells, coupling current decreases somewhat over time (179), potentially introducing another time-dependence in receptive fields. A further receptive field size dependency is introduced by neuromodulators such as dopamine (see below).

8. Feedback

Effects on cone receptive fields

Horizontal cells are post-synaptic to photoreceptors, but are also pre-synaptic, forming a *feedback* loop. Horizontal cells send wide-field visual signals back to the narrow center mechanism of cones through these feedback pathways (180-186). The effects of these pathways is revealed by adjusting the size, shape and color of the light stimuli used to evoke responses from cones. The effects of area and brightness on cone photoresponses from the retina of the tiger salamander are shown in figure 17 (183). Each pair of responses was elicited by light stimuli of the same intensity but different size. The early ON-phase of each pair of photoresponses (initial hyperpolarization) is identical regardless of the size of the stimulus, but the later phases are considerably affected by the stimulus size. With a small spot stimulus, following the initial hyperpolarization, the cell slightly recovers towards the dark potential but the membrane potential is maintained at a hyperpolarized level for the entire duration of the stimulus. When a large spot stimulus is used, a significant depolarization is seen after the initial hyperpolarizing phase (arrows in Fig. 17). This result appears independent of stimulus intensity. The late depolarizing potential reflects the activation of the negative feedback pathway from the horizontal cells to cones. Feedback effects are particularly large when cone intracellular chloride concentrations are artificially elevated (183, 185).

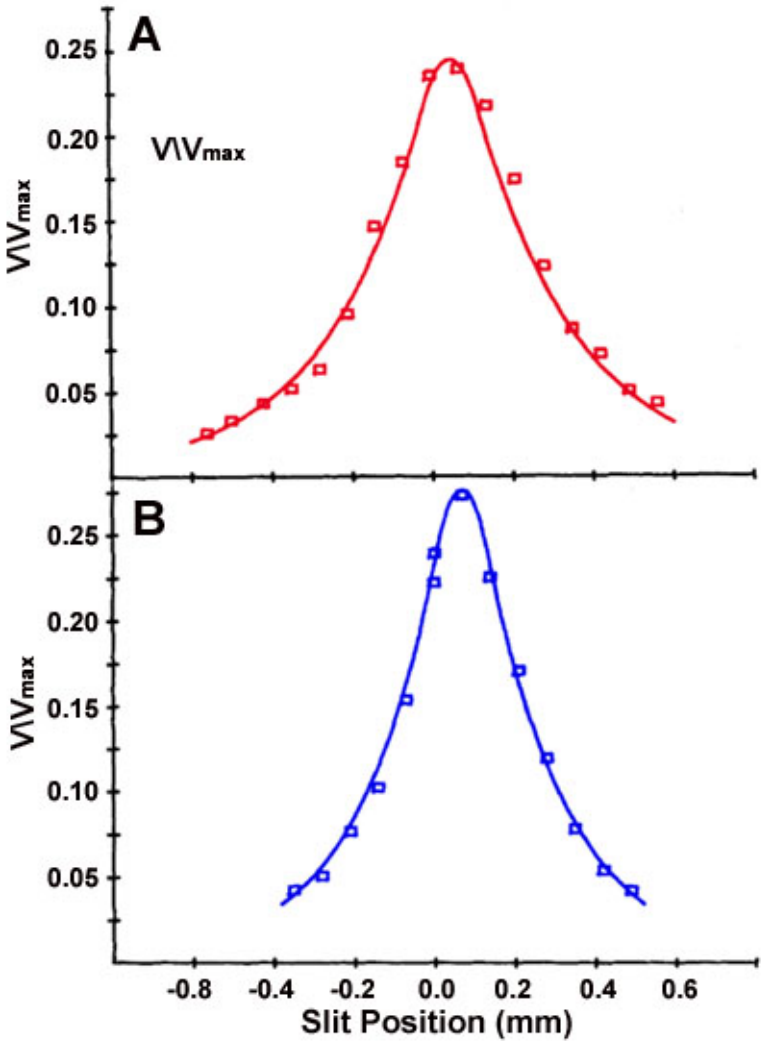

Figure 16. A-type horizontal-cell receptive field in cat retina is mapped with a long narrow slit (100 x 5000 μm). *A*. The wavelength is 647nm (242) that stimulates a mixture of cat red cone and rod responses. *B*. The wavelength is 441nm (blue) and dim enough to stimulate only rods. Rod and cone receptive fields share a common center, but differ in size. The continuous curves are generated by the conductive sheet model, with a space constant of 250 μm in *A*. and 200 μm in *B*. The figure is from Nelson, 1977 (16).

In turtle retina, the feedback pathway from horizontal cells to cones can be revealed by experiments examining the effects of size and color on cone responses (Fig. 18). With small spots, red and green light stimuli can be adjusted in brightness until equal amplitude hyperpolarizations are elicited from red and green cones. With these small-spot stimuli, the photoresponses of the red cone are very similar in shape, regardless of wavelength (upper pairs of responses). However, when the same two wavelengths of light stimuli were increased in diameter, the excitatory input from the green cones to the L1-type horizontal cells activated the feedback pathway, and caused the response of the red cone to the green light stimulus to become transient and biphasic (Fig. 18, lower left pair). In the green cone, the contribution of the feedback pathway from the red-cone input to L1-type horizontal cells is even more pronounced, and a depolarizing photoresponse is elicited in the green cone with a large diameter red-light stimulus (Fig. 18, bottom right pair). Blue cones also receive feedback signals from L-type horizontal cells (187) as shown in figure 18 (right hand traces). A large diameter red light stimulus was used to selectively isolate possible inputs that were mediated by these feedback pathways. In the dark-adapted state, a small depolarizing after potential is seen following the initial hyperpolarizing phase (trace 1). During a red background light, that selectively desensitized the red cones (L-cones), a pure hyperpolarizing photoresponse was elicited by the red light stimulus (trace 2), while a blue background augmented the relative contribution of

the feedback pathway and therefore a depolarizing photoresponse was obtained (trace 3). These and other anatomical and physiological studies provide the basis for proposing that a feedback model between cones and horizontal cells could underlie color opponency (37, 42, 86, 188).

While mammals lack color opponent horizontal cells, color opponent responses are seen in primate short-wavelength cones (blue cones) (185). With short-wavelength stimulation, primate blue cones produce outward currents in response to the closing of outer-segment cation channels by phototransduction. But long-wavelength stimuli evoke inward currents (Fig. 19A). The primate blue cone, then, is similar to the turtle blue cone in exhibiting negative feedback from long-wavelength-selective L-type horizontal cells. The long-wavelength inward currents, the feedback responses, are abolished by CNQX, an antagonist of horizontal-cell AMPA/kainate membrane channels (Fig. 19B), supporting the notion that horizontal cells are the source of the negative feedback input in cone photoreceptors. Further, the characteristics of blue-cone feedback currents resemble those of calcium currents (185), supporting the long-held idea that horizontal-cell feedback to cones operates through a modulation of calcium channels (183, 189).

Thus, in primate retina there are color opponent blue cones, but not color opponent horizontal cells. The difference with other vertebrates would appear to reside with horizontal cell circuitry. While the H2 cell of primate retina is somewhat blue cone selective (Fig. 10), it apparently is not selective enough to reveal the blue-cone depolarizing feedback signals to red stimuli. The direct hyperpolarizing long-wavelength cone input to H2 cells may mask the blue-cone feedback response.

The feedback synapse

The negative feedback circuit from horizontal cells to cones is thought to occur at the horizontal-cell lateral elements that invaginate photoreceptor terminals at the triad ribbon synapses (Fig. 3a). The problem has been that no images of a synapse with presynaptic vesicle clusters has ever been seen within the lateral elements, except for human retina (190), and there it was only noticed for axon terminal invaginations within rod spherules. However syntaxin-4, a SNARE protein involved in fusion of synaptic vesicles to the plasma membrane, has been localized to the lateral elements of mouse horizontal cells in both cones and rods (Fig 20) (191), as has VGAT, the vesicular GABA transporter (Fig. 21) (192). These molecules both suggest presynaptic activity in horizontal cells. Further, fish retinas have distinctive spinules on the dendritic endings of the horizontal-cell lateral elements in cone pedicles (Fig. 3b). Spinules may be the sites of feedback from horizontal cells to cones because they change shape and enlarge during background illumination when the effects of negative feedback are most apparent (57, 58, 193-196).

There are several candidates for the feedback neurotransmitter. In cyprinid retinas H1 horizontal cells transport GABA, which accumulates in the cytoplasm (47, 51, 162, 197, 198). GABA-induced currents can be recorded from the terminals of red-sensitive and green-sensitive cones isolated from the turtle retina (199, 200). Color opponency in fish C-type horizontal cells is eliminated upon exposure to GABA or its antagonists (201, 202). However, studies in other species have failed to show GABA effects that are supportive of a role for GABA as the inhibitory feedback neurotransmitter of the horizontal cell. GABA did not eliminate C-type responses in turtle (203) or Xenopus (89), and did not affect cone surround responses in monkey (204). In L-type horizontal cells of turtle, catfish, skate and goldfish retinas, GABA and related drugs induce depolarizations that are consistent with the activation of electrogenic GABA transporters in the horizontal cell membrane (149, 159, 160, 203, 205). Although these cells clearly have GABA uptake systems and accumulate GABA, the idea that GABA mediates the negative feedback of horizontal cells to cone photoreceptors has not received universal experimental validation. Horizontal-cell GABA could still have a feed-forward action directly upon bipolar cell dendrites or other horizontal-cell processes (156, 205). Alternatively GABA receptors on horizontal cells might simply serve the purpose of limiting transporter-generated membrane depolarizations in the presence of extracellular GABA.

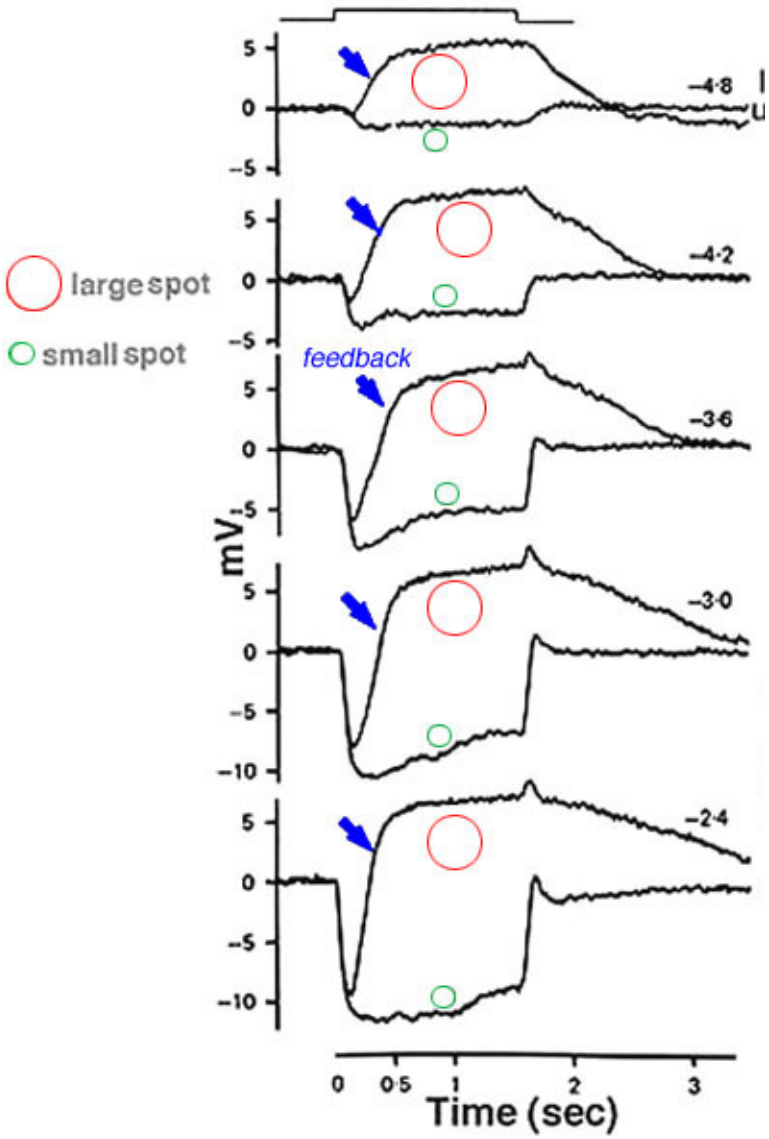

Figure 17. The contribution of the feedback pathway from L-type horizontal cells to cone responses in the retina of the tiger salamander. Cone photoresponses were elicited by light stimuli of different intensities covering a small or a large spot as indicated. The illustration is from Lasansky, 1981 (183).

A further feedback model proposes that elevated proton concentration in the synaptic cleft mediates feedback by inhibiting photoreceptor calcium channels (206). Proton buffers, particularly amino sulfonates like HEPES, block feedback (207-212). While there is general agreement that some pH buffers block feedback, there is currently disagreement whether alteration of pH in the synaptic cleft is the mechanism (213, 214).

Most feedback models propose that modulation of presynaptic calcium channels in the photoreceptor terminals is the key. Using voltage-clamp recordings from cones during illumination with spots or annuli of light, Verweij et al (1996) (215) suggest that feedback modulates the voltage-dependency of the calcium channels in the cone pedicles (Fig. 22A). The explanation takes off from an old electrical model (5) and proposes that horizontal cells can initiate large extracellular current flow through hemi-gap-junction channels into the restricted extracellular space within the triad synapse of the cone (Fig. 22B) (68, 70, 72, 189, 216). During light stimulation, the L-type horizontal cells hyperpolarize, increasing the magnitude of the inward flow of cations from extracellular space, through hemi-gap-junction channels, into horizontal cell lateral elements. This causes hyperpolarization of the extracellular space. Such hemi-gap-junctions, consisting of connexin Cx55.5, have been demonstrated

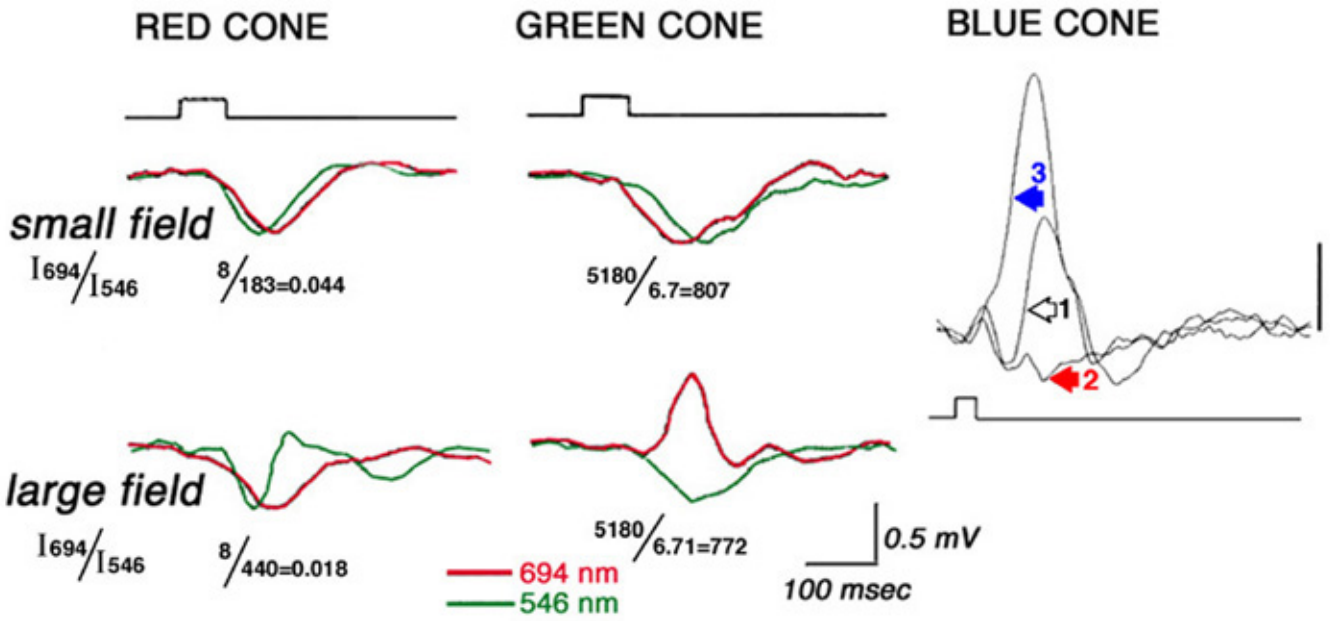

Figure 18. The contribution of negative feedback from L-type horizontal cells to the photoresponses of cones in the turtle retina. Red and green cones were stimulated with either small field or large field stimuli of either red or green light. The contribution of the negative feedback from the L-type horizontal cells was most apparent in the recording from the green cone stimulated with a large field red light stimulus. The illustration is from Perlman et al., 1985 (172). The blue cone from the retina of the turtle (*Mauremys caspica*) was stimulated with a red (700nm) light stimulus covering a large retinal area in the dark-adapted state (trace 1) and during red (trace 2) or blue (trace 3) background lights. Depolarizing feedback signals from red cone stimulation are most apparent on the blue background (trace 3). The illustration is from Itzhaki et al., 1992 (187)

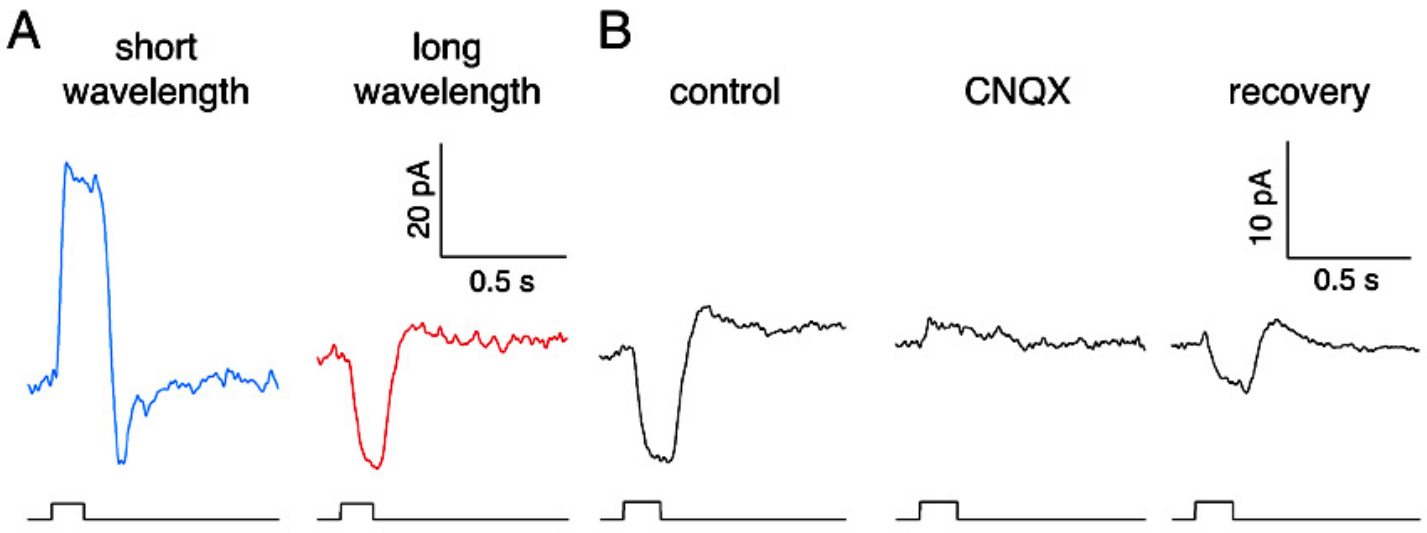

Figure 19. In monkey retina, inhibition of blue cones by long wavelength light is mediated by horizontal cell feedback. *A*. Short-wavelength blue light evokes outward photocurrents in the blue cone, but long-wavelength yellow light evokes inward feedback currents. *B*. Inward feedback currents elicited by long-wavelength stimuli are blocked by 20μM CNQX, a blocker of horizontal-cell light responses. Blue cones are voltage clamped at -40mV. The figure is adapted from Packer et al., 2010 (185).

anatomically in horizontal cell lateral elements in zebrafish retinas (Fig. 3d).The extracellular hyperpolarization activates voltage dependent calcium channels which sense the change in the same way as intracellular depolarization, leading to calcium entry, and an increase in glutamate release. The idea finds some support because when the hemi-channels are blocked with carbenoxolone (a specific gap junction blocker), the feedback signal in the cone is eliminated (189, 204).

Further evidence for the importance of connexin 55.5 and hemi gap-junctions for feedback comes from a genetic knockout in zebrafish. Feedback to cones, behavioral contrast sensitivity, and horizontal-cell color opponency were all weakened in this knockout. As this connexin is only expressed in horizontal cells, a perturbation of horizontal-cell circuitry is a likely cause. Curiously the knockout effects were strongest when horizontal cells were in a hyperpolarized state, but were less evident when they were in a depolarized state (73).

9. Modulation of physiology

The properties of horizontal cells are altered by a variety of humoral factors released by retinal cells during changing conditions of illumination. These chemicals, generally referred to as neuromodulators, are believed to adjust the modes of information processing in the retina in order to match retinal function to ambient condtions. Neuromodulators reach horizontal cells either via direct synaptic interactions or by volume transmission. In the latter mode, inter-cellular communication is mediated by passive diffusion of the chemical following its release from the source cells into extracellular space. Dopamine is the most extensively studied retinal neuromodulator, but in recent years nitric oxide and retinoic acid have been added to the list. In this section the actions of these neuromodulators on vertebrate horizontal cells is discussed.

Dopamine

Dopamine-containing neurons reside in the amacrine cell layer of the retina. In fish, where they were first discovered, dopaminergic cells are interplexiform cells (IPCs), having cell bodies in the amacrine cell layer and sending long processes to the outer plexiform layer where they arborize and synapse on horizontal cells. In other species (e.g. turtle, most mammals), the dopaminergic cells are amacrine cells with few, if any, processes extending to the outer plexiform layer (217), and therefore dopamine has to reach the horizontal cells by volume diffusion through the inner nuclear layer. The action of dopamine upon vertebrate horizontal cells has been extensively studied and reviewed (218) and involves at least 4 distinct actions.

1. Dopamine reduces the extent of gap-junction coupling, as shown by dye coupling experiments, by electrophysiological determination of receptive field size (119, 166, 176, 219-222), and by patch recordings from isolated cell pairs (69). Dopamine shrinks the receptive field, and reduces photoresponse amplitude in horizontal cells from intact fish retina (Fig. 23A). Photoresponses that were recorded during superfusion with dopamine solutions were larger in amplitude with small spot stimuli than those recorded with the same stimuli under control conditions (Fig 23A). The increase in the response to spot stimuli indicates less shunting by neighboring non-illuminated horizontal cells and is consistent with the notion that dopamine uncouples the horizontal cell network (220). Gap junction conductance is reduced through activation of adenylate cyclase by dopamine D1-type receptors (223).

By reducing gap-junction coupling, dopamine limits the spread of Neurobiotin, a low-molecular weight (323 Dalton) tracer molecule, after injection of this molecule into a cell within the horizontal cell layer. In H1 cells of monkey retina the Neurobiotin tracer field is maximal during dark adaptation (Fig. 24A). The dopamine D1 agonist SKF38393 reduces the size of the tracer field (Fig. 24D), as does light adaptation (Fig. 24B) and the gap junction blocking agent meclofenamic acid (Fig. 24C). Dark adapted space constants in monkey H1 cells are very large, in excess of 1000 μm (222). Similar results are seen in mouse retina where additionally, blockade of the dopamine D1 receptor with a D1 antagonist (SCH23390) widens the area of tracer spread, and the cAMP

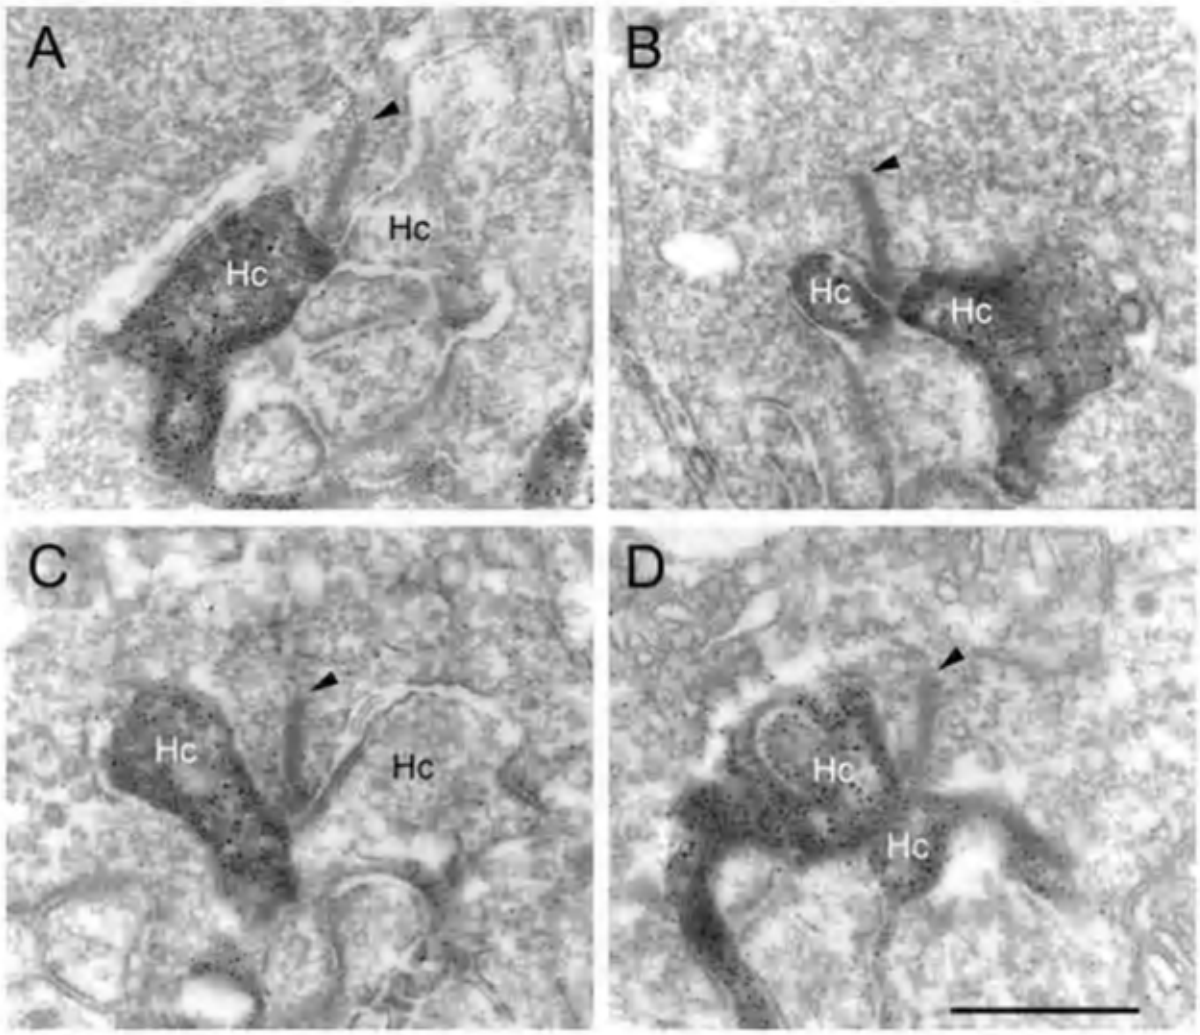

Figure 20. Electron microscopy of immunolabeled mouse retina demonstrates localization of syntaxin-4 (black granular staining) to the lateral elements of horizontal cells (Hc) in rod (*A* and *B*) and cone (*C* and *D*) ribbon synapses (arrow heads). Syntaxin-4 occurs in one or both lateral elements. The immunolabel is seen also in horizontal-cell axons and dendrites. The scale bar is 0.5 μm for *A-D*. The figure is from Hirano et al., 2007 (191).

analogue 8-bromo cyclic GMP reduces the spread of the tracer. All observations are consistent with a D1 receptor, cAMP-mediated mechanism (224).

Receptive field modulation by dopamine varies somewhat with species. Neurobiotin spread between rabbit A-type cell bodies is highly pH sensitive (165), in fact only observable at pH 7.2 +/- 0.05. Nonetheless, a particularly striking modulation of receptive field size occurs in the axon terminal systems of rabbit B-type horizontal cells (225). Modulation of tracer coupling by dopamine is robust in mouse retina (224) and in monkey retina (Fig. 24) (222). Tracer coupling between the rod-driven horizontal cells of skate retina was dopamine insensitive (226).

In isolated horizontal cell pairs dopamine uncouples gap junctions (69). In this preparation the biophysics of gap junction coupling and its modulation by dopamine can be examined in detail. In zebrafish the unitary conductance of a gap-junction channel is 50-60 pS and the open time is ~10 msec. Dopamine reduces the open time and the frequency of opening of these channels for a net reduction of 2-3 fold (227). The action is mediated through a D1 agonist and is mimicked by the cAMP analogue 8-Bromo-cAMP, suggesting an intracellular mechanism that involves increases in cAMP, a common action of D1 receptors (179). A parallel study in isolated

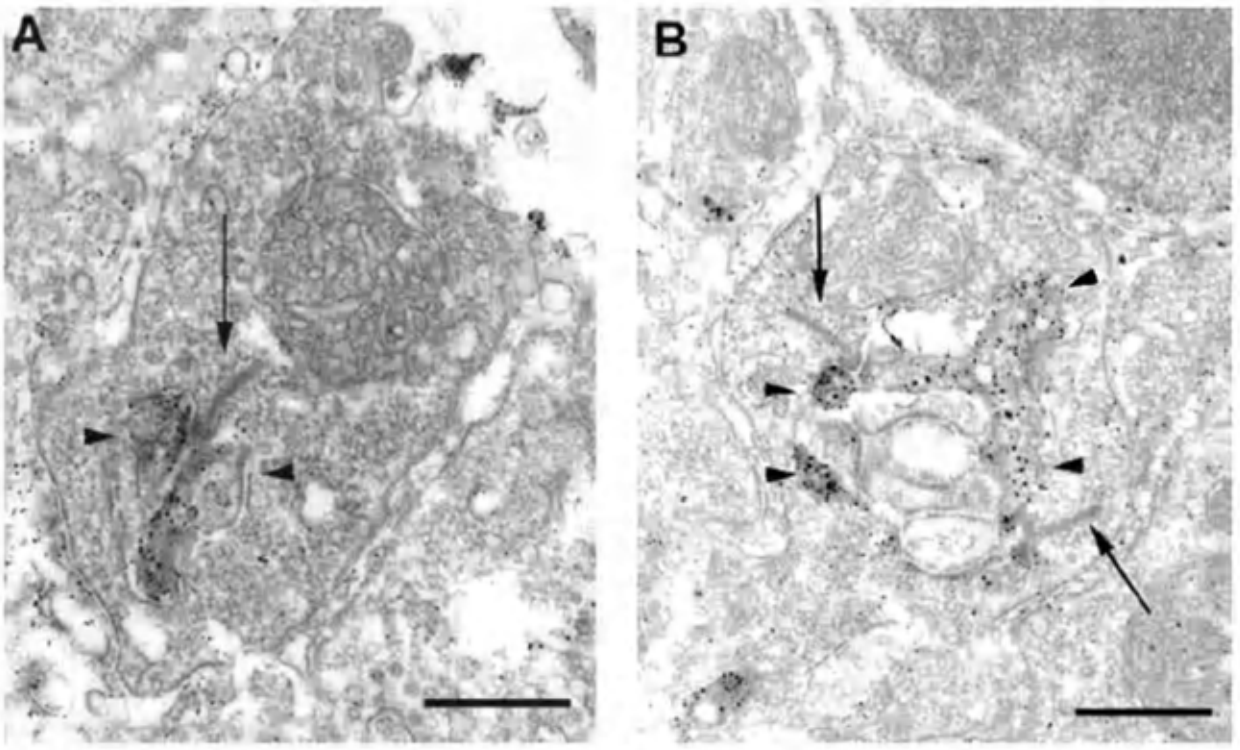

Figure 21. Electron microscopy shows immunolabeling (dark granules) for vesicular γ-aminobutryric acid transporter (VGAT) in mouse (*A*) and rat (*B*) horizontal cell lateral elements (arrow heads) in rod spherules. Rod synaptic ribbons are indicated by long arrows. The scale bars are 0.5 μm. The illustration is from Cueva et al., 2002 (192).

catfish horizontal-cell pairs yielded similar results. Dopamine D1 receptors raised intracellular cAMP, closing gap junctions. Further, intracellular pH and Ca^{2+} ions were ruled out as mediators (228).

2. Dopamine induces the formation of spinules in fish horizontal cells in a manner similar to that seen with bright-light background illumination (193, 229).

3. In fish retina, dopamine reduces the amplitude of horizontal-cell photoresponses (220, 230), as shown in figure 23A. This phenomenon is attributed to dopamine modulation of the interaction between L-glutamate and AMPA/KA receptors on the horizontal cell membrane. Dopamine increases the binding of L-glutamate to horizontal-cell-membrane receptors (231), as illustrated in figure 23B. Dopamine by itself evoked no current in the isolated horizontal cell (Fig. 23B, upper trace), but it significantly augmented the kainate-induced glutamate-receptor current (Fig. 23B, lower traces). Further studies show that this dopamine action is dependent on extracellular magnesium ions (232). In the intact retina, the photoresponses of horizontal cells reflect the unbinding of glutamate from its receptors. If dopamine increases the affinity of glutamate for its receptors on the horizontal cell membrane, then unbinding at light onset will be at a slower rate. The flicker photoresponses of cat and rabbit horizontal cells were in fact phase-delayed by both D1 and D2 selective dopamine agonists, in agreement with the idea of slower unbinding of glutamate. In these species flicker photoresponses increased in amplitude with dim lights, but decreased with bright lights (233). Pflug et al (233) suggest that the dopamine-induced increase in glutamate binding by horizontal cells may induce a maintained depolarized bias that shifts cone calcium activation through feedback interaction towards more depolarized levels, tending to facilitate dim-stimulus synaptic transmission, while truncating bright-stimulus transmission (233), an elaboration of the ideas put forward by Mangel and Dowling (234).

In other species this appears not to be the case. Such modulations are not clear in the turtle retina (176, 221).

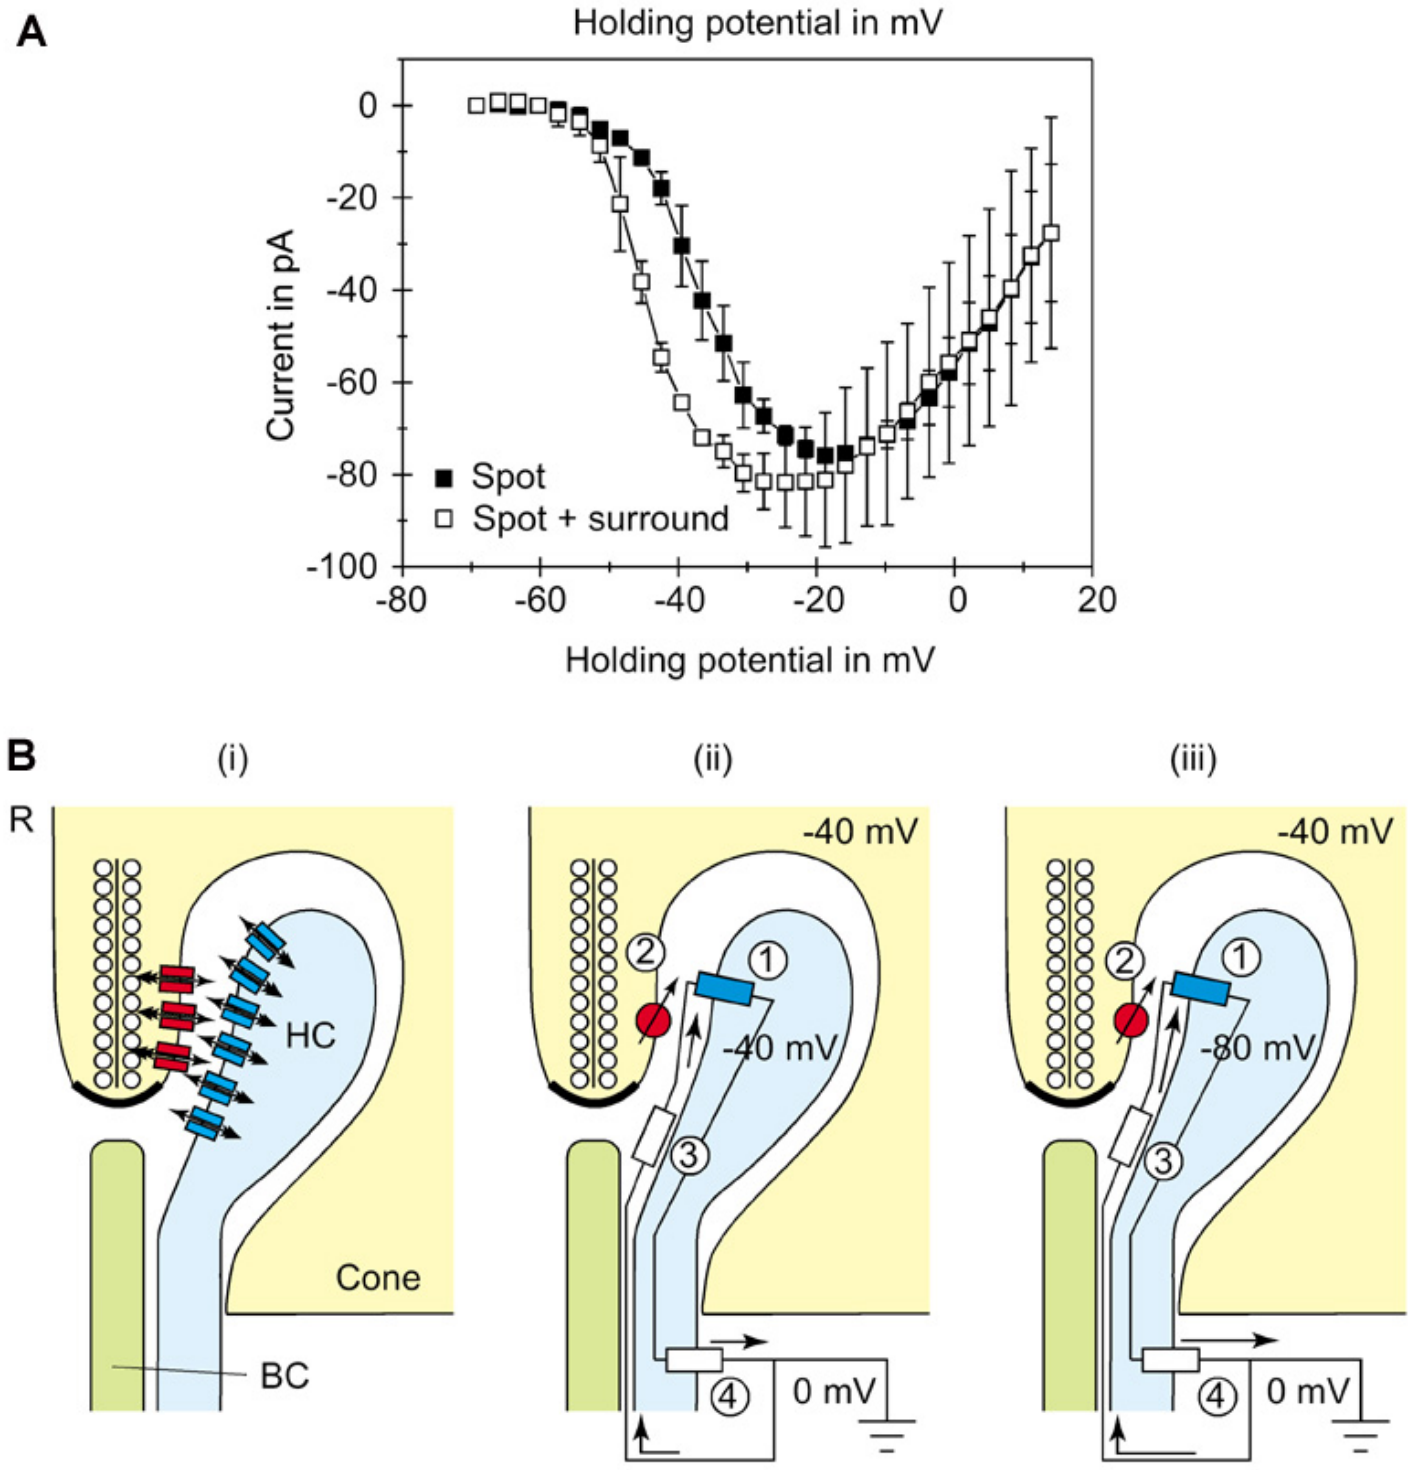

Figure 22. Electrical feedback model. *A*. The activation range of calcium currents in cone synaptic terminals shifts towards more hyperpolarized values during surround stimuli that hyperpolarize horizontal cells. *B.* The electrical or 'ephaptic' feedback model argues that the voltage within the enclosed extracellular space surrounding horizontal-cell invaginated dendritic tips is influenced by horizontal-cell membrane polarization. With surround stimulation, these dendrites hyperpolarize, causing extracellular space to hyperpolarize also. This affects synaptic calcium channels in the same way as would intracellular depolarization of the cone terminal. The more hyperpolarized the horizontal cell dendrite, the more calcium enters the cone terminal, and the more neurotransmitter is released. The effect is opposite to the light-induced closing of cone outer segment cation channels that suppress neurotransmitter release. (i) Calcium channels (242) are located on the cone presynaptic membrane, adjacent to the ribbon. Gap junction hemichannels (blue), polarize adjacent extracellular space. Extracellular current flow hyperpolarizes extracellular space to a greater extent in the light (ii) than in the dark (i) The illustration is from Kamermans and Fahrenfort, 2004 (216).

4. Dopamine changes the balance between rod and cone inputs to horizontal cells in Xenopus retina, in order to augment the rod contribution in the dark-adapted state and the cone contribution in the light-adapted state. This action is thought to depend on different dopamine sensitivities of AMPA/KA receptors postsynaptic to rods and cones (235, 236).

Nitric oxide

Involvement of nitric oxide (NO) in physiolological regulation of retina is indicated by the presence of cells containing the enzyme nitric oxide synthase (NOS) that synthesizes NO from L-arginine (237). Immunoreactivity to NOS isoforms or demonstration of NADPH-diaphorase activity has been seen in every vertebrate retina studied (238). In all species NOS occurs in some types of amacrine cells, but reports of NOS in photoreceptors, horizontal cells, bipolar cells and Müller cells have also been published. In fish retinas, evidence for NOS in horizontal cells has been demonstrated by immunostaining and NADPH diaphorase histochemistry (239-241). In the turtle retina, n-NOS has been reported in horizontal cell processes at photoreceptor ribbon synapses and in the inner segments of the photoreceptors, and e-NOS has been seen in the H1 cell axon terminals and in Müller cells (47, 242-244). In the rabbit retina, NADPH diaphorase activity, an indicator for NOS presence in horizontal cells, has been shown to depend upon the state of adaptation and the activity of glutamatergic pathways. It is increased in the dark-adapted state (245) or by the activation of AMPA/KA type receptors (246). Indeed nitric oxide has been suggested as a player in horizontal-cell feedback mechanisms (247).

Regardless of the exact cellular source of NO, this molecule exerts profound effects on the physiology of horizontal cells. Raising NO level by either exogenous application (NO donors) or by adding L-arginine, the substrate for its synthesis, reduces the size of the horizontal cell receptive field (177, 248, 249). This effect reflects direct action of NO on the gap junctions between adjacent horizontal cells. It is thought to be mediated through cGMP-dependent protein kinase pathways (249, 250), in a pathway parallel to cAMP, dopaminergic modulation.

NO modifies the photoresponses of both A-type and B-type horizontal cells in the rabbit retina (Fig. 25). These responses were elicited by a series of disks of fixed intensity and different radii, both in control conditions and during exposure to SNAP (an NO donor). For every light stimulus, the photoresponse is larger during SNAP application as compared to control conditions (gray vs black responses, Fig.25). This is illustrated graphically in figure 25B and 25D where the peak responses of photoresponses shown in parts A and C respectively are plotted as a function of stimulus diameter. SNAP clearly causes augmentation of the photoresponses to large diameter stimuli. NO acts in the distal rabbit retina to augment the photoresponses of the horizontal cells and to reduce the receptive field size (249).

A similar augmentation of horizontal-cell responses by NO has been seen in L-type horizontal cells of carp (177) and turtle retinas (251). The NO effect in horizontal cells can reflect either NO action upon the phototransduction process in the photoreceptor outer segments (251, 252) or upon the neurotransmitter release from the photoreceptors (253). Furthermore, NO can modulate the interaction between L-glutamate and its receptors on the horizontal cell membrane (254), and thus can alter the responsivity of horizontal cells independently of effects upon phototransduction. In order to distinguish the above possibilities, the influence of NO-related drugs on the transfer function between cone photoreceptors and L1-type horizontal cells (L1-HC) were studied in the turtle eyecup preparation as shown in figure 26 (251). In the dark-adapted state (Fig. 26A), the cone to L1-HC synapse is non-linear and is characterized by high amplification for dim light stimuli that elicit low amplitude cone photoresponses. Reducing the retinal level of NO by adding L-NAME, increased this non-linearity, while raising retinal NO level by adding either L-arginine or SNP, reduced the non-linearity and linearized the cone-to-horizontal cell transfer function. In the light-adapted state (Fig. 26B), the cone to L1-HC transfer function was linear under control conditions consistent with high NO level. Further increase of retinal NO (adding L-arginine or SNP) did not change the transfer function or synaptic amplification, while lowering retinal level of NO (adding L-NAME) changed the transfer function into a non-linear one with high amplification for small amplitude cone photoresponses. What is clear in figure 26 is a direct effect on synaptic

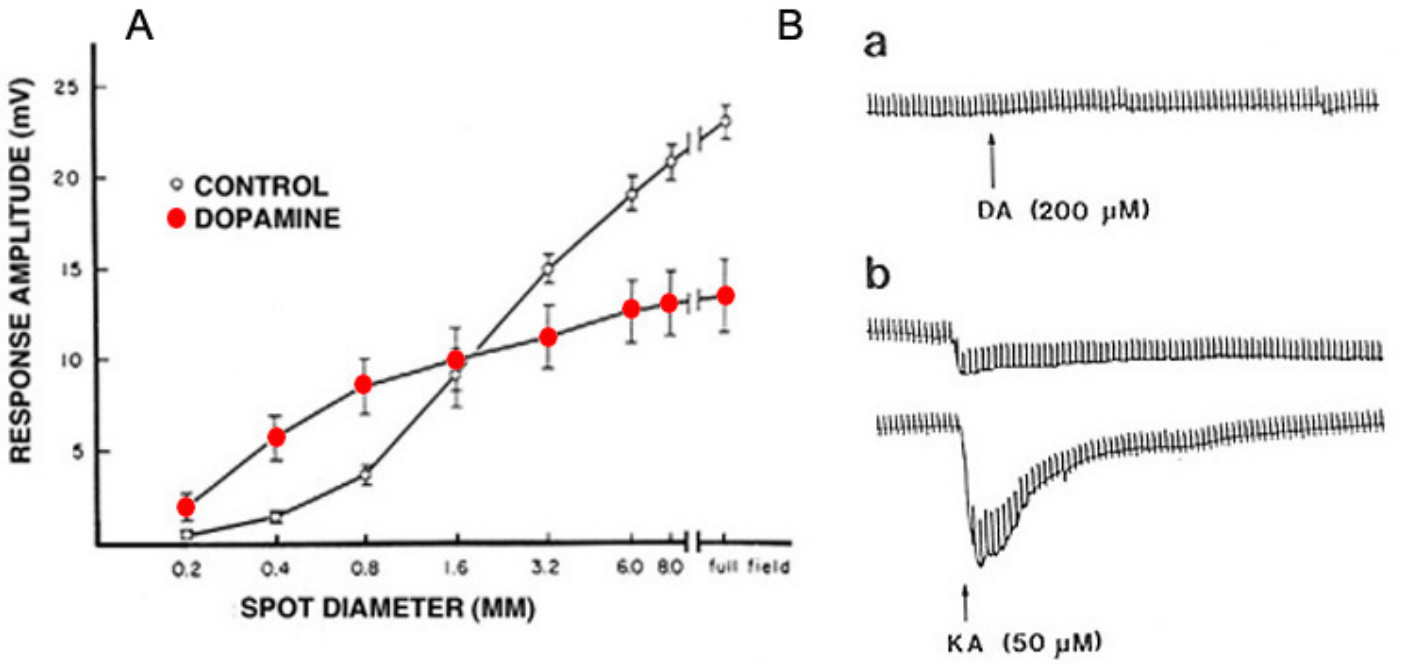

Figure 23. Dopamine affects synaptic gain and receptive fields in fish horizontal cells. *A*. Photoresponses were recorded from a horizontal cell in the intact carp retina using light stimuli of fixed intensity but different diameter, under control conditions and after exposure to dopamine. The illustration is from Mangel and Dowling, 1985 (220). *B*. Dopamine by itself did not elicit any current response in a horizontal cell isolated from white perch retina (upper trace). However in the presence of dopamine the inward current elicited by the AMPA/kainate agonist kainic acid (middle trace) was significantly augmented (bottom trace). The illustration is from Knapp and Dowling, 1987 (231).

transfer from cones to horizontal cells. This may include neurotransmitter release and/or neurotransmitter interactions with its post-synaptic receptors.

In contrast to dopamine, NO does not influence the process of spinule formation in fish horizontal cells during exposure to background lights (177).

Retinoic acid

Retinoids are of great importance in the eye having roles in both the photopigment cycle and in the embryonic development of the eye. The retinoid 11-cis retinaldehyde serves as the chromophore of the rhodopsin molecule, the visual pigment of the vertebrate photoreceptors (255, 256). The retinoid retinoic acid activates transcription factors which are important during eye development (257-260). Most recently a further role for retinoic acid has been proposed; that of a neuromodulator linked to background adaptation, affecting horizontal cells in particular (64, 65, 261). Retinoic acid is produced in the pigment epithelium as a side effect of the rhodopsin transduction process in bright illumination.

Retinoic acid induces synaptic plasticity at the terminal dendrites of horizontal cells and promotes the growth of spinules in fish horizontal cells, in a pattern similar to that induced by background lights (64, 65). It exerts a pronounced effect on the electrical coupling between horizontal cells in mammalian and non-mammalian retinas and reduces the receptive fields of the horizontal cells (261, 262) as shown in figure 27. Adding retinoic acid to retinal preparations of carp, rabbit and mouse, reduces the conductance of the gap junctions between neighboring horizontal cells thus reducing the degree of dye coupling (Fig. 27a), in a manner similar to that seen during background illumination. Intracellular recordings in horizontal cells also show that retinoic acid produces effects similar to those of light adaptation. The amplitudes of the horizontal cell photoresponses to full

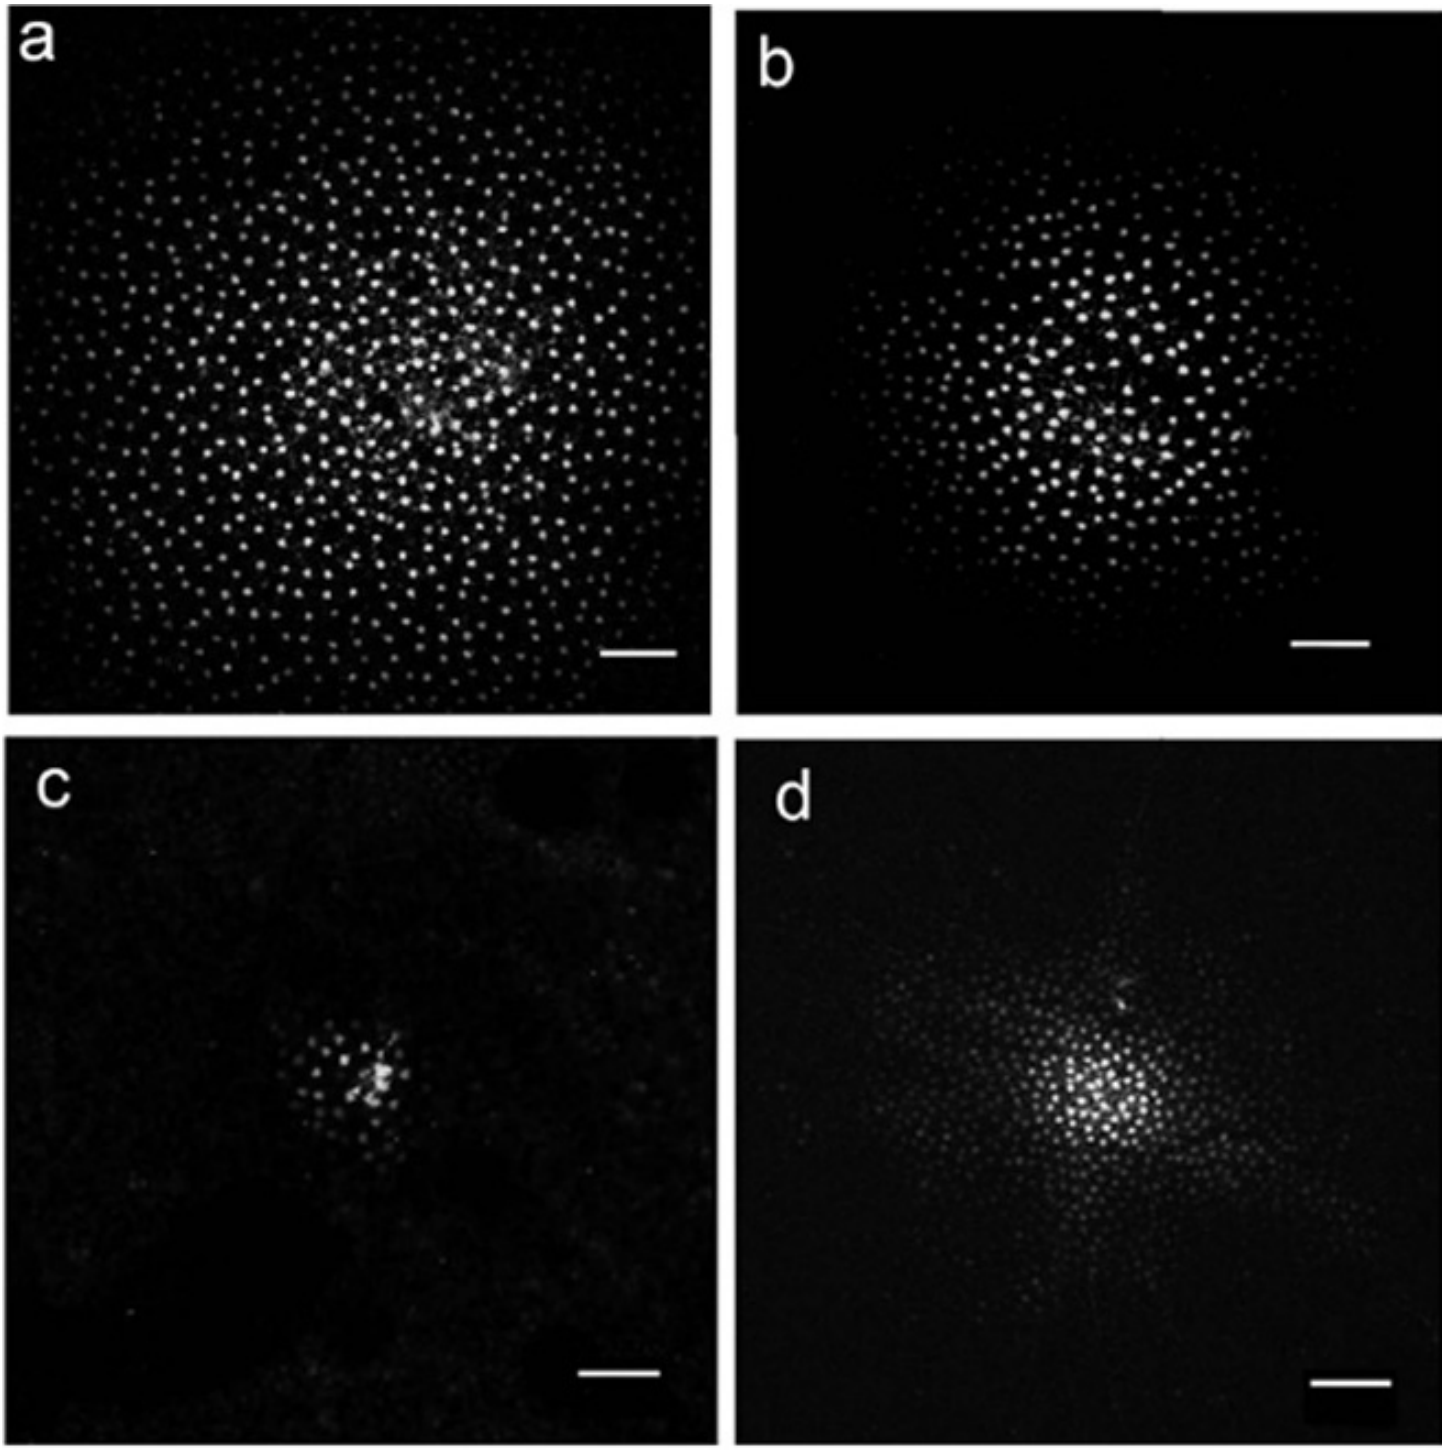

Figure 24. Modulation of horizontal-cell coupling in monkey retina. *a*. Neurobiotin tracer reveals maximal coupling-field occurs in H1 horizontal cells under dark adaptation. *b*. Mesopic (500 nm) background illumination shrinks the coupling field. *c*. Meclofenamic acid, a gap junction blocking agent, prevents tracer spread. *d*. The dopamine D1 receptor agonist SKF38393 greatly reduces the spread of tracer. The scale bars are 100 μm. The illustration is from Zhang, Jacoby and Wu, 2011 (222).

field stimuli are increased by retinoic acid (Fig. 27b). The responses to stimulation with bright light annuli are reduced by retinoic acid, and those to spot illumination are increased (Fig. 27c). Thus, retinoic acid, like dopamine and nitric oxide, seems to modulate the physiological properties of vertebrate horizontal cells in order to adjust their function during changing conditions of ambient illumination.

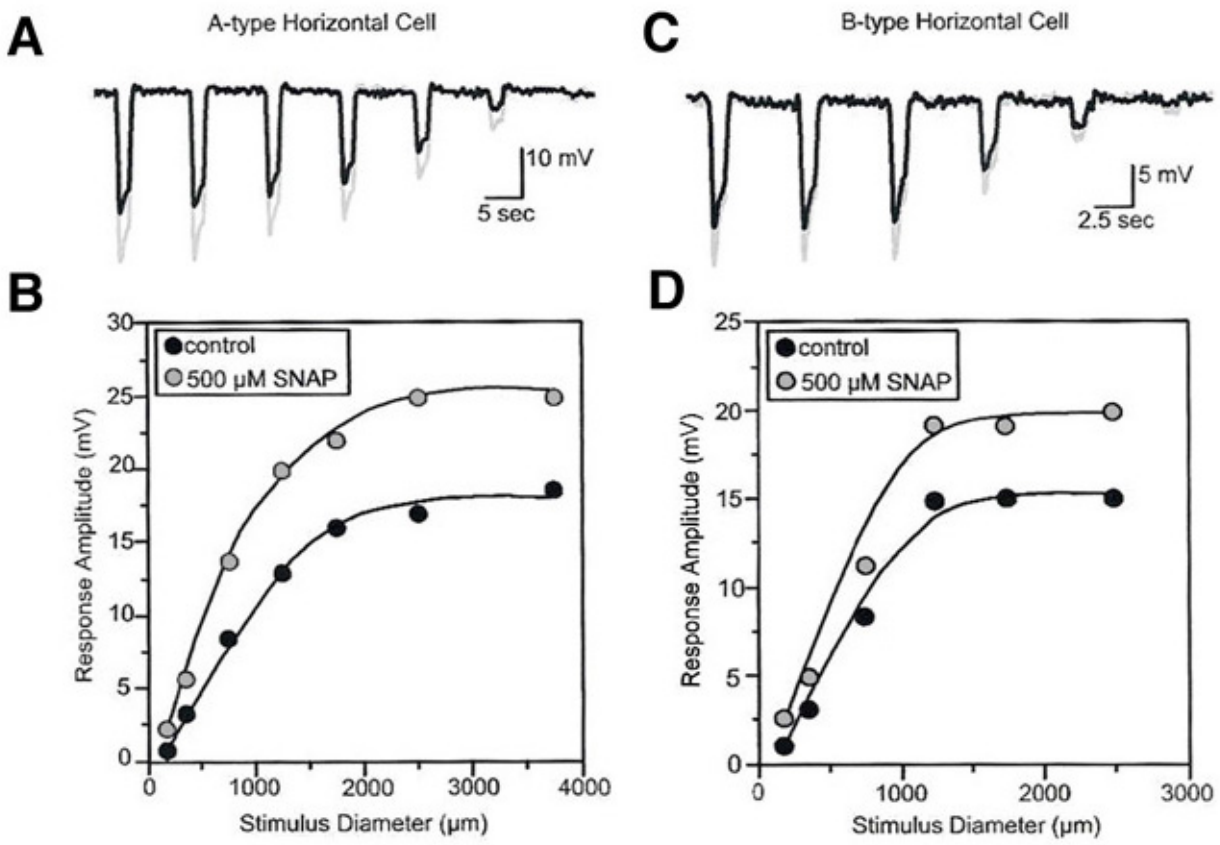

Figure 25. The actions of nitric oxide (NO) upon the physiology of horizontal cells in the rabbit retina. *A.* & *C.* The effects of NO were tested by adding SNAP, an NO donor, and observing the effects upon photoresponses that were elicited by disks of fixed intensity but different diameters. *B.* & *D.* The relationship between response amplitudes and stimulus diameters indicates that NO augments the photoresponses of both A-type and B-type horizontal cells and reduces their receptive field sizes (black traces, control; gray traces, SNAP). The illustration is from Xin and Bloomfield, 2000 (249).

10. Functional Roles

The major functional roles of horizontal cells in the vertebrate retina are 1) initiating the organization of spatially opponent receptive fields for second and third order neurons in the retina, 2) modulation of the photoreceptor signal with different lighting conditions and 3) adjustment of synaptic gain. These roles represent both neuronal signal processing and neuronal adaptation at the first synaptic level in the retina.

In the half century since Svaetichin (80, 263) first described S-potentials in the vertebrate retina, we have made progress in our understanding of the many ways that horizontal cells can influence the kinetics and spatial organization of the photoreceptor response, and as a consequence, the physiology of all downstream retinal neurons. These include rod-cone balance changes, distal color opponency, center surround opponency, and gain regulation at the photoreceptor synapse. Further, the horizontal cell itself is under neuromodulatory control, and reorganizes its synaptic connections, glutamate sensitivity, and receptive field under the influence of dopamine, retinoic acid and nitric oxide. The horizontal cell forms an important link between inner and outer retina because this cell type controls distal retinal signal processing, while being itself under the influence of centrifugal neuromodulatory control from both within the retina and even from the brain itself.

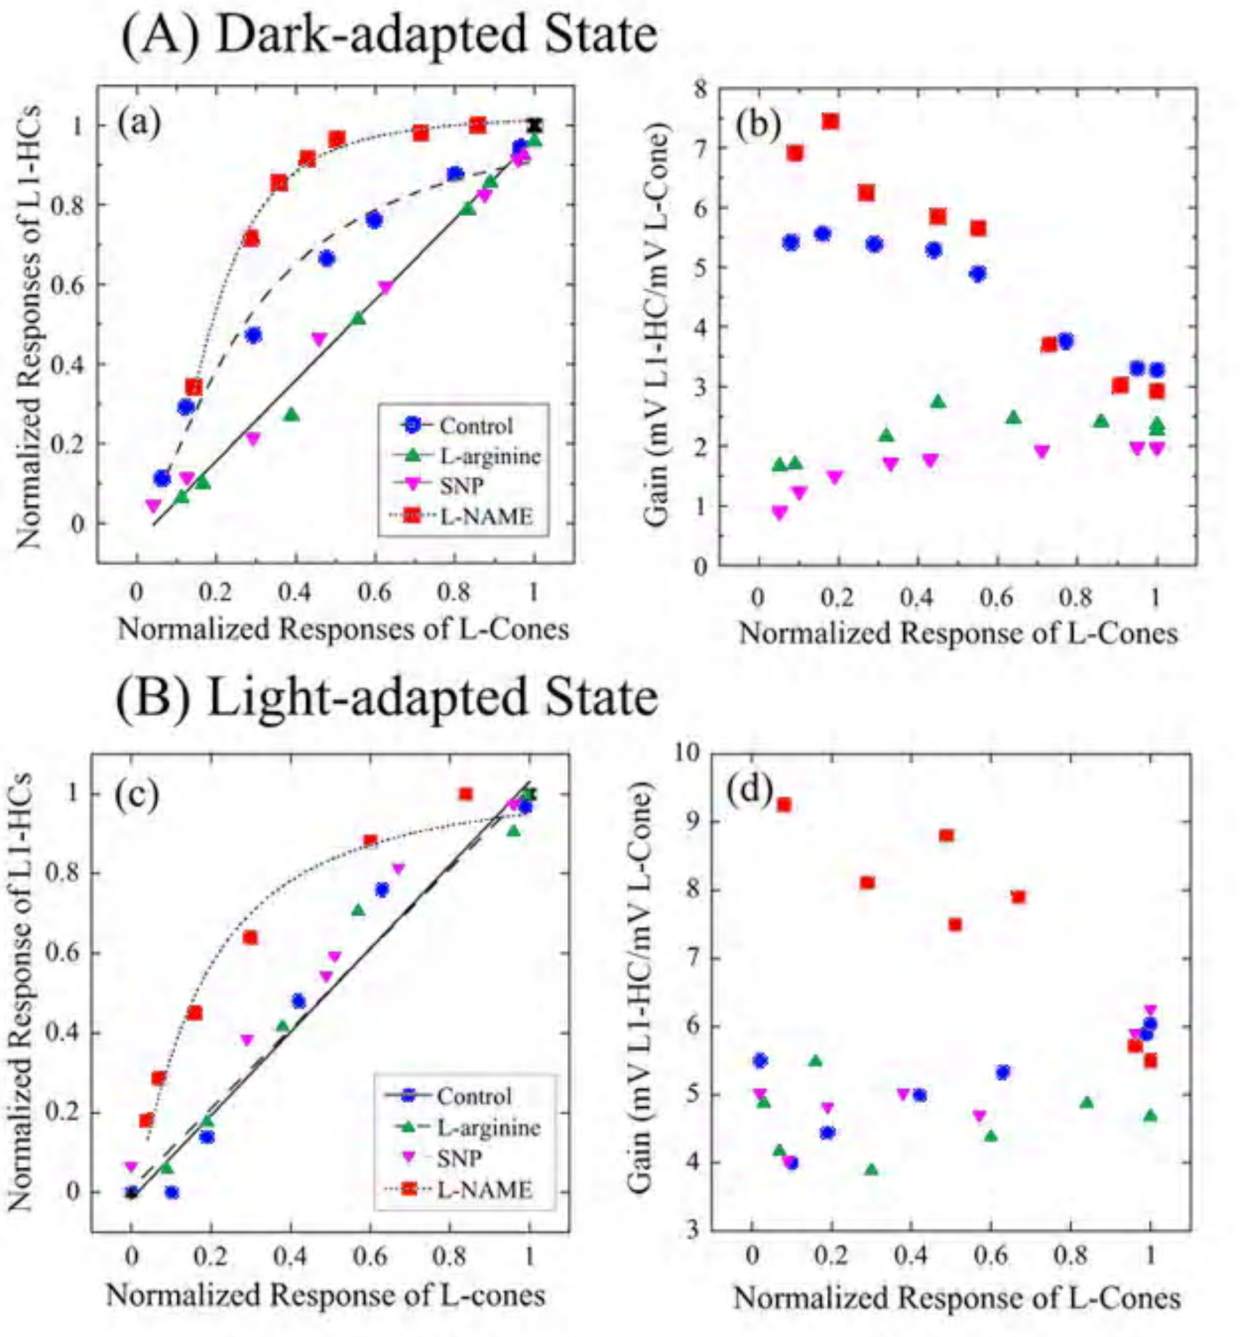

Figure 26. The effects of nitric oxide (NO) upon transfer function and synaptic amplification between cone photoreceptors and L1-type horizontal cells in the turtle eyecup preparation. The transfer function and synaptic amplification were calculated by comparing the mean photoresponses of L1-horizontal cells to those of cones for each recording condition. *A*. In the dark-adapted state, the transfer function under control conditions is non-linear (open circles) having highest synaptic amplification for small amplitude cone photoresponses, elicited by dim light stimuli. Lowering retinal NO level by adding L-NAME, increased non-linearity (open squares), while raising retinal NO level, by adding L-arginine or sodium nitroprusside (SNP), linearized the transfer function and made synaptic amplification independent of cone response amplitude (triangles and inverted triangles respectively). *B*. The control light-adapted transfer function is linear having constant synaptic amplification for the entire range of cone photoresponses (open circles). Raising retinal NO level (L-arginine – triangles; SNP – inverted triangles) had no effect, while lowering retinal NO level (adding L-NAME) transformed the transfer function into a non-linear function having highest synaptic amplification for small amplitude cone photoresponses (open squares). The figure is adopted from Levy et al., 2004 (251).

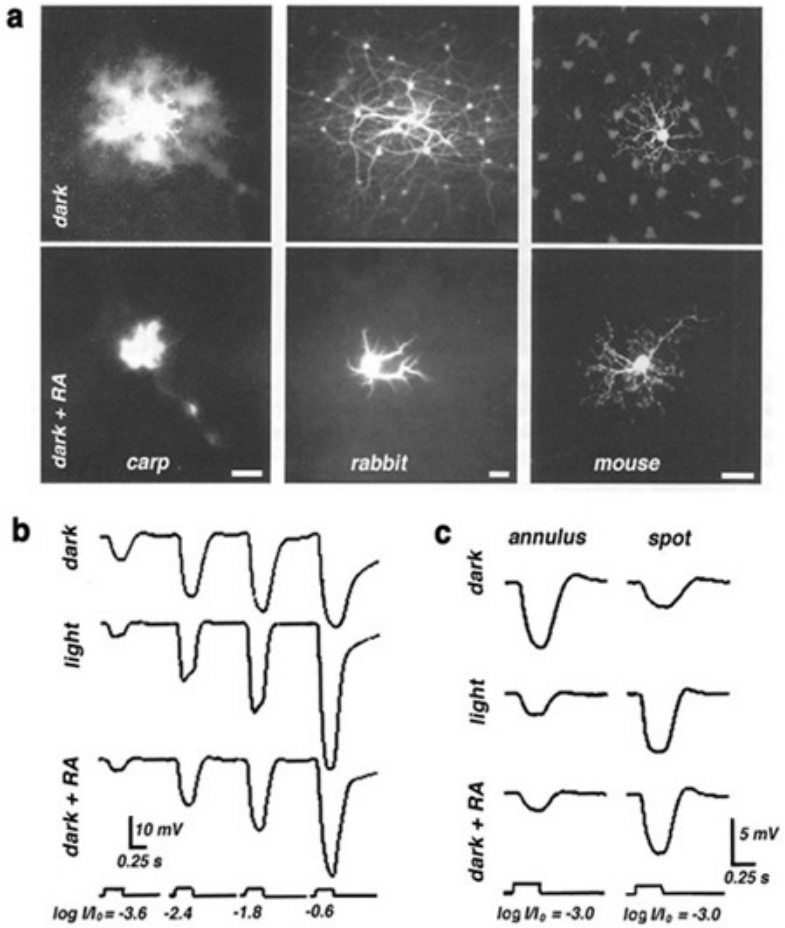

Figure 27. The effects of retinoic acid upon the physiology of horizontal cells in different species. *a*. In carp, rabbit and mouse retinas, retinoic acid added in the dark-adapted state reduced the extent of dye coupling. *b*. Retinoic acid added in the dark-adapted state exerts effects similar to those of light adaptation by augmenting the photoresponses of fish horizontal cells. *c*. Retinoic acid, like background illumination, reduces the response to an annulus stimulus and augments that to a spot stimulus in fish horizontal cells. The illustration is from Weiler et al., 2001 (261).

Photoreceptor synaptic modulation

Calcium entry into synaptic structures induces the release of neurotransmitter by promoting fusion of neurotransmitter-laden synaptic vesicles with the presynaptic membrane. Calcium enters through specialized membrane channels regulated by voltage, by second messengers, and by neurotransmitters. In the ephaptic model for horizontal cell modulation of gain at cone synapses (189, 215, 216), depolarized, dark-adapted horizontal cells produce an electrical gradient in the extracellular space that reduces the rate of calcium entry into cone terminals. This in turn, reduces the rate of neurotransmitter release (Fig. 22B). Background illumination hyperpolarizes horizontal cells, increases the extracellular currents, shifts the voltage dependency of the calcium channels in the cone terminals to more hyperpolarized levels (Fig. 22A), and increases the rate of transmitter release for a given potential of the cone as compared to the rate of release in the absence of horizontal cell feedback. Light-evoked hyperpolarization of horizontal cells increases neurotransmitter release from cones, while light evoked hyperpolarization of cones depresses the same release.

Horizontal-cell feedback modulation of horizontal cells

Horizontal-cell modulation of transmitter release from cones serves to complete a negative feedback loop between horizontal cells and cones. This in turn regulates the horizontal cell membrane potential. When

horizontal cells become depolarized, calcium influx into the cone synapse is reduced, as is transmitter efflux from the synapse. The effect sends horizontal cell membrane potential in a hyperpolarized direction. Thus horizontal cell membrane potential becomes controlled by the network, rather than strictly by factors intrinsic to the cell itself.

Horizontal cells do not express overt center-surround organization of their receptive fields; however, they do express color opponency, a very likely result of their own feedback. This is discussed in the section Physiological types above. Horizontal-cell receptive fields also show evidence of spatial effects from their own feedback circuitry. Small spot responses from horizontal cells are increased in amplitude and quickened in time course when a feedback-stimulating annular background is added (Fig. 28). In the illustration (264) small-spot, white-noise stimuli are used to calculate impulse functions under conditions where the spot is presented either with, or without an annulus. The white noise impulse function provides a very accurate depiction of changes in response dynamics. It is clear that the gain of the small spot response is increased, and the temporal tuning of the response is changed to higher frequencies and shorter latencies in the presence of the feedback-stimulating annulus. The increased gain agrees with the idea that an inhibitory feedback influence on photoreceptor synaptic transmission has been removed by the annulus causing greater transmitter release, and consequently greater modulation of that release by light. The change in dynamics is not yet modeled, but it would appear that clearance of glutamate from the photoreceptor synaptic cleft has been accelerated through feedback also.

The illustrated effect (Fig. 28) is shown for turtle and catfish horizontal cells (264), but has also been reported in Xenopus, mudpuppy and cat horizontal cells (168, 265, 266). In these latter species horizontal cell responses contain mixed rod and cone signals. In these species it is particularly rod-selective wide-field stimuli that are effective in increasing the amplitudes of cone-driven spot responses and shortening their latencies (168, 265, 266). The effect is thought to be analogous to 'suppressive rod cone interaction' (SRCI), a behavioral paradigm where dim rod backgrounds make flickering, cone-selective, small spots more visible (267). These observations suggest that feedback provides more than just wide field inhibition of cones, it also regulates synaptic gain and response dynamics.

Bipolar cell receptive fields

Bipolar cells respond with opposite voltage polarity to light stimuli illuminating either the center or the surround (4, 268). Bipolar cells perceive horizontal-cell negative feedback and synaptic gain modulation as spatial opponency. This is true for both ON- and OFF-center bipolar cells. The increase in photoreceptor transmitter release caused by horizontal cell hyperpolarization due to annular light stimuli is just the reverse of the decrease in transmitter release that occurs as cones are hyperpolarized by small spots of light. Thus through horizontal cell feedback onto cones, for bipolar cells, wide field annular stimuli have just the opposite effect as small spot stimuli. Feedback also provides synaptic gain in bipolar cells. Small-spot center responses of bipolar cells, as well as small-spot responses of horizontal cells, are amplified by feedback (265, 269).

Horizontal cell feedback is not necessarily the only way of influencing bipolar cell receptive field architecture. Horizontal cells can impinge directly on bipolar cells, feeding visual information forward to these second-order retinal neurons. Typical chemical synapses from horizontal to bipolar cells have been described in non-mammalian retinas (270, 271). In one study, in the presence of APB to block synaptic transmission from photoreceptors to ON-center bipolar cells, the light stimulus induced a hyperpolarizing response in the bipolar cell thus supporting the idea of a direct input, possibly from horizontal cells (123).

The best candidate for the feed-forward neurotransmitter is GABA, as seen in experiments on salamander retina (272). Horizontal cells make the GABA synthetic enzyme GAD in one of two isoforms, GAD 65 or GAD 67 (273); and further, in some species, they express uptake systems for GABA (51, 161). $GABA_A$ receptors are found postsynaptic to horizontal cells on the dendritic tips of both flat and invaginating bipolar cells in cat, macaque, and human retinas (274, 275). While GABA inhibition from horizontal cells might serve for the

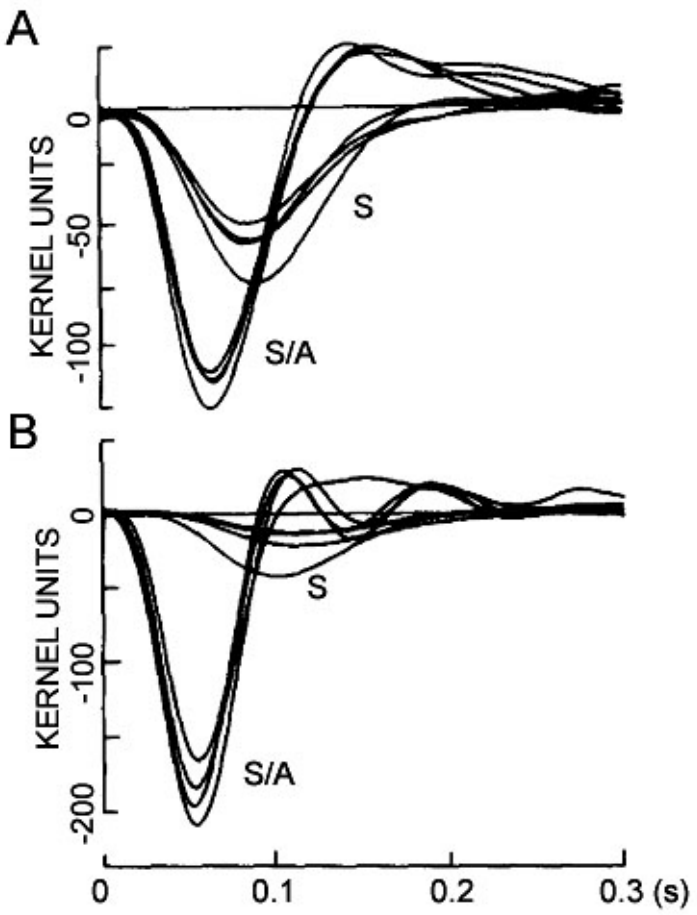

Figure 28. The effects of feedback on horizontal-cell gain and speed. Using small-spot, white-noise stimuli, impulse functions were calculated for horizontal-cell light responses. S is the impulse function for the spot stimulus alone. S/A is the impulse function for the spot stimulus with additional maintained annular stimulation in the surround to stimulate feedback. In the presence of an annulus the peak time of the spot impulse function shortens, the amplitude increases, and the shape becomes biphasic or differentiating. *A*. Turtle horizontal cells. *B*. Catfish horizontal cells. In each case results are superimposed for 4 different horizontal cells. The illustration is from Chappell, et al., 1985 (264)

antagonistic surround of OFF bipolar cells, GABA excitation would be required for ON-bipolar cells. GABA responses are mediated by the chloride gradient in post-synaptic bipolar cells. This gradient is governed in part by the actions of chloride transporters. The transporter KCC2 localized on the dendritic tips of OFF-center bipolar cells, probably maintains a chloride gradient suitable for GABA inhibition (276). ON bipolar cell dendrites express the chloride transporter NKCC, as do horizontal cells, setting up a chloride gradient suitable for GABAergic excitation. A further potential excitatory pathway for GABA in the distal retina might be provided by GABA transporters. These induce sodium entry, depolarizing, at least, horizontal cells (161, 162), but possibly some bipolar cells as well.

Not all bipolar cells exhibit spatial antagonism. The ON-bipolar for the rod system and some OFF-center cone bipolar cells in cat retina appear to lack surrounds (277, 278). Regardless of the exact neuronal pathway, whether feedforward or feedback, it is generally accepted that horizontal cells play an important role in spatial information processing in retinal neurons in the distal retina (3, 4, 171, 279-287).

Horizontal cell feedback also serves to generate color opponency in bipolar cells and therefore contributes to the physiology of color-opponent ganglion cells. Figure 29B summarizes, the manner in which single and double opponent bipolar-cell receptive fields can be formed in the fish retina according to the cascade model of color

opponency (43, 86, 288). The opponent surround of the single opponent cell is easy to model (Fig. 29B, top). This bipolar cell receives an excitatory input from red cones only and therefore, is defined as a red OFF-center cell. Negative feedback from monophasic and biphasic horizontal cells oppose each other in the red range of the spectrum and strengthen each other in the green and blue range. If the degree of feedback from both horizontal cells is the same, then the bipolar surround will be of an ON pattern with spectral sensitivity highest in the green part of the spectrum. If the feedback from the monophasic horizontal cell is weaker compared to that of the biphasic horizontal cell, then the spectral response of the bipolar cell to surround illumination will be hyperpolarizing for red light and depolarizing for green light (R-G+) (86).

In the double opponent bipolar cell (Fig. 29B, bottom), the bipolar cell responds in its center with hyperpolarizations to red light stimuli and with depolarizations to green and blue light stimuli. This central color opponency is generated by different types of inputs from different types of cones; excitatory input from the red cones and inhibitory input from the green cones. Indeed in the retina of giant danio a color opponent cone bipolar cell with bistratified axonal morphology has been found to respond to both AMPA/kainate agonists (OFF type receptors) and to EAAT agonists (ON type receptors) suggesting both ON and OFF dendritic input from spectrally distinct cones (289). If the monophasic and the biphasic horizontal cells feed back onto both spectral types of cone (86), then the feedback through the green cones would work against the feedback through the red cones because of the different synaptic interactions. When the feedback pathways from each horizontal cell onto the red and green cones differ, then color opponency can be generated by the feedback pathways. However, when the strength of the feedback from each horizontal cell to both types of cones is equal, the surround response could be achromatic. Under these conditions, color opponency in the surround of the bipolar cell can occur only through direct input from one or both horizontal cells to the bipolar cell itself.

Horizontal cells influence ganglion-cell discharge

In experiments where horizontal-cell membrane potentials are directly polarized by injections of current through intracellular microelectrodes (Fig. 30), ganglion cell discharges characteristic of 'surround responses' or 'large-spot responses' are evoked (284, 290). A hyperpolarizing current step injected into a rabbit horizontal cell depresses the firing rate in an ON-center ganglion cell, but increases the firing rate in an OFF-center ganglion cell (Fig. 30). Both actions resemble surround responses. This current-evoked response reflects the negative feedback pathway from horizontal cells to cones and/or direct input from the horizontal cells to bipolar cells. Evidence for both possibilities has been reported. The glutamate agonist 2-amino-4 phosphonobutyrate (APB), a selective blocker for transmission between cones and ON-center bipolar cells, blocks the light responses of ON-center ganglion cells, and also the 'surround-like' responses evoked by injection of current into horizontal cells (290). Moreover, sub-millimolar concentrations of cobalt ions selectively block the feedback pathway from horizontal cells to cone photoreceptors. In turtles this results in the absence of surround components in ganglion cells in proximal retina (291). Similarly the feedback blocker HEPES, a cationic buffer which selectively attenuates horizontal-cell area effects in cone responses, blocks the surround responses of parasol ganglion cells in monkey (209). This evidence suggests that a major influence of horizontal cells at the ganglion cell level is through interactions with photoreceptors, that this interaction influences the discharge patterns of ganglion cells, and by extension, plays a very important role in vision and visual perception.

About the Authors

The biosketches for Ido Perlman, Helga Kolb and Ralph Nelson appear elsewhere in Webvision.

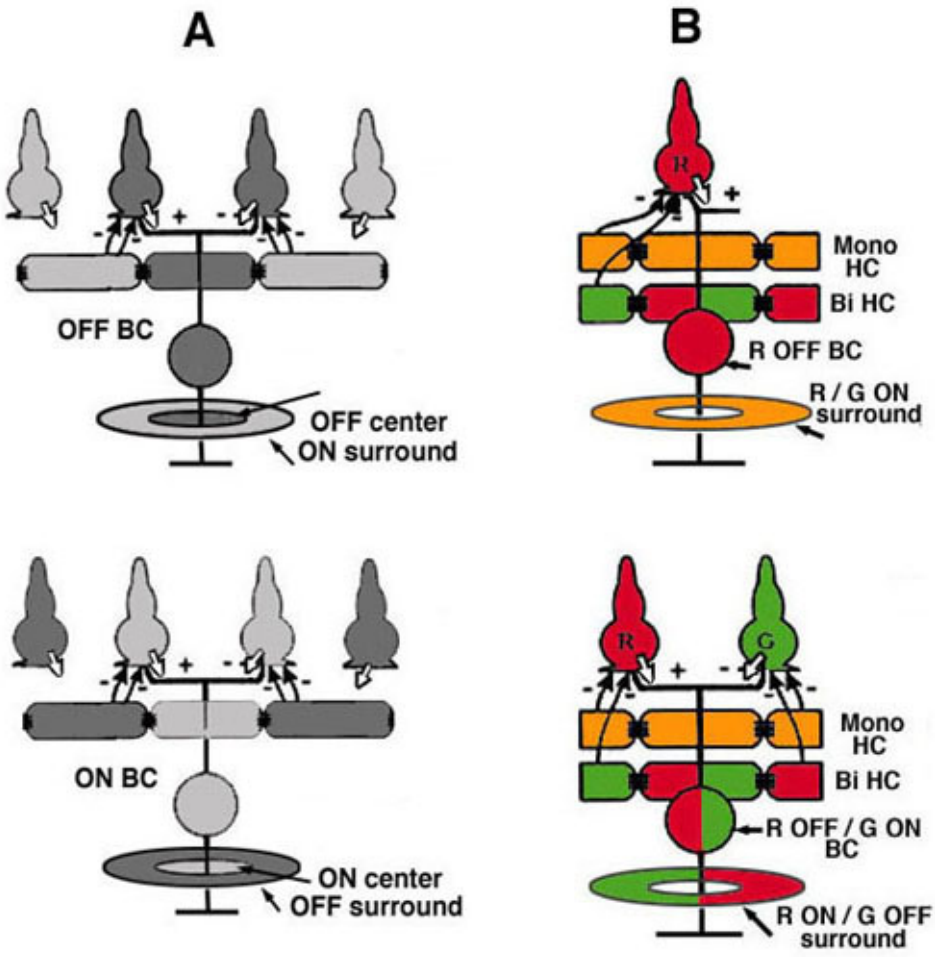

Figure 29. Schematic drawing of the horizontal-cell lateral inhibition onto cones that forms the concentrically organized receptive fields of bipolar cells. In (*A*), a simple feedback from monophasic (L-type) horizontal cells onto cones can affect the hyperpolarizing OFF-center or depolarizing ON-center bipolar cells to provide the opponent ON- or OFF- surround respectively. In (*B*), the same mechanism can be used to model the generation of color opponent responses in bipolar cells. The drawing illustrates the manner in which biphasic (Bi) chromaticity horizontal cells and monophasic (Mono) luminosity horizontal cells can feed back through a single cone type to give the opponent color surround to a red OFF bipolar cell. In the lower cartoon, red cones provide excitatory input and green cone inhibitory input to produce a red OFF, green ON center double opponent bipolar cell. The red ON and green OFF surround is added by the chromatic (Bi) and luminosity (mono) horizontal cells. The model is adapted from Kamermans and Spekreijse, 1995 (86).

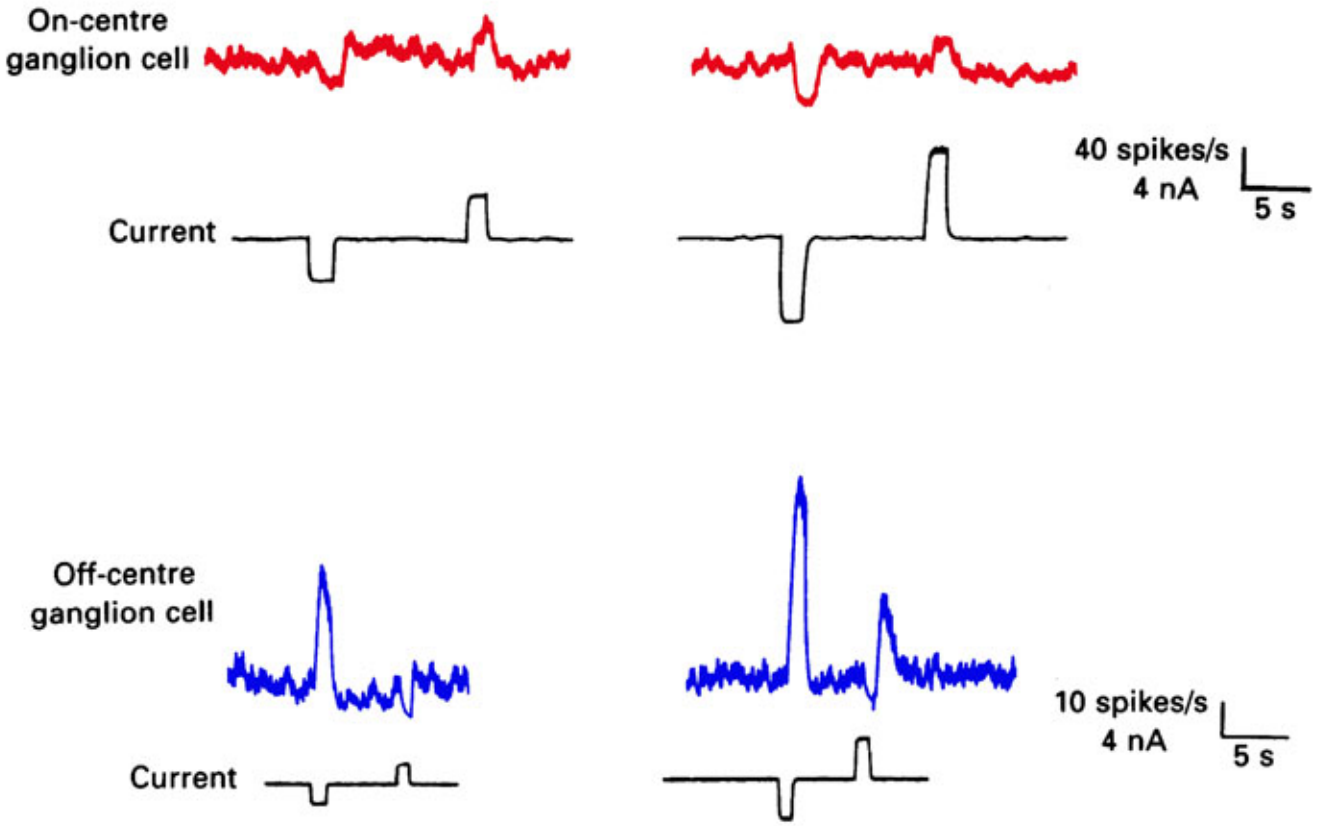

Figure 30. Retinal ganglion cells are influenced by current injection into horizontal cells. Horizontal cells were penetrated with intracellular electrodes while extracellular spikes were recorded from ganglion cells close to the horizontal cell recording site. The firing rate of an ON-center ganglion cell was reduced by hyperpolarizing current injection, and increased by depolarizing currents (red, above). The firing rate of an OFF-center ganglion cell was increased by hyperpolarizing currents, and slightly decreased by depolarizing currents (blue, below). The actions mimicked ganglion-cell surround responses. The illustration is taken from Mangel, 1991 (290).

Glutamate and Glutamate Receptors in the Vertebrate Retina

Victoria Connaughton

Created: May 1, 2005; Updated: May 7, 2007.

General Overview of Synaptic Transmission

Cells communicate with each other electrically, through gap junctions, and chemically, using neurotransmitters. Chemical synaptic transmission allows nerve signals to be exchanged between cells that are electrically isolated from each other. The chemical messenger, or neurotransmitter, provides a way to send the signal across the extracellular space, from the presynaptic neuron to the postsynaptic cell. The space is called a **cleft** and is typically more than 10 nanometers across. Neurotransmitters are synthesized in the presynaptic cell and stored in vesicles in presynaptic processes, such as the axon terminal. When the presynaptic neuron is stimulated, calcium channels open, and the influx of calcium ions into the axon terminal triggers a cascade of events leading to the release of neurotransmitter. Once released, the neurotransmitter diffuses across the cleft and binds to receptors on the postsynaptic cell, allowing the signal to propagate. Neurotransmitter molecules can also bind onto presynaptic autoreceptors and transporters, regulating subsequent release and clearing excess neurotransmitter from the cleft. Compounds classified as neurotransmitters have several characteristics in common (reviewed in Massey (1) and Erulkar (2)).

Briefly: 1) the neurotransmitter is synthesized, stored, and released from the presynaptic terminal; 2) specific neurotransmitter receptors are localized on the postsynaptic cells; and 3) there exists a mechanism to stop neurotransmitter release and clear molecules from the cleft. Common neurotransmitters in the retina are glutamate, GABA, glycine, dopamine, and acetylcholine. Neurotransmitter compounds can be small molecules, such as glutamate and glycine, or large peptides, such as vasoactive intestinal peptide (VIP). Some neuroactive compounds are amino acids, which also have metabolic functions in the presynaptic cell.

Glutamate (Fig. 1) is believed to be the major excitatory neurotransmitter in the retina. In general, glutamate is synthesized from ammonium and α-ketoglutarate (a component of the Krebs cycle) and is used in the synthesis of proteins, other amino acids, and even other neurotransmitters (such as GABA) (3). Although glutamate is present in all neurons, only a few are glutamatergic, releasing glutamate as their neurotransmitter. Neuroactive glutamate is stored in synaptic vesicles in presynaptic axon terminals (4). Glutamate is incorporated into the vesicles by a glutamate transporter located in the vesicular membrane. This transporter selectively accumulates glutamate through a sodium-independent, ATP-dependent process (4-6), resulting in a high concentration of glutamate in each vesicle. Neuroactive glutamate is classified as an excitatory amino acid (EAA), because glutamate binding onto postsynaptic receptors typically stimulates, or depolarizes, the postsynaptic cells.

Histological Techniques Identify Glutamatergic Neurons

Using immunocytochemical techniques, neurons containing glutamate are identified and labeled with a glutamate antibody. In the retina, photoreceptors, bipolar cells, and ganglion cells are glutamate immunoreactive (7-12) (Fig. 2). Some horizontal and/or amacrine cells can also display weak labeling with glutamate antibodies (7, 8, 10, 13). These neurons are believed to release GABA, not glutamate, as their neurotransmitter (14), suggesting that the weak glutamate labeling reflects the pool of metabolic glutamate used in the synthesis of GABA. This has been supported by the results from double-labeling studies using antibodies to both GABA and glutamate; glutamate-positive amacrine cells also label with the GABA antibodies (8, 13).

Photoreceptors, which contain glutamate, actively take up radiolabeled glutamate from the extracellular space, as do Muller cells (Fig. 3) (15, 16). Glutamate is incorporated into these cell types through a high-affinity glutamate transporter located in the plasma membrane. Glutamate transporters maintain the concentration of glutamate within the synaptic cleft at low levels, preventing glutamate-induced cell death (17). Although Muller cells take

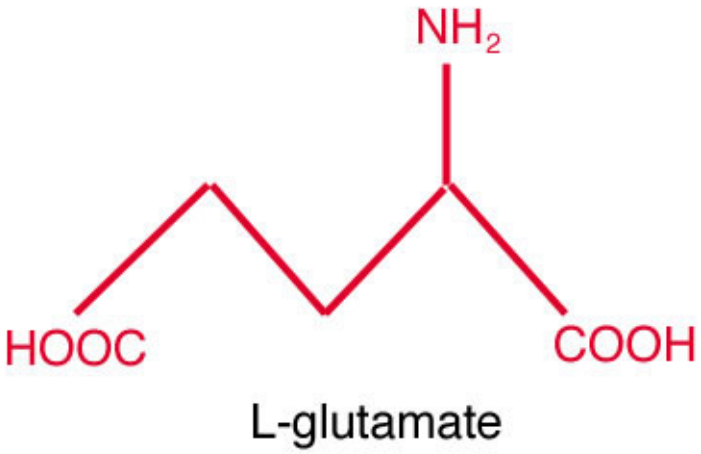

Figure 1. Structure of the glutamate molecule.

up glutamate, they do not label with glutamate antibodies (8). Glutamate incorporated into Muller cells is rapidly broken down into glutamine, which is then exported from glial cells and incorporated into surrounding neurons (18). Neurons can then synthesize glutamate from glutamine (18, 19).

Thus, histological techniques are used to identify potential glutamatergic neurons by labeling neurons containing glutamate (through immunocytochemistry) and neurons that take up glutamate (through autoradiography). To determine whether these cell types actually release glutamate as their neurotransmitter, however, the receptors on postsynaptic cells have to be examined.

Glutamate Receptors

Once released from the presynaptic terminal, glutamate diffuses across the cleft and binds onto receptors located on the dendrites of the postsynaptic cell(s). Multiple glutamate receptor types have been identified. Although glutamate will bind onto all glutamate receptors, each receptor is characterized by its sensitivity to specific glutamate analogs and by the features of the glutamate-elicited current. Glutamate receptor agonists and antagonists are structurally similar to glutamate (Fig. 4), which allows them to bind onto glutamate receptors. These compounds are highly specific and, even in intact tissue, can be used in very low concentrations because they are poor substrates for glutamate uptake systems (20, 21).

Two classes of glutamate receptors (Fig. 5) have been identified: 1) ionotropic glutamate receptors, which directly gate ion channels; and 2) metabotropic glutamate receptors, which may be coupled to an ion channel or other cellular functions via an intracellular second messenger cascade. These receptor types are similar in that they both bind glutamate, and glutamate binding can influence the permeability of ion channels. However, there are several differences between the two classes.

Ionotropic Glutamate Receptors

Glutamate binding onto an ionotropic receptor directly influences ion channel activity because the receptor and the ion channel form one complex (Fig. 5a). These receptors mediate fast synaptic transmission between neurons. Each ionotropic glutamate receptor, or iGluR, is formed from the co-assembly of individual subunits. The assembled subunits may or may not be homologous, with the different combinations of subunits resulting in channels with different characteristics (22-26).

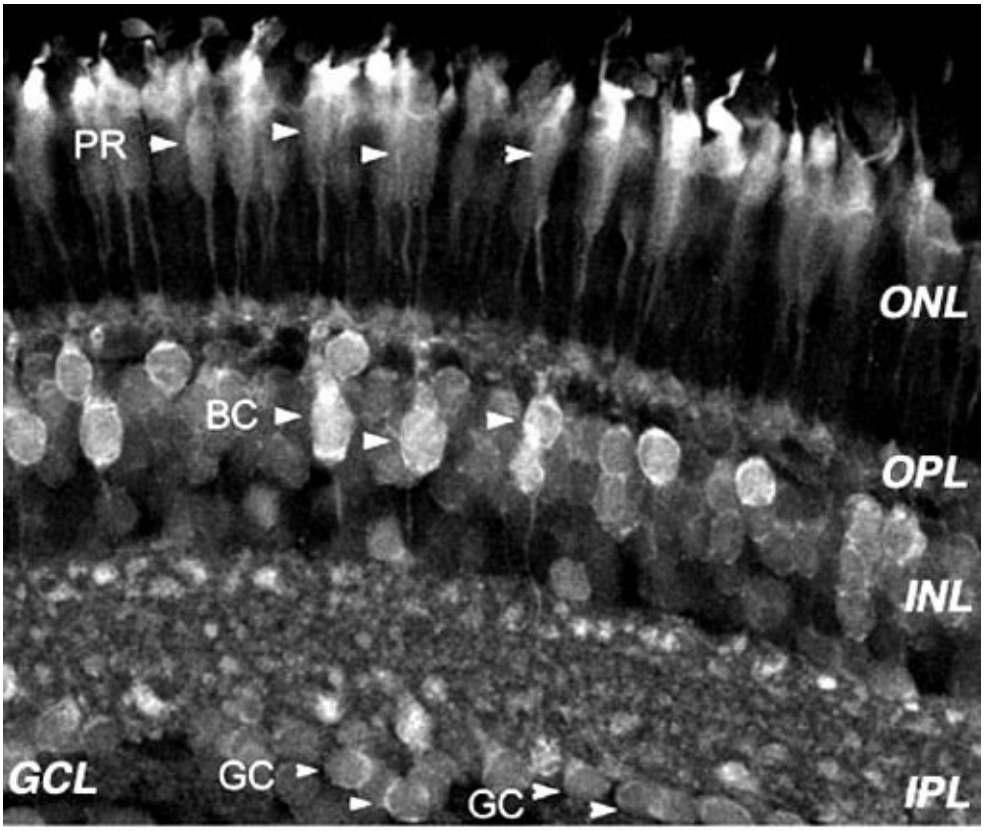

Figure 2. Glutamate immunoreactivity.

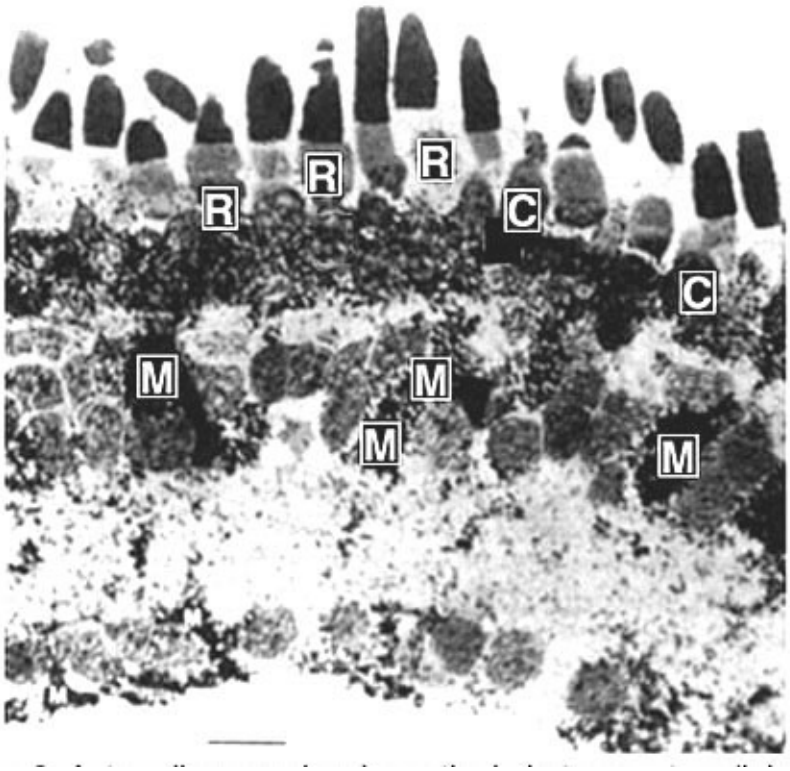

Figure 3. Autoradiogram of glutamate uptake through glutamate transporters.

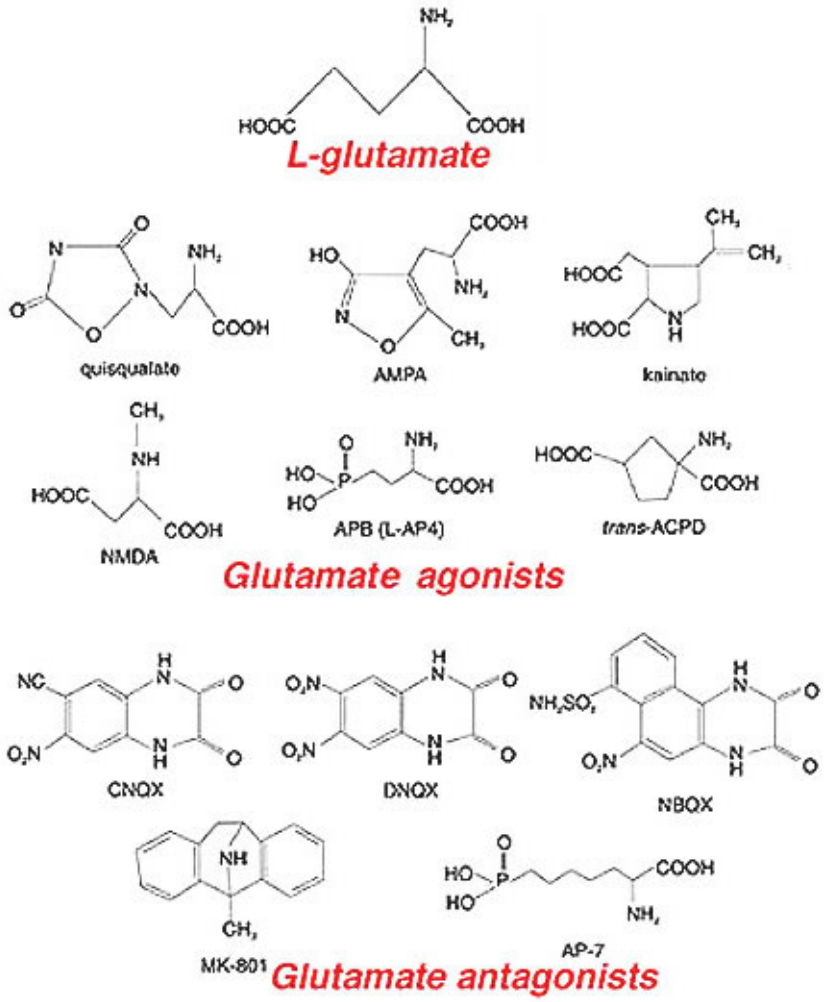

Figure 4. Glutamate receptor agonists and antagonists.

Two iGluR types (Fig. 6) have been identified: 1) NMDA receptors, which bind glutamate and the glutamate analog *N*-methyl-D-aspartate (NMDA) and 2) non-NMDA receptors, which are selectively agonized by kainate, AMPA, and quisqualate, but not NMDA.

Non-NMDA Receptors

Glutamate binding onto a non-NMDA receptor opens non-selective cation channels more permeable to sodium (Na^+) and potassium (K^+) ions than calcium (Ca^{2+}) (27). Glutamate binding elicits a rapidly activating inward current at membrane potentials negative to 0 mV and an outward current at potentials positive to 0 mV. Kainate, quisqualate, and AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) are the specific agonists at these receptors; CNQX (6-cyano-7-nitroquinoxaline-2,3-dione), NBQX (1,2,3,4-tetrahydro-6-nitro-2,3-dione-benzo[*f*]quinoxaline-7-sulfonamide), and DNQX (6,7-dinitroquinoxaline-2,3-dione) are the antagonists.

In retina, non-NMDA receptors have been identified on horizontal cells, OFF-bipolar cells, amacrine cells, and ganglion cells (see below). Patch clamp recordings (28-32) indicate that AMPA, quisqualate, and/or kainate application can evoke currents in these cells. However, the kinetics of the ligand-gated currents differ. AMPA- and quisqualate-elicited currents rapidly desensitize, whereas kainate-gated currents do not (Fig. 7a). The desensitization at AMPA/quisqualate receptors can be reduced (Fig. 7b) by adding cyclothiazide (33), which stabilizes the receptor in an active (or non-desensitized) state (33, 34).

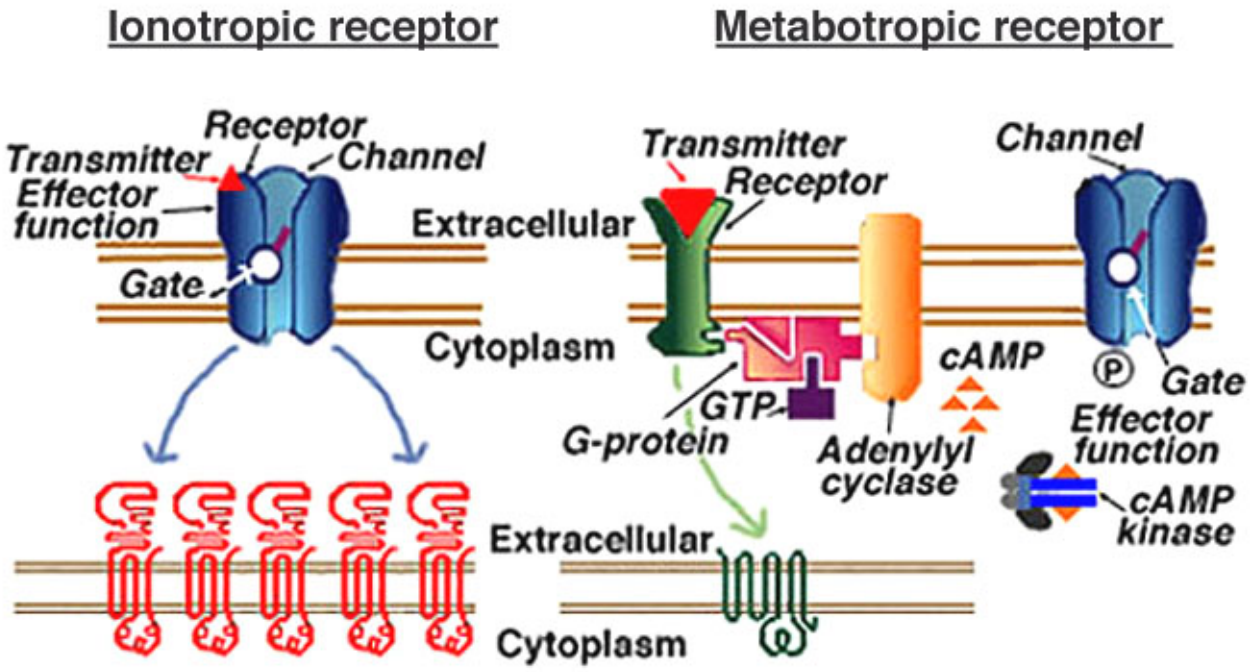

Fig. 5a. Ionotropic receptors and their associated ion channels form one complex (top). Each iGluR is formed from the co-assembly of multiple (4-5) subunits (From Kandel et al., 1991).

Fig. 5b. Metabotropic receptors are coupled to their associated ion channels by a second messenger cascade (top). Each mGluR is composed of one polypeptide, which is coupled to a G-protein (from Kandel et al., 1991).

Figure 5. Ionotropic and metabotropic glutamate receptors and channels. From Kandel et al. (127).

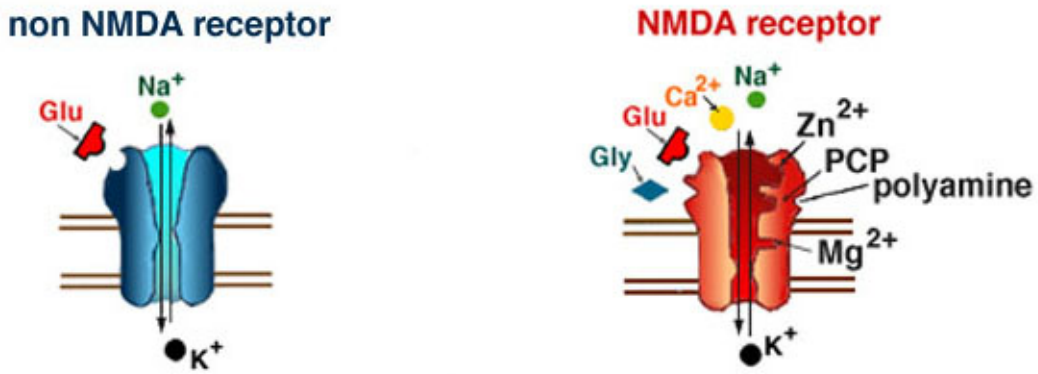

Fig. 6a. Non-NMDA receptors are selectively agonized by kainate, AMPA and quisqualate. The associated ion channels are more perm eable to Na+ and K+ ions tha Ca+2 (from Kandel et al,.1991).

Fig. 6b. NMDA receptors are structurally complex, with separate binding sites for glutamate, glycine MG+2, Zn+2 and polyamines. NMDA-gated channels are more permeable to Ca+2 than Na+ ions (from Kandel et al., 1991).

Figure 6. Comparison between NMDA and non-NMDA receptors. From Kandel et al. (127).

Each non-NMDA receptor is formed from the co-assembly of several subunits (25, 35, 36). To date, seven subunits (named GluR1 through GluR7) have been cloned (22, 35-40). Expression of subunit clones in *Xenopus* oocytes revealed that GluR5, GluR6, and GluR7 (along with subunits KA1 and KA2) co-assemble to form kainate(-preferring) receptors, whereas GluR1, GluR2, GluR3, and GluR4 are assembled into AMPA(-preferring) receptors (25).

NMDA Receptors

Glutamate binding onto an NMDA receptor also opens non-selective cation channels, resulting in a conductance increase. However, the high conductance channel associated with these receptors is more permeable to Ca^{2+} than Na^{+} ions (27), and NMDA-gated currents typically have slower kinetics than kainate- and AMPA-gated channels. As the name suggests, NMDA is the selective agonist at these receptors. The compounds MK-801, AP-5 (2-amino-5-phosphonopentanoic acid), and AP-7 (2-amino-7-phosphoheptanoic acid) are NMDA receptor antagonists.

NMDA receptors are structurally complex, with separate binding sites for glutamate, glycine, magnesium ions (Mg^{2+}), zinc ions (Zn^{2+}), and a polyamine recognition site (Fig. 6b). There is also an antagonist binding site for PCP and MK-801 (41). The glutamate, glycine, and magnesium binding sites are important for receptor activation and gating of the ion channel. In contrast, the zinc and polyamine sites are not needed for receptor activation but affect the efficacy of the channel. Zinc blocks the channel in a voltage-independent manner (42). The polyamine site (43, 44) binds compounds such as spermine or spermidine, either potentiating (43, 44) or inhibiting (44) the activity of the receptor, depending on the combination of subunits forming each NMDA receptor (44).

To date, five subunits (NR1, NR2a, N2b, N2c, and N2d) of NMDA receptors have been cloned (45-49). As with non-NMDA receptors, NMDA receptor subunits can co-assemble as homomers (i.e., five NR1 subunits) (23, 49) or heteromers (one NR1 + four NR2 subunits) (23, 46-48). However, all functional NMDA receptors express the NR1 subunit (23, 25, 46).

The glutamate, glycine, and Mg^{2+} binding sites confer both ligand-gated and voltage-gated properties onto NMDA receptors. NMDA receptors are ligand gated because the binding of glutamate (ligand) is required to activate the channel. In addition, micromolar concentrations of glycine must also be present (Fig. 8) (50, 51). The requirement for both glutamate and glycine makes them co-agonists (51) at NMDA receptors.

Mg^{2+} ions provide a voltage-dependent block of NMDA-gated channels (52). This can be seen in the current-voltage (I-V) relationship presented in Fig. 9 (from Nowak et al. (52)). I-V curves plotted from currents recorded in the presence of Mg^{2+} have a characteristic J-shape (Fig. 9, dotted line), whereas a linear relationship is calculated in Mg^{2+}-free solutions (Fig. 9, solid line). At negative membrane potentials, Mg^{2+} ions occupy the binding site, causing less current to flow through the channel. As the membrane depolarizes, the Mg^{2+} block is removed (52).

Retinal ganglion cells and some amacrine cell types express functional NMDA receptors in addition to non-NMDA receptors (i.e., 29, 53-57). The currents elicited through these different iGluR types can be distinguished pharmacologically. Non-NMDA receptor antagonists block a transient component of the ganglion cell light response, whereas NMDA receptor antagonists block a more sustained component (29, 53, 57, 58). These findings suggest that the currents elicited through colocalized NMDA and non-NMDA receptors mediate differential contributions to the ON- and OFF-light responses observed in ganglion cells (53).

Metabotropic Glutamate Receptors

Unlike ionotropic receptors, which are directly linked to an ion channel, metabotropic receptors are coupled to their associated ion channel through a second messenger pathway. Ligand (glutamate) binding activates a G-

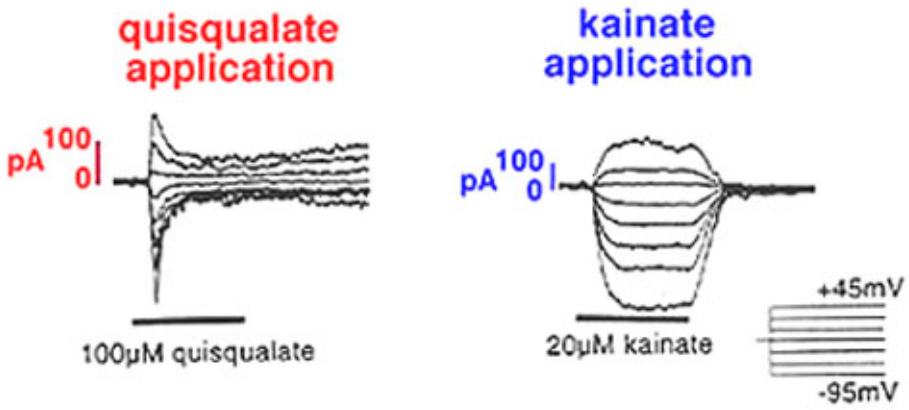

Fig. 7a. Families of whole-cell current traces show the rapid kinetics and desensitization of quisqualate- (and AMPA-) gated currents (left traces). Kainate-gated currents (right), in contrast, do not desensitize (from Gilbertson et al., 1991, Fig. 1).

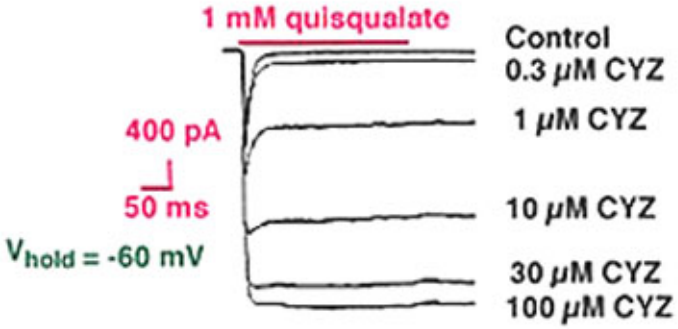

Fig. 7b. Cyclothiazide (CYZ) reduces desensitization at quisqualate receptors in a concentration-dependent manner (from Yamada and Tang, 1993, Fig. 2).

Figure 8. NMDA receptor activation.

protein and initiates an intracellular cascade (59). Metabotropic glutamate receptors (mGluRs) are not co-assembled from multiple subunits but are one polypeptide (Fig. 5b). To date, eight mGluRs (mGluR1 through mGluR8) have been cloned (60-66). These receptors are classified into three groups (I, II, and III) based on

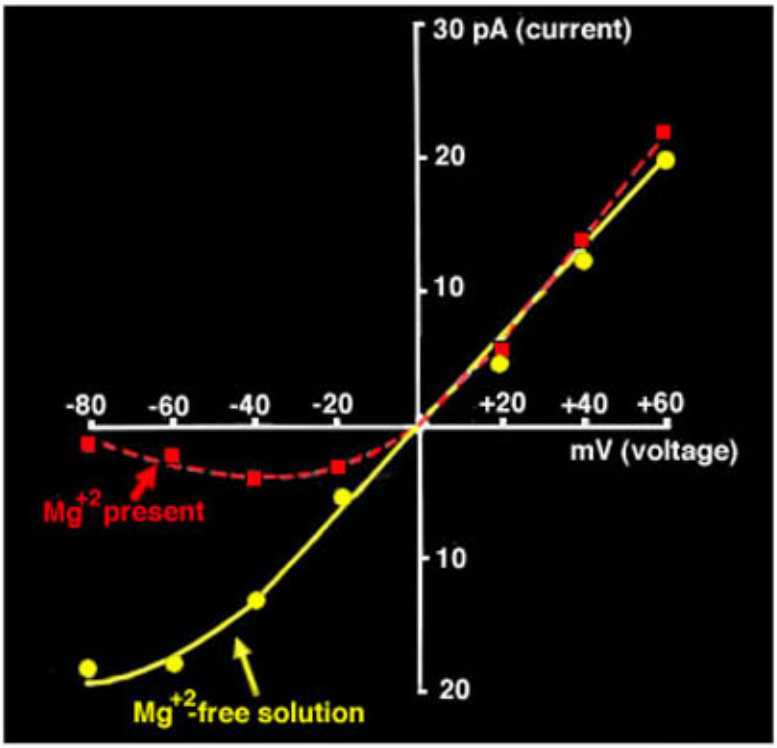

Figure 9. Mg^{2+} ions block NMDA receptor channels.

structural homology, agonist selectivity, and their associated second messenger cascade (Table 1) (reviewed in Nakanishi (67), Knopel et al. (68), Pin and Bockaert (69), and Pin and Duvoisin (70)).

In brief, Group I mGluRs (mGluR1 and mGluR5) are coupled to the hydrolysis of fatty acids and the release of calcium from internal stores. Quisqualate and *trans*-ACPD are Group I agonists. Group II (mGluR2 and mGluR3) and Group III (mGluR4, mGluR6, mGluR7, and mGluR8) receptors are considered inhibitory because they are coupled to the downregulation of cyclic nucleotide synthesis (70). L-CCG-1 and *trans*-ACPD agonize Group II receptors; L-AP4 (also called APB) selectively agonizes Group III receptors. *In situ* hybridization studies have revealed that the mRNAs encoding Groups I, II, and III mGluRs are present in retina (see below); however, with the exception of the APB receptor, the function of all of these receptor types in retina has not been characterized.

Table 1. Metabotropic glutamate receptor groups (from Pin and Duvoisin (70)).

Group	mGluR	Agonist(s)	Intracellular pathway
I	mGluR1, mGluR5	quisqualate, ACPD	Increase phospholipase C activity, increase cAMP levels, increase protein kinase A activity
II	mGluR2, mGluR3	L-CCG-1, ACPD	Decrease cAMP levels
III	mGluR4, mGluR6. mGluR7, mGluR8	L-AP4 (APB)	Decrease cAMP or cGMP levels

APB Receptor

In contrast to non-NMDA and NMDA receptors, glutamate binding onto an APB receptor elicits a conductance decrease (71-73) because of the closure of cGMP-gated, non-selective cation channels (74) (Fig. 10).

APB application selectively blocks the ON-pathway in the retina (Fig. 11) (73), i.e., ON-bipolar cell responses and the ON-responses in amacrine cells (75) and ganglion cells (29, 76, 77) are eliminated by APB. Experimental evidence (73, 78) suggests that the APB receptor is localized to ON-bipolar cell dendrites. Inhibition of amacrine and ganglion cell light responses, therefore, is due to a decrease in the input from ON-bipolar cells, not a direct effect on postsynaptic receptors.

APB (2-amino-4-phosphobutyric acid, also called L-AP4) is the selective agonist for all Group III mGluRs (mGluR4, mGluR6, mGluR7, and mGluR8). So, which is the APB receptor located on ON-bipolar cell dendrites? MGluR4, mGluR7, and mGluR8 expression has been observed in both the inner nuclear layer and the ganglion cell layer (61, 79), suggesting that these mGluRs are associated with more than one cell type. In contrast, mGluR6 expression has been localized to the inner nuclearmlayer (INL) (64, 79) and the outer plexiform layer (OPL) (80), where bipolar cell somata and dendrites are located. Furthermore, ON-responses are abolished in mice lacking mGluR6 expression (81). These mutants also display abnormal ERG b-waves, suggesting an inhibition of the ON-retinal pathway at the level of bipolar cells (81). Taken together, these findings suggest that the APB receptor on ON-bipolar cells is mGluR6.

Glutamate Transporters and Transporter-like Receptors

Glutamate transporters have been identified on photoreceptors (15, 21, 82) and Muller cells (15, 16). From glutamate labeling studies, the average concentration of glutamate in photoreceptors, bipolar cells, and ganglion cells is 5 mM (10). Physiological studies using isolated cells indicate that only μM levels of glutamate are required to activate glutamate receptors (32, 83, 84). Thus, the amount of glutamate released into the synaptic cleft is several orders of magnitude higher than the concentration required to activate most postsynaptic receptors. High-affinity glutamate transporters located on adjacent neurons and surrounding glial cells rapidly remove glutamate from the synaptic cleft to prevent cell death (17). Five glutamate transporters, EAAT-1 (or GLAST), EAAT-2 (or GLT-1), EAAT-3 (or EAAC-1), EAAT-4, and EAAT-5, have been cloned (85-90).

Glutamate transporters are pharmacologically distinct from both iGluRs and mGluRs. L-Glutamate, L-aspartate, and D-aspartate are substrates for the transporters (21, 82, 91); glutamate receptor agonists (20, 21, 82, 91) and antagonists (82, 92) are not. Glutamate uptake can be blocked by the transporter blockers dihydrokainate (DHKA) and DL-*threo*-β-hydroxyaspartate (HA) (82, 92).

Glutamate transporters incorporate glutamate into Muller cells along with the co-transport of three Na^+ ions (91, 93) and the antiport of one K^+ ion (93, 94) and either one OH– or one HCO^{3-} ion (94) (Fig. 12). The excess sodium ions generate a net positive inward current, which drives the transporter (91, 93). More recent findings indicate that a glutamate-elicited chloride current is also associated with some transporters (85, 95).

It should be noted that the glutamate transporters located in the plasma membrane of neuronal and glial cells (discussed in this section) are different from the glutamate transporters located on synaptic vesicles within presynaptic terminals (see General Overview of Synaptic Transmission). The transporters in the plasma membrane transport glutamate in a Na^+- and voltage-dependent manner independent of chloride (17, 91, 93). L-Glutamate, L-aspartate, and D-aspartate are substrates for these transporters (91). In contrast, the vesicular transporter selectively concentrates glutamate into synaptic vesicles in a Na+-independent, ATP-dependent manner (4-6) that requires chloride (4, 6).

Glutamate receptors with transporter-like pharmacology have been described in photoreceptors (96-98) and ON-bipolar cells (99, 100). These receptors are coupled to a chloride current. The pharmacology of these receptors is similar to that described for glutamate transporters, because the glutamate-elicited current is: 1) dependent upon external Na^+; 2) reduced by transporter blockers; and 3) insensitive to glutamate agonists and antagonists. However, altering internal Na^+ concentration does not change the reversal potential (100) or the amplitude (96, 99) of the glutamate-elicited current, suggesting that the receptor is distinct from glutamate

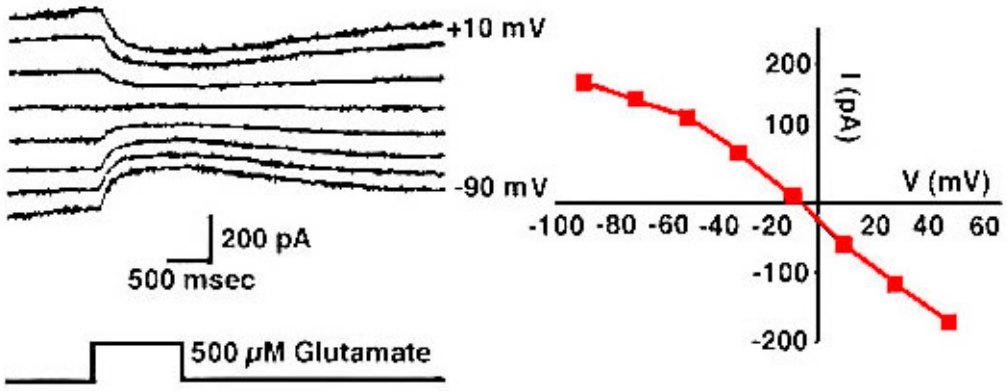

Figure 10. Whole-cell current traces to show kinetics of APB receptor-gated currents.

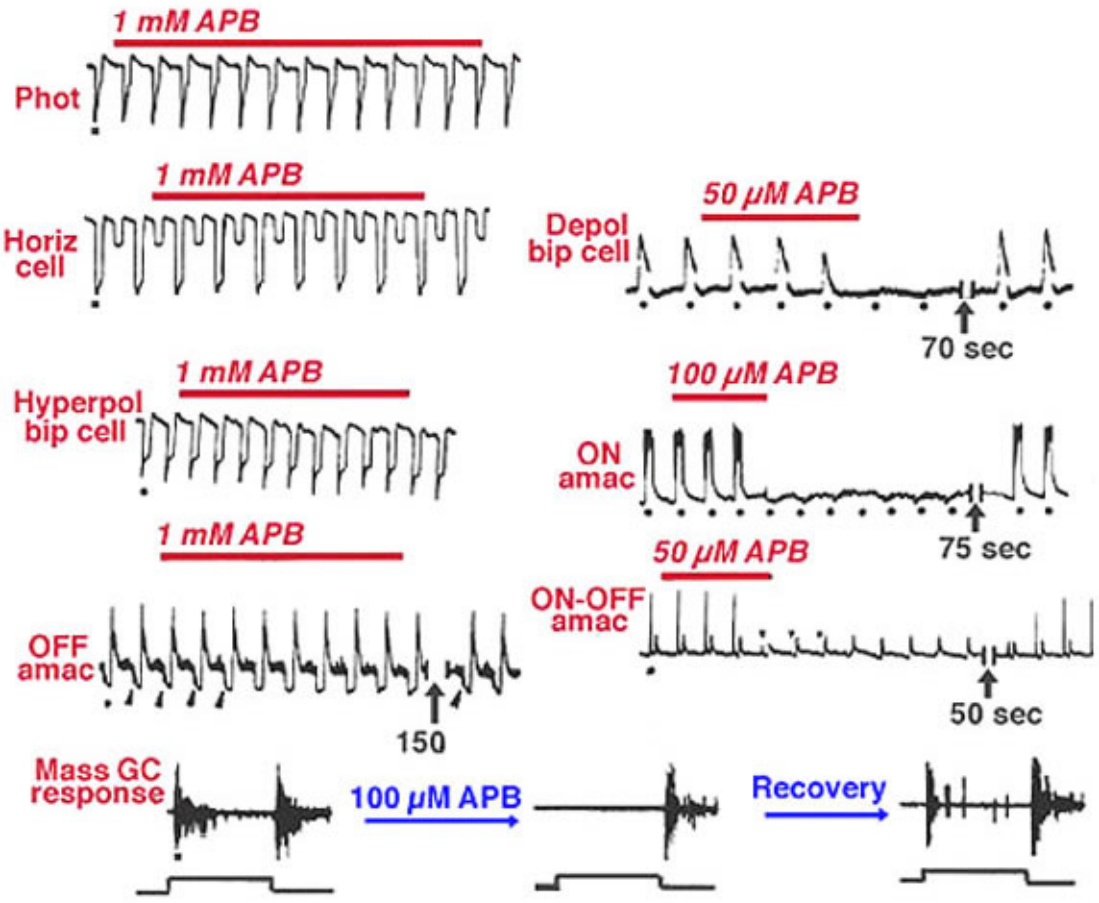

Figure 11. Intracellular recordings to show that APB selectively antagonizes the ON-pathways.

transporters. At the photoreceptor terminals, the glutamate-elicited chloride current may regulate membrane potential and subsequent voltage-gated channel activity (99). Postsynaptically, this receptor is believed to mediate conductance changes underlying photoreceptor input to ON-cone bipolar cells (99).

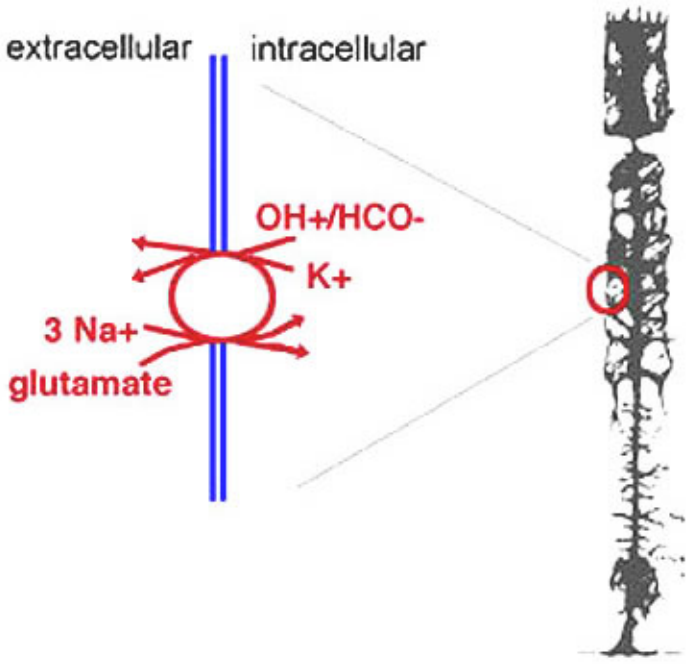

Figure 12. Glutamate transporters in Muller cells are electrogenic.

Localization of Glutamate Receptor Types in the Retina

Photoreceptor, bipolar, and ganglion cells compose the vertical transduction pathway in the retina. This pathway is modulated by lateral inputs from horizontal cells in the distal retina and amacrine cells in the proximal retina (Fig. 13). As described in the previous sections, photoreceptor, bipolar, and ganglion cells show glutamate immunoreactivity. Glutamate responses have been electrically characterized in horizontal and bipolar cells, which are postsynaptic to photoreceptors, and in amacrine and ganglion cells, which are postsynaptic to bipolar cells. Taken together, these results suggest that glutamate is the neurotransmitter released by neurons in the vertical pathway. Recent *in situ* hybridization and immunocytochemical studies have localized the expression of iGluR subunits, mGluRs, and glutamate transporter proteins in the retina. These findings are summarized below.

Retinal Neurons Expressing Ionotropic Glutamate Receptors

In both higher and lower vertebrates, electrophysiological recording techniques have identified ionotropic glutamate receptors on the neurons composing the OFF-pathway (Table 2). In the distal retina, OFF-bipolar cells (Fig. 14) (84, 101, 102) and horizontal cells (Fig. 15) (32, 103, 104) respond to kainate, AMPA, and quisqualate application, but not NMDA nor APB. (However, NMDA receptors have been identified on catfish horizontal cells (105, 106), and APB-induced hyperpolarizations have been reported in some fish horizontal cells (107-109)).

Non-NMDA agonists also stimulate both amacrine cells (Fig. 16a) (28, 54, 55) and ganglion cells (Fig. 16b) (29, 31, 53, 57, 58). Ganglion cells responses to NMDA have been observed (29, 53, 55-57), whereas NMDA responses have been recorded in only some types of amacrine cells (28, 54, 55) but see Hartveit and Veruki (110).

Consistent with this physiological data, antibodies to the different non-NMDA receptor subunits differentially label all retinal layers (Table 3) (111-114), and mRNAs encoding the different non-NMDA iGluR subunits are similarly expressed (115-117). In contrast, mRNAs encoding NMDA subunits are expressed predominantly in

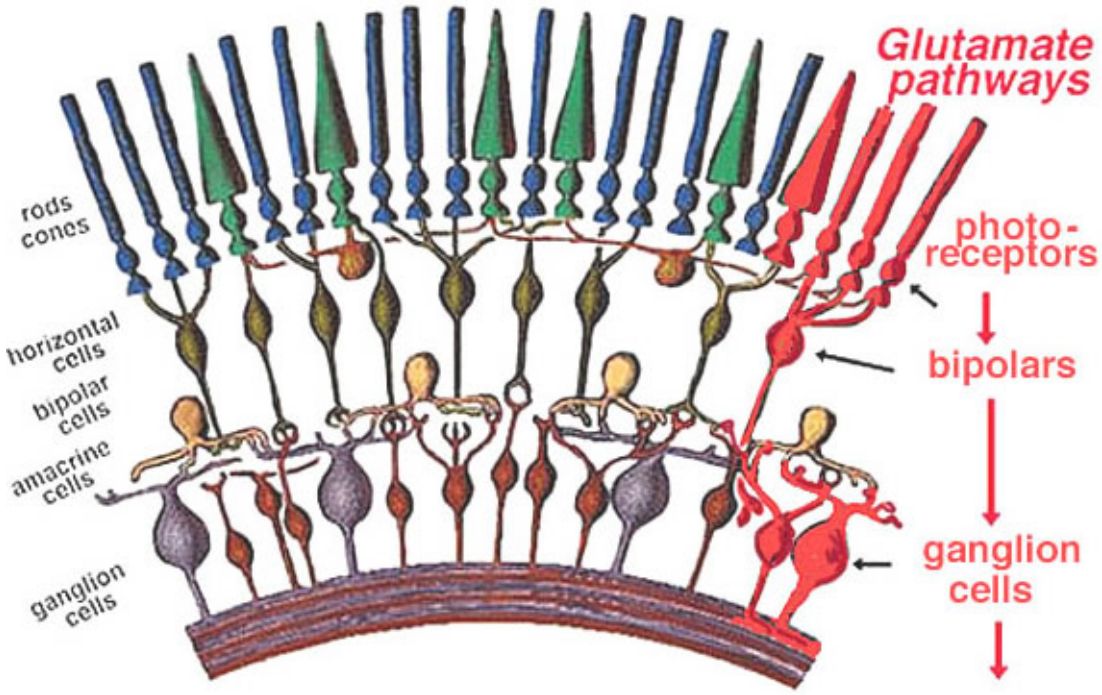

Figure 13. The types of neurons in the vertebrate retina.

the proximal retina, where amacrine and ganglion cells are located (INL, IPL, GCL) (Table 3) (111, 115), although mRNA encoding the NR2a subunit (111) has been observed in the OPL and antibodies to the NR2d (118) and the NR1 subunits (112) label rod bipolar cells.

Retinal Neurons Expressing Metabotropic Glutamate Receptors

All metabotropic glutamate receptors, except mGluR3, have been identified in retina either through antibody staining (113, 114, 119, 120) or *in situ* hybridization (61, 64, 79). MGluRs are differentially expressed throughout the retina, specifically in the outer plexiform layer, inner nuclear layer, inner plexiform layer, and the ganglion cell layer (Table 4). Although different patterns of mGluR expression have been observed in the retina, only the APB receptor on ON-bipolar cells has been physiologically examined.

Retinal Neurons Expressing Glutamate Transporters

The glutamate transporters GLAST, EAAC1, and GLT-1have been identified in retina (Table 5). GLAST (L-**gl**utamate/L-**as**partate **t**ransporter) immunoreactivity is found in all retinal layers (121) but not in neuronal tissue. GLAST is localized to Muller cell membranes (121-124). In contrast, EAAC-1 (**e**xcitatory **a**mino **a**cid **c**arrier-1) antibodies do not label Muller cells or photoreceptors. EAAC-1 immunoreactivity is observed in ganglion and amacrine cells in chicken, rat, goldfish, and turtle retinas. In addition, bipolar cells positively labeled with EAAC-1 antibody in lower vertebrates, and immunopositive horizontal cells were observed in rat (90). GLT-1 (**gl**utamate **t**ransporter-1) proteins have been identified in monkey (125), rat (124), and rabbit (126) bipolar cells. In addition, a few amacrine cells were weakly labeled with the GLT-1 antibody in rat (124), as were photoreceptor terminals in rabbit (126).

Summary and Conclusions

Histological analyses of presynaptic neurons and physiological recordings from postsynaptic cells suggest that photoreceptor, bipolar, and ganglion cells release glutamate as their neurotransmitter. Multiple glutamate receptor types are present in the retina. These receptors are pharmacologically distinct and differentially distributed. IGluRs directly gate ion channels and mediate rapid synaptic transmission through either kainate/AMPA or NMDA receptors. Glutamate binding onto iGluRs opens cation channels, depolarizing the postsynaptic cell membrane. Neurons within the OFF-pathway (horizontal cells, OFF-bipolar cells, amacrine cells, and ganglion cells) express functional iGluRs. mGluRs are coupled to G-proteins. Glutamate binding onto mGluRs can have a variety of effects, depending on the second messenger cascade to which the receptor is coupled. The APB receptor, found on ON-bipolar cell dendrites, is coupled to the synthesis of cGMP. At these receptors, glutamate decreases cGMP formation, leading to the closure of ion channels. Glutamate transporters, found on glial and photoreceptor cells, are also present at glutamatergic synapses (Fig. 17). Transporters remove excess glutamate from the synaptic cleft to prevent neurotoxicity. Thus, postsynaptic responses to glutamate are determined by the distribution of receptors and transporters at glutamatergic synapses which, in retina, determine the conductance mechanisms underlying visual information processing within the ON- and OFF-pathways.

About the Author

Dr. Victoria Connaughton was born in Sellersville, Pennsylvania. She received her B.A. from Bucknell University in Biology in 1989 and her Ph.D. in Marine Studies from The University of Delaware in 1994. She is currently an Assistant Professor in the Biology Department at American University, Washington, DC. In her thesis work under Dr. Charles Epifano, she studied the visually guided feeding behavior of larval fish. Dr. Connaughton pursued postdoctoral studies with Dr. Greg Maguire at the University of Houston and Dr. Ralph Nelson at the National Institutes of Health. Dr. Connaughton's current research interests include electrophysiological examination of zebrafish mutants with visual system defects and the characterization of light responses in zebrafish retinal bipolar cells.

Bipolar Cell Pathways in the Vertebrate Retina

Ralph Nelson, PhD[1] and Victoria Connaughton, PhD[2]

Created: May 24, 2007; Updated: January 20, 2012.

1. Introduction

Retinal ganglion cells are typically only two synapses distant from retinal photoreceptors, yet ganglion cell responses are far more diverse than those of photoreceptors. The most direct pathway from photoreceptors to ganglion cells is through retinal bipolar cells. Thus, it is of great interest to understand how bipolar cells transform visual signals.

Light response physiology

Werblin and Dowling (1) were among the first to investigate light-evoked responses of retinal bipolar cells. Based on these studies using penetrating microelectrodes, they proposed that retinal bipolar cells lacked impulse activity, and that they processed visual signals through integration of analogue signals, that is synaptic currents and non-spike-generating voltage-gated membrane currents. They also proposed that retinal bipolar cells come in two fundamental varieties: ON-center and OFF-center (Fig. 1). Both types displayed a surround region in their receptive field that opposed the center, similar to the classic, antagonistic center-surround organization earlier described for ganglion-cell receptive fields (2). Ganglion cell receptive field organization is further reviewed in the Webvision chapter on ganglion cells. ON-center bipolar cells are depolarized by small spot stimuli positioned in the receptive field center. OFF-center bipolar cells are hyperpolarized by the same stimuli. Both types are repolarized by light stimulation of the peripheral receptive field outside the center (Fig. 1). Bipolar cells with ON-OFF responses were not encountered (1). ON-OFF responses, excitation at both stimulus onset and offset, first occur among amacrine cells, neurons postsynaptic to bipolar cells.

The Werblin and Dowling characterization of bipolar-cell physiology has proved quite durable over many decades. The notion that bipolar cells do not spike has found exception for some bipolar types. Dark-adapted Mb1 (rod bipolar cells) of goldfish generate light-evoked calcium spikes. These spikes originate in bipolar-cell axon terminals (3, 4). Through genetic imaging techniques this finding has been extended to the axon terminals of many zebrafish bipolar-cell types. In these studies bipolar terminals were labeled transgenically with the Ca^{2+} reporter protein SyGCaMP2 and light-induced fluctuations in Ca^{2+} were followed by 2-photon photometry. Fully 65% of the terminals delivered a spiking Ca^{2+} signal (4). In the cb5b bipolar-cell type of ground squirrel retina Na^{+} action potentials are driven by light. Other bipolar types in this retina do not exhibit spiking (5). These results suggest that bipolar cells are responsible for significantly more of the encoding of visual signals than had been previously supposed, and that axon-terminal spiking is actively involved. Impulse generation in bipolar cells is further discussed in the section on *Voltage-gated currents*.

Morphology and connectivity

Anatomical investigations of bipolar cells reveal a multiplicity (4-22 depending on species) of different morphological types (6-12), significantly more than the just two types that early physiology implied. The diversity of human retinal bipolar types is illustrated in Fig. 2. Nonetheless all of these are either ON- or OFF-types and their diversity results from other factors, such as differing connectivity with photoreceptors and differing postsynaptic targets, as evidenced in the diversity of dendritic and axon-terminal ramification patterns. Some bipolar cells are postsynaptic only to rods, others only to cones (Fig. 2), and still others receive mixed rod-

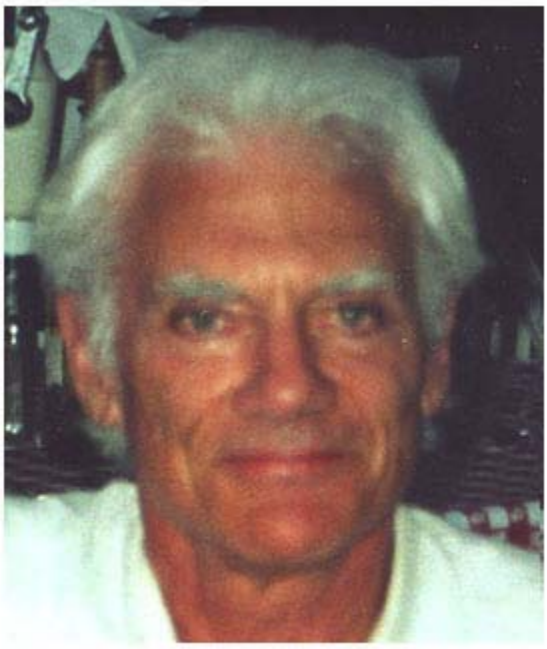
John E. Dowling



Frank Werblin

Frank Werblin and John Dowling discovered the 'ON or OFF' light-evoked physiology of retinal bipolar cells (1). They characterized these neurons as processors of analogue visual signals that did not use impulse generation. The work was done at Johns Hopkins University as a part of Frank Werblin's doctoral dissertation under the John Dowling's mentorship.

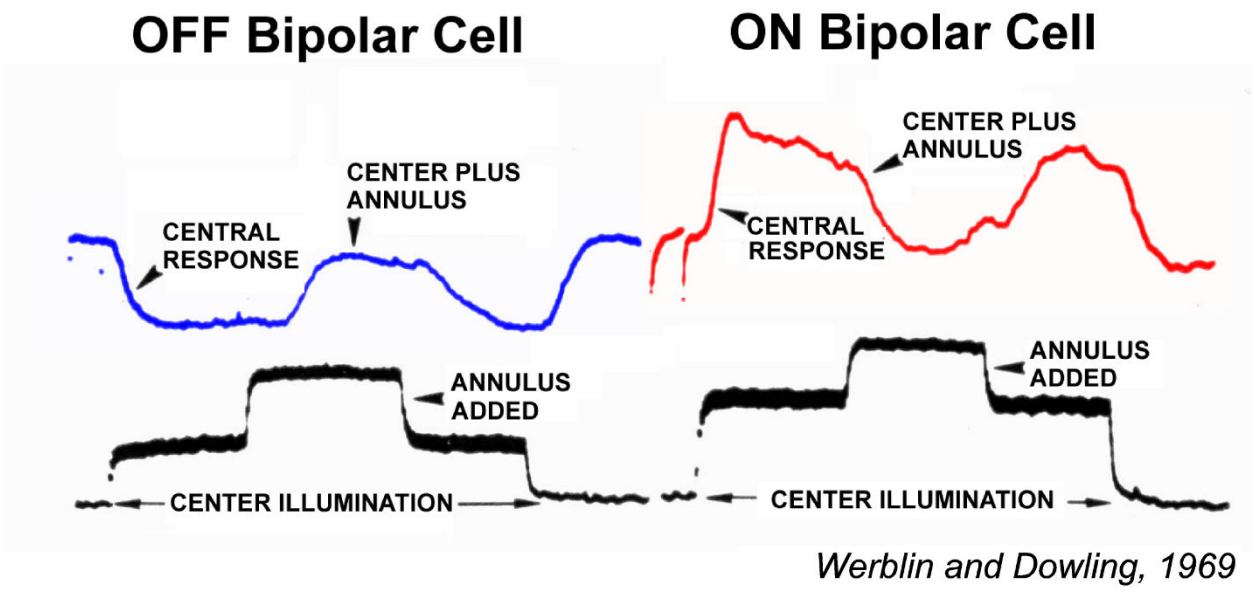


Figure 1. Retinal bipolar cells initiate ON and OFF pathways. Microelectrode recordings of voltage responses from mudpuppy retinal neurons reveal two sorts of retinal bipolar cells: those hyperpolarized by central illumination (OFF Bipolar Cell) and those depolarized by central illumination (ON Bipolar Cell). In each case membrane potential is restored by concomitant illumination of annular rings surrounding the center. Such responses are typically 10 mV in amplitude and lack impulse activity. The absolute response latency to the light step above is about 100 msec for these suprathreshold stimuli. The illustration is taken from Werblin and Dowling, 1969 (1).

cone input. Among cone-selective bipolar cells, some innervate only red, green, or blue cones, while others are 'diffuse', that is, not selective (13-19). Different bipolar types express different glutamate receptors at subsynaptic contacts with cones.

Bipolar cell axon terminals are either mono- or multistratified, depending on the location of axonal boutons and branches in the inner plexiform layer (IPL). Differing terminal position and branching morphology within the IPL suggests that different morphological types selectively innervate different types of amacrine and ganglion cell (Fig 2). In primate retinas, bipolar cells are described as diffuse or midget types, based on the extent of the dendritic arbor. Midgets contact only a single cone, while diffuse types contact multiple cones. Bipolar cells are also termed 'flat' or 'invaginating' (20) depending on the placement of dendritic tips, either on the surface of (flat), or penetrating within photoreceptor synaptic terminals to approach presynaptic ribbons (invaginating). Fig. 2 illustrates 11 morphological types of bipolar cell seen in Golgi-stained human retinas.

2. Different glutamate receptor types for ON and OFF bipolar cells

Light responses in bipolar cells are initiated by synapses with photoreceptors. Photoreceptors release only one neurotransmitter, glutamate (21); yet bipolar cells react to this stimulus with two different responses, ON-center (glutamate hyperpolarization) and OFF-center (glutamate depolarization). Different postsynaptic glutamate receptor proteins mediate these different membrane polarizing mechanisms. The different glutamate-gated responses are associated with the differential expression of either ionotropic (iGluR) glutamate receptors (OFF bipolar cells), metabotropic (mGluR) glutamate receptor types (ON bipolar cells) or glutamate transporters (ON bipolar cells). As a result, signal transduction at the photoreceptor-to-bipolar synapse has a range of properties. The process of splitting images into multiple components tuned to selective visual features begins with differentiation of different photoreceptor types but is then greatly elaborated at the synapses between photoreceptors and bipolar cells.

Metabotropic responses of ON bipolar cells: mGluR6, G_o, TRPM1, Nyctalopin

The conductance of ON bipolar cells increases in the light, whereas OFF bipolar cell conductance decreases (22, 23). The decrease in OFF bipolar cell conductance is easily explained as a loss of excitation by glutamate, as light inhibits glutamate release from photoreceptors (24). The positive reversal potential of the ON bipolar cell light response, coupled with a conductance increase (22, 25), implies that glutamate blocks a cation-permeable channel. Originally a puzzle, this was the first evidence of what we now understand as the action of metabotropic glutamate receptors (mGluRs). These receptors do not form ion channels themselves, but act as isolated antennae on the cell surface sensing glutamate and activating intracellular pathways, ultimately affecting membrane potential through mechanisms several steps removed from the binding site for glutamate. Metabotropic receptors have been identified on the axon terminals of both photoreceptors (26) and bipolar cells (27) where they serve as autoreceptors regulating glutamate release. However, the expression of one specific mGluR in the subsynaptic membrane of ON bipolar cell dendrites, the APB receptor, is unique to retina, where it is used in the direct signal transmission pathway from photoreceptors to ON bipolar cells.

The mGluR6 receptor

Slaughter and Miller (28) were the first to observe that the metabotropic glutamate agonist 2-amino-4-phosphonobutric acid (APB or DL-AP4, with the L enantiomer being effective) completely blocks the light responses of ON bipolar cells. In these neurons, APB acts as a substitute for photoreceptor-released glutamate (Fig. 3AB). Thus, ON bipolar cells utilize a metabotropic pathway to sense light-induced variations in release of photoreceptor glutamate. The metabotropic receptor has been identified as mGluR6 (29, 30). Transgenic

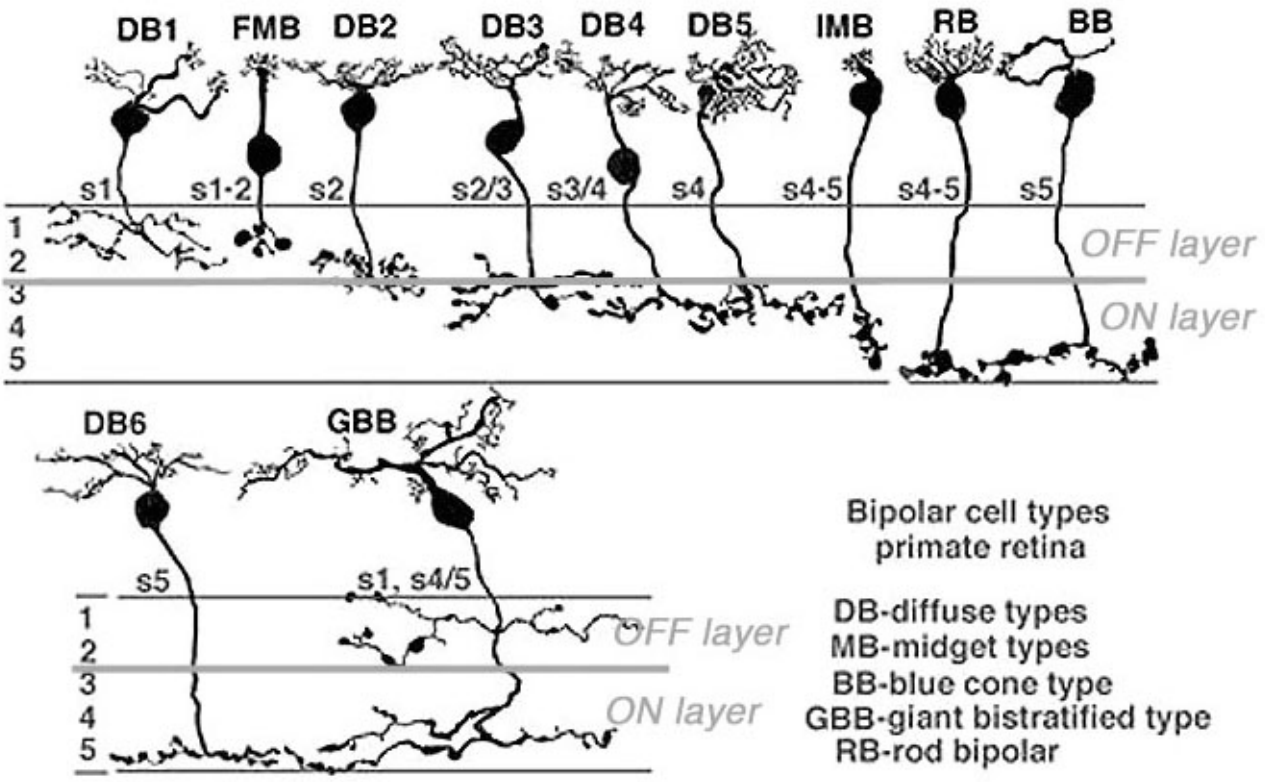

Figure 2. Dendritic and axonal stratification patterns of bipolar cell types in human retina. The illustration is courtesy of Helga Kolb.

knockout mice lacking the mGluR6 gene lack the electroretinographic b-wave (Fig. 4AB), an evoked-potential component associated with ON bipolar activity (31). The relation of electroretinogram components to cellular electrophysiology is further discussed in the Webvision chapter '*The Electroretinogram: ERG*'. Immunocytochemical localization for mGluR6 shows staining in the invaginating dendritic tips of monkey bipolar cells (Fig. 5) (32). Invaginating bipolar cells are thought to be mainly ON types in primate retina. Some foveal flat contacts also stained for mGluR6 (32).

The G-protein G_o

In addition to mGluR6, the G-protein G_o is cytoplasmically localized in the dendritic tips of ON bipolar cells (Fig. 6) (33). Removal of the alpha subunit ($G\alpha_o$) by knockout results in b-wave loss (34), similar to the mGluR6 knockout. G_o was originally localized in rod bipolar cells, known to be ON-type, in a screen of potential G-protein second messengers for the metabotropic light response (35). This suggests that G_o is directly involved in the intracellular pathway following mGluR6 activation.

The ion channel coupled to the APB receptor was originally thought to be cGMP-modulated (36).The closure of ion channels following APB binding onto mGluR6 seemed to require GTP and phosphodiesterase similar to phototransduction (36). However, the exact cascade by which this happened was less clear, as blocking phosphodiesterase (PDE) activity, or adding non-hydrolyzable cGMP analogs, did not inhibit the glutamate responses generated through APB-receptors (37). Further, it was G_o that suppressed glutamate-gated current in ON bipolar cells, not transducin, the G-protein of the phototransduction cascade (37). Thus, removal of cGMP appears not to be required for channel closure (37).

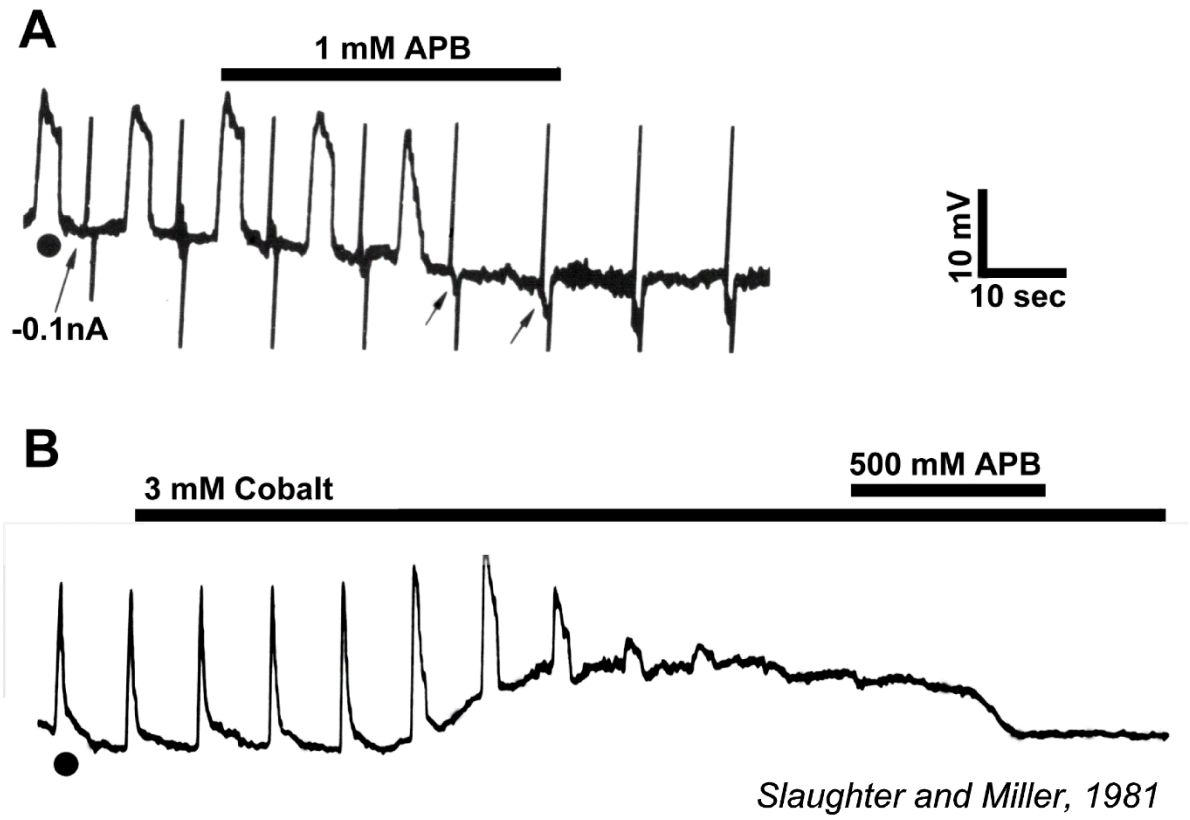

Figure 3. Metabotropic glutamate receptors in the ON pathway. The glutamate agonist 2-Amino-4-Phosphonobutric acid (APB, later termed DL-AP4) interferes with light responses and membrane physiology of ON-center bipolar cells in mudpuppy. *A*. APB abolishes light responses (the rectangular depolarizing events), hyperpolarizes the membrane potential, and increases the membrane resistance. The latter is measured by the amplitude of voltage responses to injected current pulses (arrow). *B*. 3 mM cobalt, a blocker for synaptic release of glutamate from photoreceptors, abolishes light responses in an ON bipolar cell and depolarizes the membrane potential. The membrane potential can be later restored by application of APB, which acts as a substitute for the missing photoreceptor glutamate. As APB is selective for a subset of metabotropic glutamate receptors, synaptic transmission of light responses to ON bipolar cells must rely on a metabotropic mechanism. The illustration is adapted from Slaughter and Miller, 1981 (28).

The TRPM1 channel

In agreement with these findings, recent work suggests the ON-bipolar-cell ion channel downstream of the mGluR6 receptor is not cGMP-gated (38). Rather, this non-selective cation channel – identified as a TRPM1-L channel – appears to be regulated by $G\alpha_o$ (38-40) in conjunction with $G\beta\gamma$ (41). The activity of the TRPM1 channel requires the presence of mGluR6, as the channel, though present, can not be activated in mGluR6 knockout mice (42).

TRP channels, or transient receptor potential channels, first identified in *Drosophila* photoreceptors (43), are present in all animal groups, including vertebrates (44), and as many as 28 channel subtypes have been identified. The TRP superfamily includes 7 subfamilies separated into two groups: TRPC, TRPV, TRPM, TRPN, and TRPA channels form Group 1; TRPP and TRPML channels form Group 2. TRPM1-L or melastatin, a melanoma related TRP channel, belongs to Group 1, and is found in ON bipolar cells. All channels share structural similarities and are permeable to cations; however, there is great functional diversity among the different channel subtypes. TRP channels are involved in many sensory systems including vision, hearing, taste, temperature-sensitivity, and osmoregulation, and are also involved in human disease (44-48).

In retina, TRP channels have been identified on photoreceptors (49), amacrine cells (50, 51), and ON-type bipolar cells. ON-bipolars (Fig. 7A), specifically, are antigenic for TRPM1 channels (52, 53) or TRPM1-L (38, 39,

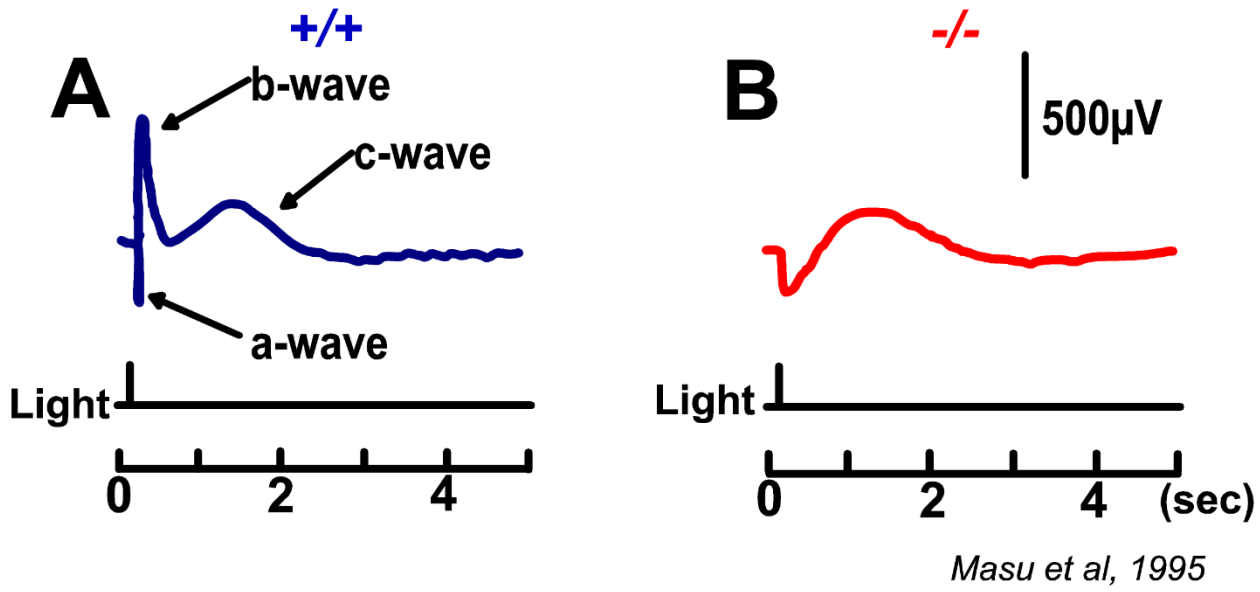

Figure 4. MGluR6 is the metabotropic glutamate receptor expressed by ON bipolar cells. Light evoked ERG responses from the eye of a wild type (*A*, +/+) and a mutant (*B*, -/-) mouse deficient in the gene encoding mGluR6. The b-wave, which originates from the light responses of ON bipolar cells is absent in the mutant mouse. The illustration is adapted from Masu et al, 1995 (31)..

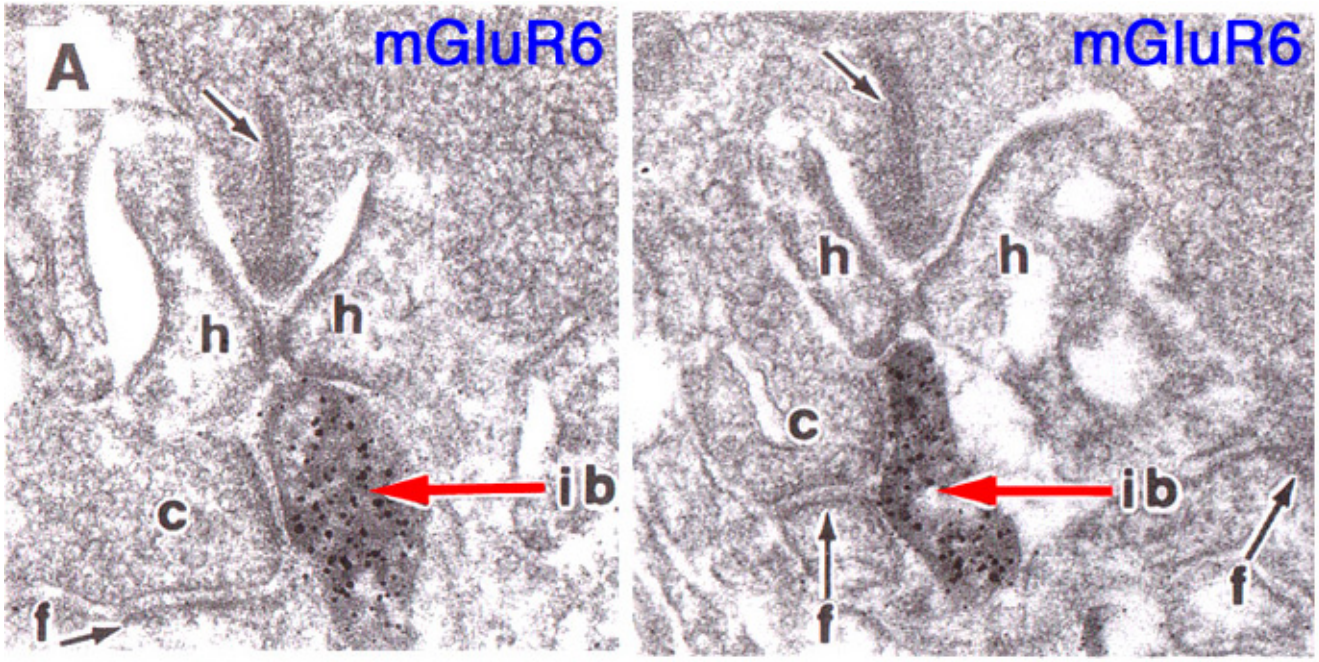

Figure 5. Immunostaining for the metabotropic glutamate receptor mGluR6 selectively labels dendritic tips of invaginating bipolar cells (ib) in monkey retina. The adjacent dendritic contacts from horizontal cells (h) and the flat contact (f) from a flat cone bipolar cell are not labeled, nor is the presynaptic cone pedicle (c).The illustration is from Vardi et al., 1998 (33).

54). Immunocytochemical and/or *in situ* hybridization studies have localized TRPM1 expression to the dendritic tips of ON-bipolar cells (38, 39, 52), though labeling is seen in cell bodies and axons as well (Fig. 7A). TRP channels are absent in OFF-type bipolar cells. TRPM1-L channel currents have a reversal potential ~0mV (38) similar to the reversal potential of glutamate-gated currents in these cells. TRPM1-L has been shown to co-localize with and/or be functionally coupled to mGluR6 (38, 40, 42, 52). In transfected CHO cells that express

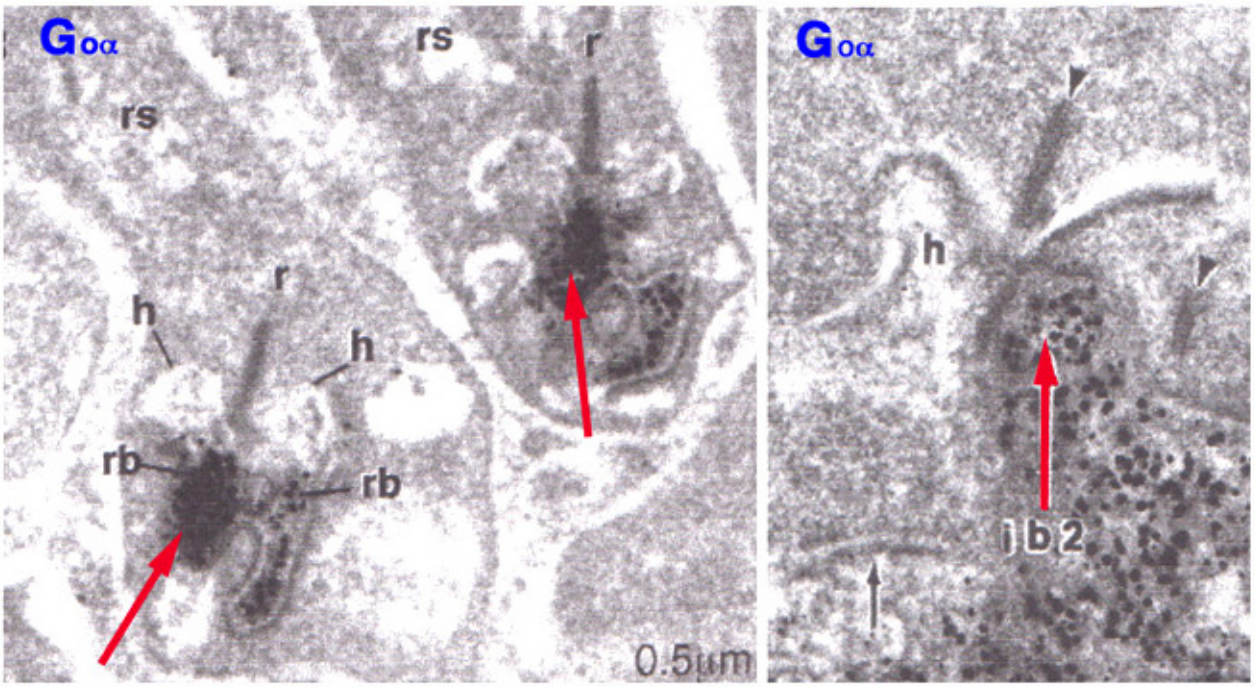

Figure 6. Immunostaining for $G\alpha_o$, the the alpha subunit of the G-protein G_o, localizes to the invaginating dendritic tips of a rod bipolar cell (left) and a cone bipolar cell (right) in cat retina. $G\alpha_o$ is required for light activation of ON bipolar cells. The illustration is from Vardi, 1998 (33).

mGluR6, $G\alpha_o$, and TRPM1-L, Koike and colleagues (38) showed that all three of these components must be present for glutamate-evoked whole-cell currents to be recorded. Cells expressing only mGluR6 and $G\alpha_o$, or only $G\alpha_o$ and TRPM1-L, did not respond to glutamate application (38, 39). These findings suggest TRPM1 channels are downstream of the mGluR6 receptor and are necessary for glutamate-elicited responses in these cells. Further, TRPM1 -/- knockout mice (Fig. 7B) do not have light-evoked ON-bipolar-cell responses and there is no ERG b-wave (38, 39, 55). The loss of response is similar to that reported for mGluR6 -/- mice (Fig. 4) (31, 56), again suggesting that both mGluR6 and TRPM1 channels are required for ON-bipolar-cell photic responses. While all cone bipolar cells in mouse appear to use an mGluR6 synapse with cones, there is evidence that some of these cells may modulate a cation channel in addition to TRPM1-L. In the TRPM1 -/- mouse, the mGluR6 antagonist CPPG still blocks a minor APB-induced membrane current (52).

The proteoglycan nyctalopin

Nyctalopin is another protein expressed on the dendritic tips of ON-bipolar cells (Fig. 8a). It is encoded by the *NYX* gene. *NYX* is required for light- and glutamate-elicited responses in ON bipolar cells (57). Mutant *nob* mice (58) lack an ERG b-wave and are not responsive to focal applications of glutamate onto the bipolar cell dendritic arbor (57). In wild type mice ON bipolar cells respond with outward currents to this treatment, but in *nob* mice they do not (Fig. 9). The *nob* strain is an *NYX* -/- mutant (59). Generation of transgenic *nob* mice selectively expressing EYFP-nyctalopin fusion protein in bipolar cells completely rescued the mutant phenotype. Cellular expression was restricted to bipolar cells using a regulatory sequence for GABAcρ1, a GABA receptor subunit selectively produced by bipolar cells. In the EYFP-*NYX* line, the fusion protein expression was localized to the tips of ON-bipolar cells (Fig. 8a), the b-wave was restored, and inner retinal function was similar to controls (57).

In zebrafish a membrane-targeted yellow fluorescent protein (MYFP) reporter strain has been generated using the upstream regulatory sequences for the *NYX* gene to express MYFP. This reporter marks a subset of ON-type bipolar cells with characteristic long axons and terminal boutons restricted to the inner half of the inner

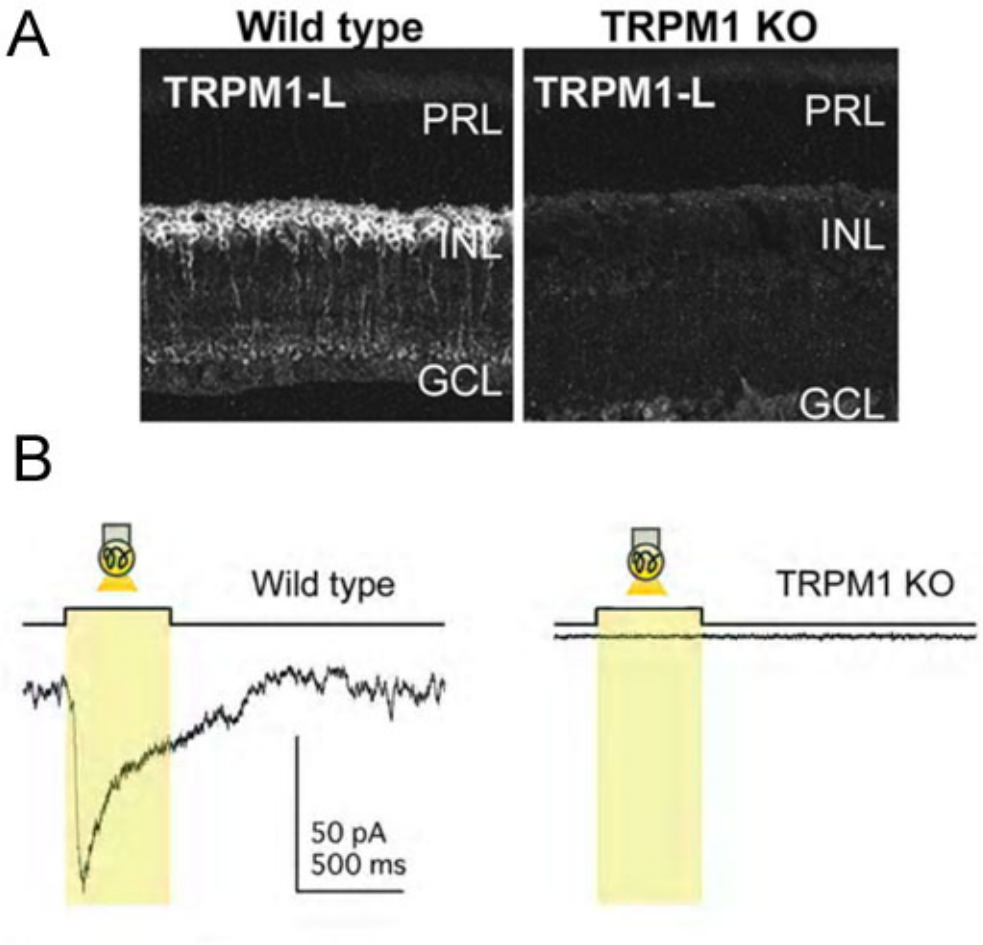

Figure 7. TRPM1 channel knockouts lack photoresponses in ON-bipolar cells. *A*. In a wild type mouse, antibody staining for TRPM1 reveals localization in bipolar cells. No antibody staining is evident in the knockout. *B*. ON-bipolar-cell patch recordings in wild type mice reveal inward currents in response to light stimulation. This is the normal response of an ON-type bipolar cell as these cells are excited by light. No inward currents occur in ON-bipolar-cell recordings from the knockout. The illustrations are from Koike et al, 2010 (38).

plexiform layer. Many of these also express the ON-bipolar marker protein kinase C (PKC) (60). This genetic reporter shows the complete morphology of the cells expressing the nyctalopin gene. This transgenic tool was used to follow embryonic refinement and development of axonal projection patterns for nyctalopin-expressing ON bipolars (60) (Fig. 8b).

Subsequent studies have reported that nyctalopin complexes with both mGluR6 and TRPM1 channels in ON-bipolar cells, serving a structural role that allows proper assembly and organization of the receptor and the channel (61). In addition, nyctalopin is able to modulate TRPM1 channels, as is mGluR6 (42, 62). Thus, glutamate binding onto mGluR6 activates a G-protein ($G\alpha_o$ and/or $G\beta\gamma$) leading to the closure of TRPM1 channels. The receptor and the channel are held in close proximity by nyctalopin. Alteration or mutation of any of these components - mGluR6, nyctalopin, TRPM1, and/or G_o – can lead to a loss of response by ON-bipolar cells. In agreement with this, individuals with congenital stationary night blindness (CSNB – discussed below) display a loss of ON-bipolar cell responses as evidenced in an absent ERG b-wave, and mutations in the genes encoding mGluR6, nyctalpin, and TRPM1 are associated with at least 75% of CSNB cases (62).

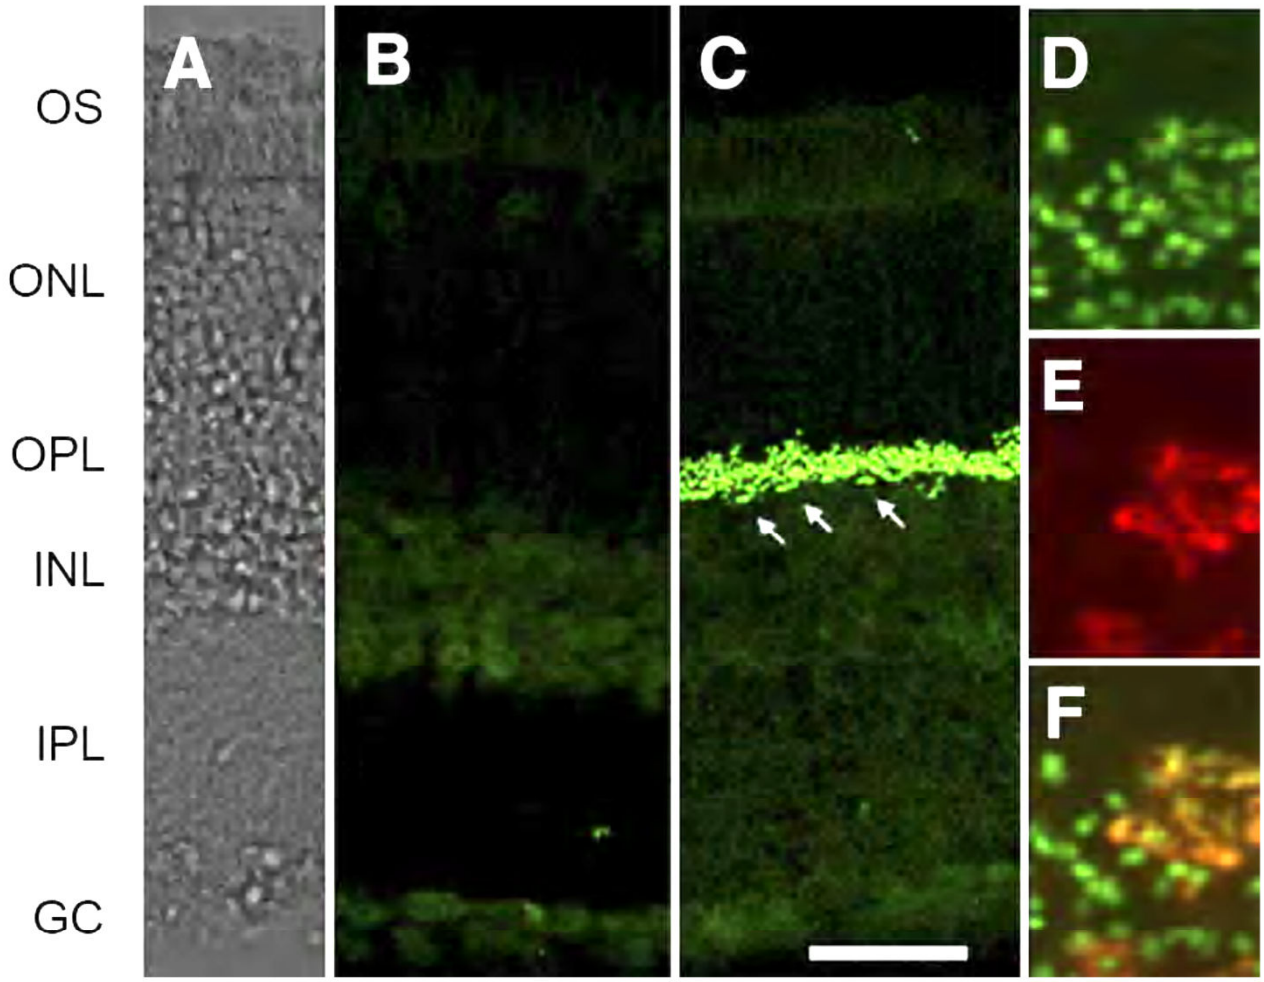

Figure 8a. The insertion of the fusion protein EYFP-nyctalopin into *nob NYX* -/- mice re-establishes nyctalpin expression. Expression can be localized with EYFP antibodies. *A*. DIC image of mouse retinal slice. OS, outer segments; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GC, ganglion cell layer. *B*. High magnification of C. *E*. peanut agglutinin reaction labels cone terminals. *F*. Overlay of D and E shows *NYX* expression (nyctalpin) is localized in cone terminals (yellow). Green localization is presumed in rod terminals. Scale bar in *A*, *B* and *C* is 50 μm. The illustration is from Gregg et al, 2007 (57).

Modulators and subtypes

Calcium ions are a modulator of the ON bipolar metabotropic ion channel. Calcium ions, entering through the TRPM1 ion channel (63, 64) affect channel function, either by directly down regulating the channel (63) or by activating calcium-dependent enzymes, such as CaMKII (65-67), which modulate ion channel conductance. cGMP has been shown to selectively enhance ON bipolar cell responses to dim light, and may play a modulatory role for the TRPM1 channel (68).

Metabotropic receptors for ON-center bipolar cells have sustained and transient subtypes (69). The molecular basis is not yet known. However, it appears that the sustained and transient responses of ON-center ganglion cells, such as the classic X- and Y-types (70), may have their origin, at least in part, in the type of glutamate receptor expressed on the bipolar cells which innervate them (71).

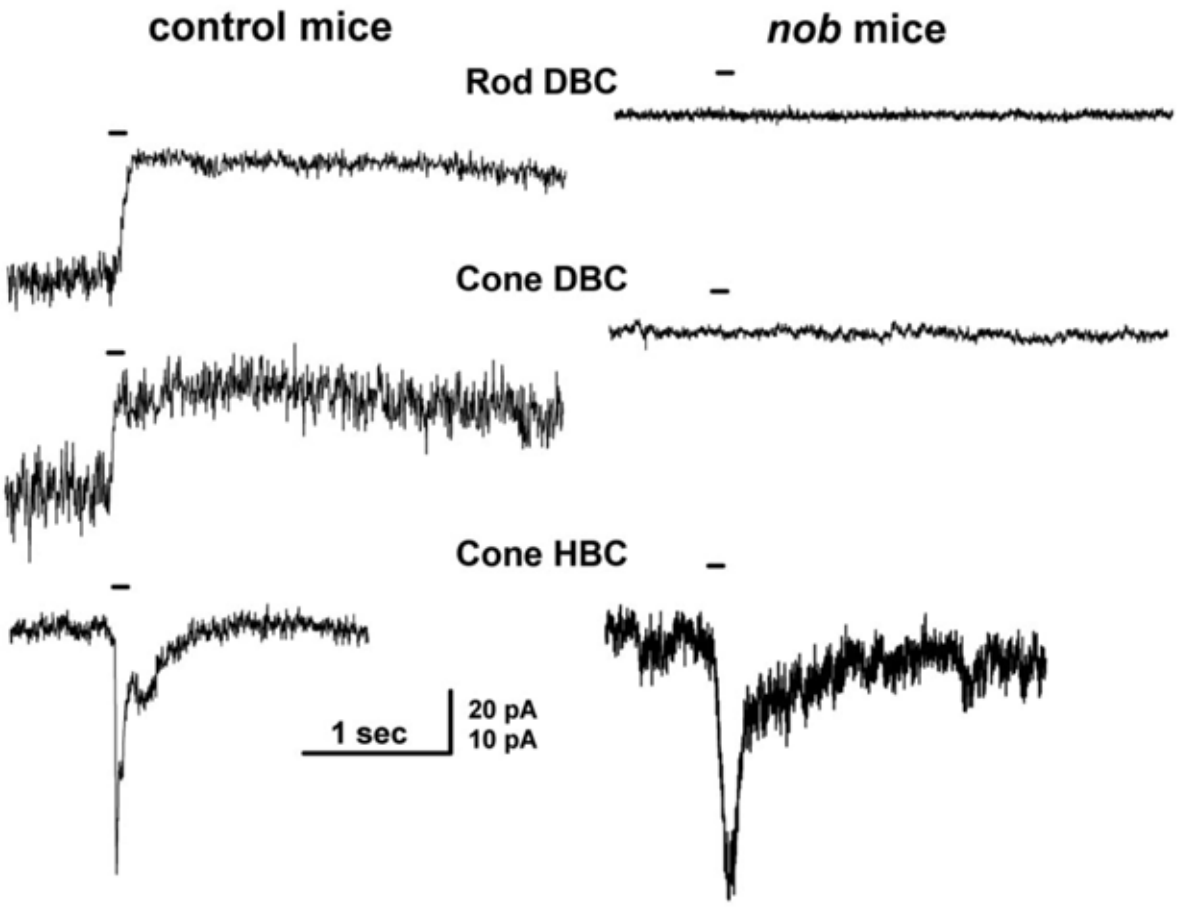

Figure 9. Bipolar-cell glutamate responses in the *nob* (nyctalopin) knockout mouse. Patch recordings of glutamate-responses reveal outward, metobotropic glutamate, currents in both rod bipolar cells and ON-type cone bipolar cells (DBC) in control mice. No glutamate currents are recorded for these cell types in *nob* mice. OFF cone bipolar cells (HBC) respond with inward AMPA/kainate currents in both control and *nob* mice. The holding potential was -60 mV. Glutamate puffs are 100 msec from pipettes filled with 1-5mM glutamate. The illustration is from Gregg et al, 2007 (57).

Glutamate transporter mediated responses of ON bipolar cells

Ionotropic glutamate receptors with transporter-like properties are also present on some ON-center bipolar-cell dendrites. When photoreceptor glutamate binds to these transporters, a Cl^- conductance forms and hyperpolarizes the cells in the dark (Fig. 10). Release from this Cl^- inhibition occurs in the light with the decrease in glutamate released from photoreceptors. This allows the bipolar cells to depolarize (Fig. 10). Like transporters, this glutamate-gated Cl^- mechanism requires $[Na^+]_o$ in order to function. Thus far this mechanism has been found as a dendritic glutamate 'receptor' only in cyprinid ON bipolar cells (72-74), though it is reported in turtle, salamander and mouse photoreceptors (75-78) and is also present in mammalian central nervous system (79). Interestingly it occurs on the axon terminals of mouse rod and cone bipolar cells, where it acts to regulate glutamate release through inhibitory feedback (78).

Some non-mammalian bipolar cells contain both the APB and the ionotropic (transporter-like) receptor on their dendrites, while other ON-cells express either the metabotropic or the ionotropic receptor but not both (72, 73). EAAT5 has been identified as the chloride-channel-forming glutamate transporter (80). The ionotropic mechanism is used for sustained transmission between cones and bipolar cells (81, 82), and is likely to be a fast

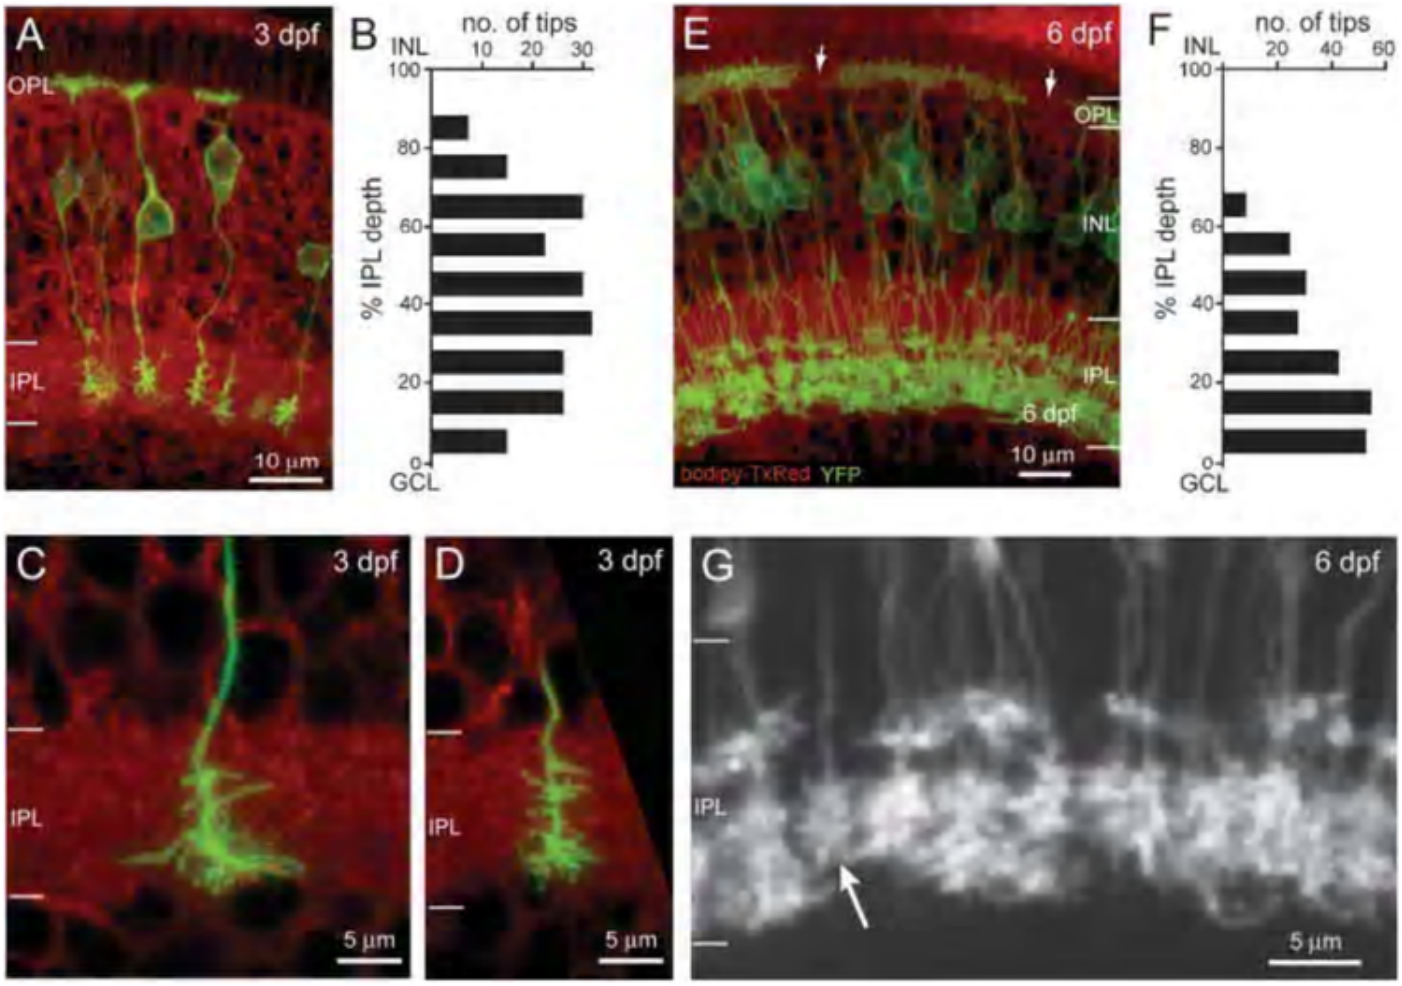

Figure 8b. Morphology of zebrafish retinal neurons expressing nyctalopin. The transgenic strain contains an MYFP gene driven by the regulatory sequence for *NYX* (nyctalopin). *A-D* retinas from 3-day post fertilization (3 dpf) larvae show only bipolar cells, with a broad distribution of axonal filopodia within the inner plexiform layer (IPL). *E-G*. By 6 dpf the filopdial pattern of bipolar cell axons is restricted to the inner half of the IPL, a characteristic of ON bipolar morphology. The illustration is from Schroeter, Wong and Gregg, 2006 (60).

mechanism as compared to metabotropic pathways, which involve multi-step intracellular pathways and are often relatively slow (22).

The classic Mb rod bipolar cell of fish makes synapses with both rods and cones. The rod synapse mediates a conductance increase with reversal potential positive to resting potential. The cone synapse mediates a conductance decrease with reversal potential negative to the resting potential (82). Both mechanisms provide ON-type photic responses. In retrospect it would appear that the rod synapse is metabotropic, while the cone synapse is transporter-like, two different, selectively directed post-synaptic glutamate mechanisms on the same neuron.

AMPA kainate receptor expression in ON bipolar cells

ON-center bipolar cells of mammals are immunoreactive for ionotropic AMPA receptors as well as metabotropic mGluR6 receptors (83-85). In figure 11 (left panel) and figure 12 (right panel) immunoreactivity for GluR1 and GluR2/3, ionotropic AMPA subunits, appeas at invaginating, ON-type ribbon contacts in cat. Similarly in teleost retinas, ON-center bipolar cells are immunoreactive for ionotropic kainate receptors (86, 87). Particularly in mammals, no physiological role has been suggested for these conventional ionotropic receptors, usually

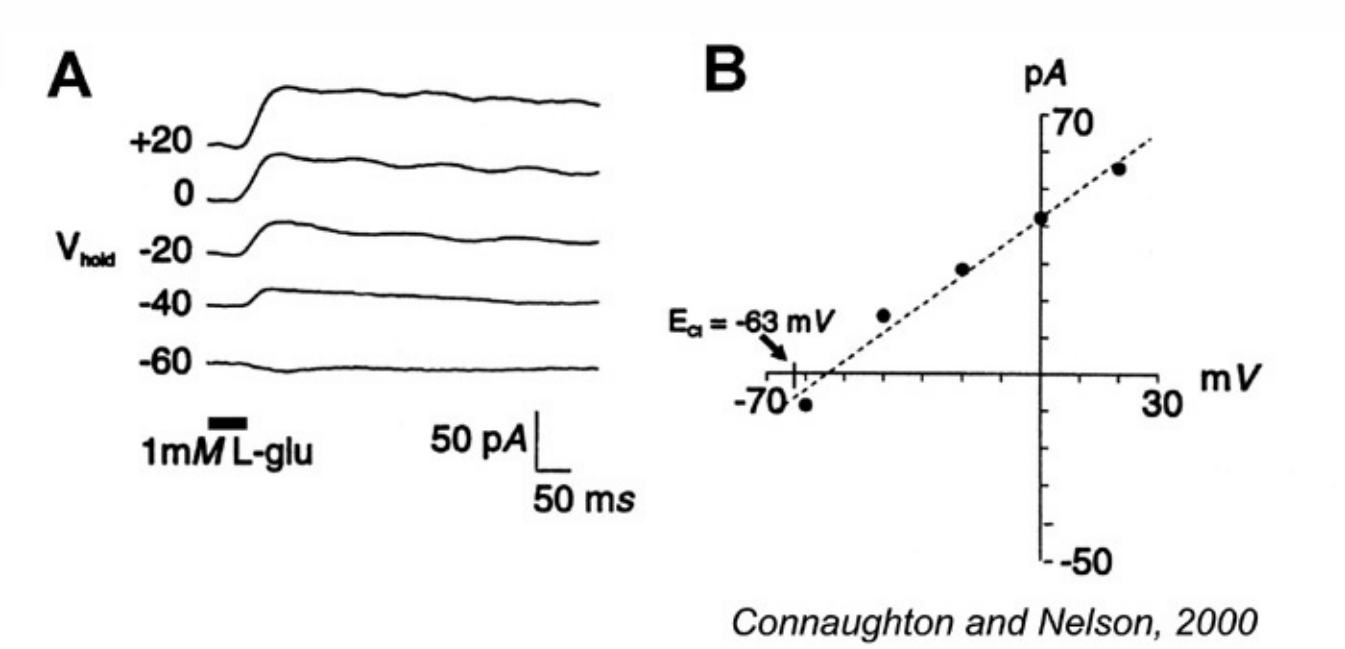

Figure 10. An alternate ON-bipolar synaptic mechanism is a glutamate-activated-chloride channel. Puffs of glutamate mimic photoreceptor dark release in patch recordings from bipolar cells in a zebrafish retinal slice. *A*. Glutamate-evoked currents are outwards for physiological ranges of membrane potential, which are positive to ECl (Cl^- reversal potential). They are inwards at more negative potentials. The results are consistent with an ON-center mechanism driven by changes in Cl^- conductance. *B*. The –63 mV reversal potential is consistent with a model where photoreceptor glutamate opens Cl^- channels. Glutamate gated Cl^- currents are called I_{glu} (73) and result from the binding of glutamate to excitatory amino acid (EAAT) transporters. The illustration is from Connaughton and Nelson, 2000 (72).

associated with OFF bipolar cells, but also seen in ON-center bipolar cells. In giant danio Wong and Dowling find that bistratified cone bipolar cells mix ON-type and OFF-type glutamate receptor mechanisms, and utilize both transporter-like receptors and AMPA/kainate receptors in generating ON and OFF color responses respectively to different spectral stimuli (88).

Ionotropic glutamate responses of OFF bipolar cells

Like ON bipolar cells, OFF bipolar cells express more than one type of glutamate receptor, though all are ionotropic. There are three principal types of ionotropic glutamate receptors (AMPA, kainate, and NMDA) as originally defined by agonist selectivity. Though immunocytochemical studies (84, 89, 90) and in situ hybridization (91) have identified specific NMDA receptor subunits in the outer retina, OFF bipolar cells have never been observed to utilize NMDA receptors in the generation of light responses. OFF bipolar cells selectively express either AMPA or kainate receptors (92, 93). AMPA receptor subunit GluR1 immunoreactivity is found at the 'flat' contacts between OFF- bipolar-cell dendrites and cones (Fig. 11, left and right). Kainate receptor subunit GluR6/7 immunoreactivity is also found at these flat contacts (Fig. 12, left). AMPA and kainate receptors resensitize at different rates after exposure to glutamate (Fig. 13), and as a result, emphasize different temporal characteristics of the light signal. Kainate-type glutamate receptors transfer the sustained characteristics of the visual stimulus. AMPA receptors are more selective for the transient components of the signal (92). In ground squirrel retina bipolar cells are selective for one or the other (93). The situation is interesting in so far as neurons using kainate receptors exclusively are rare in the central nervous system. Nonetheless, AMPA and kainate receptors on retinal bipolar cells are pharmacologically well-behaved. Bipolar-cell AMPA-type responses can be selectively suppressed by the lipophilic AMPA receptor antagonist GYKI 52466 (94). Conversely, bipolar-cell kainate-type responses are blocked by the desensitizing kainate receptor agonist SYM 2081 (95).

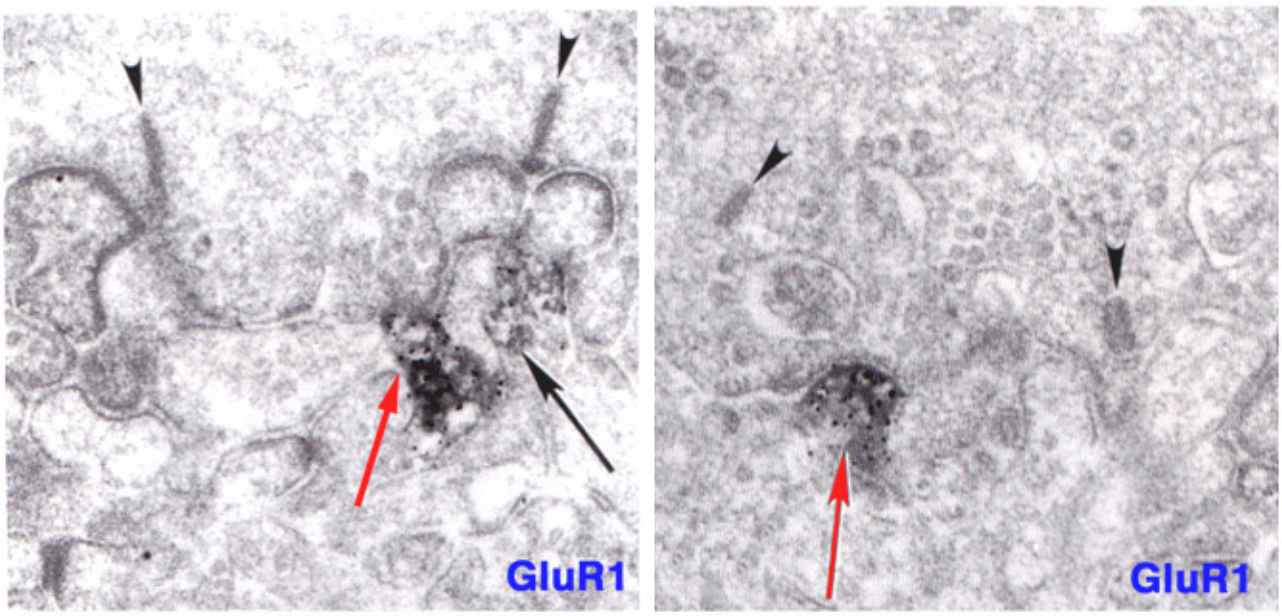

Figure 11. Immunostaining for the ionotropic glutamate receptor GluR1 in bipolar cell dendrites contacting cone pedicles in cat retina. Red arrows point to flat contacts, the black arrow points to an invaginating contact, and the arrowheads point to synaptic ribbons in the cone pedicle. The illustration is from Qin and Pourcho, 1999 (261).

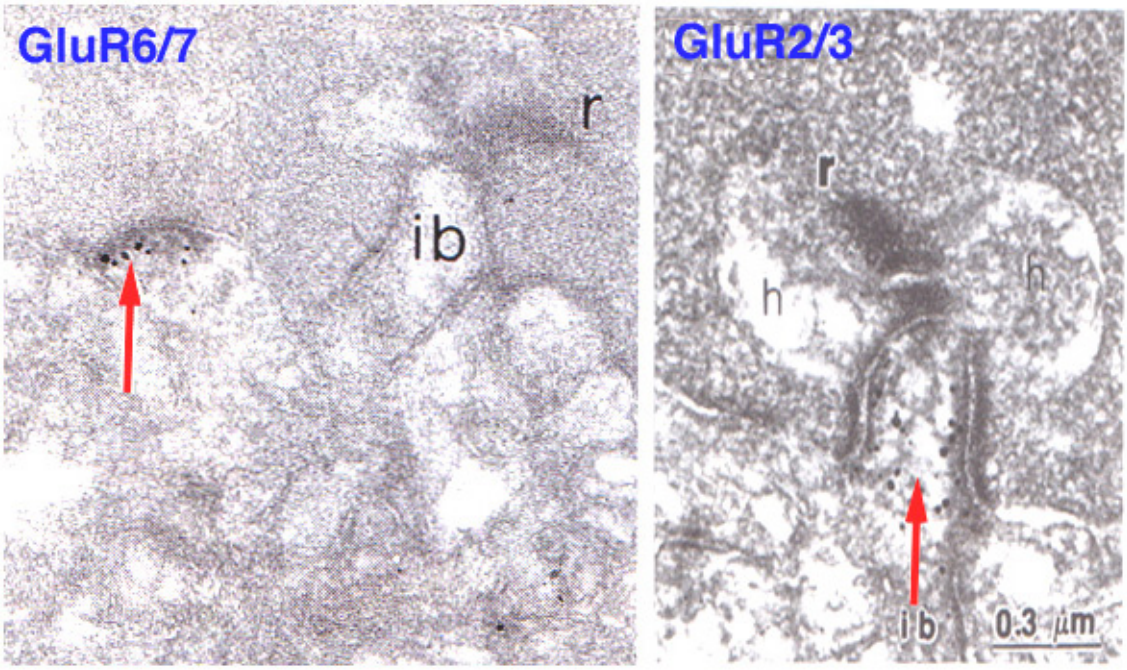

Figure 12. Immunostaining for ionotropic glutamate receptors in the dendritic tips of cat bipolar cells. GluR6/7 subunits are found in kainate receptors. GluR2/3 subunits are found in AMPA receptors. The red arrow (left, GluR6/7) points to a immuno-stained flat contact. The red arrow (right, GluR2/3) points to an immuno-stained invaginating contact. Letter labels are invaginating bipolar (ib), horizontal cell lateral element (h), and rod (r). The illustration is from Vardi et al., 1998 (83). .

While all retinas contain ON and OFF bipolar cell pathways, it is easy to imagine that among these pathways natural selection might cause a divergence in the expression of dendritic glutamate receptor types depending on the visual requirements of the species. In agreement with this hypothesis, species-specific differences between ON and OFF bipolar cell dendritic glutamate responses have been found. For example, ionotropic glutamate

channels with transporter-like pharmacology occur exclusively in ON type bipolar cells in fish retinas. Conversely in salamander, OFF bipolar cells utilize only AMPA receptors (96). This may also be the case in zebrafish retina where dissociated cells fail to respond to the kainate agonist SYM 2081 (86) and electroretinographic OFF responses (d-waves) are blocked by the AMPA antagonist GYKI 52466 (97). One might expect also that even within the broad classes of AMPA and kainate receptors, subforms may have evolved to fit particular visual niches. In salamander retina indeed, there are separate classes of AMPA receptors postsynaptic to rods and to cones (96, 98).

3. Bipolar-cell axons: ON and OFF lamination in the inner plexiform layer

In work performed at the National Institutes of Health in the mid 1970s (99, 100), it was noted that the ON or OFF property of cat retinal ganglion cells was related to the level of stratification of dendrites within the retinal inner plexiform layer. This led to a general scheme for ON and OFF layering illustrated in figure 14. The dendrites of OFF-center ganglion cells always arborize distal to the dendrites of ON-center ganglion cells. The zone of OFF-center dendritic arborization is called sublamina *a*, while the zone of ON-center dendritic arborization is called sublamina *b* (Fig. 14). Within each sublamina ganglion cells make selective contacts with ON- or OFF-type bipolar cells. The pattern of ON and OFF layering of bipolar cell synaptic terminals and ganglion cell dendrites has proved to be a consistent pattern among all vertebrate retinas examined (101, 102). ON and OFF layering is particularly pronounced in retinas where ganglion cell types are predominantly monostratified. However, in more anatomically complex retinas, (i.e., turtle) with multistratified and/or diffusely stratified ganglion cell types, the ON vs. OFF layering pattern applies to monostratified cells only. The physiology of cells with processes ramifying throughout the IPL is more difficult to predict based on morphology alone (103).

Stratification of cone bipolar cell axon terminals

The axon terminals of ON and OFF bipolar cells ramify in distinct IPL layers, where they are presynaptic to ON- and OFF-type ganglion cells, respectively. The axon terminal arborizations of OFF-type cone-contacting bipolar cells lie in sublamina a, where they synapse with the dendrites of OFF-type ganglion cells, while the axon terminal arborizations of ON-type cone contacting bipolar cells lie in sublamina b, where they contact the dendrites of ON-center ganglion cells. Synapses between OFF-type bipolar terminals and ganglion cell dendrites in sublamina a, and ON-type cells in sublamina b, have been observed electron-microscopically (104-109). Synapses between pairs of bipolar and ganglion cells with mismatched response polarity were never observed, even where processes come in close proximity (105). Melanopsin ganglion cells may provide an exception to this rule. The outer stratifying melanopsin ganglion cells of mouse and primate receive synapses from ON-cone bipolar cell axons en passant (110, 111).

Awatramani and Slaughter (69) proposed a further refinement of the bipolar-cell stratification scheme: cells with a glutamate receptor physiology emphasizing transients in the visual pattern are layered more toward the center of the IPL, while those with glutamate receptor patterns emphasizing sustained contrast are layered more towards IPL inner and outer edges. Although based in salamander retina, such a pattern would be appropriate to the layering of the sustained X (IPL inner and outer edge) and transient Y type ganglion cells of the cat retina (central IPL), as well as P and M cells of the primate retina. Wu et al (11) find a similar pattern in salamander, but attribute it to an elaboration of other circuitry elements, as bipolar cells with arbors in the mid-IPL tend to be cone dominated, emphasizing speed and transient response, whereas bipolar cells with axon terminals stratified at the inner and outer edges of the IPL process rod signals, which are relatively more lethargic in wave form (11).

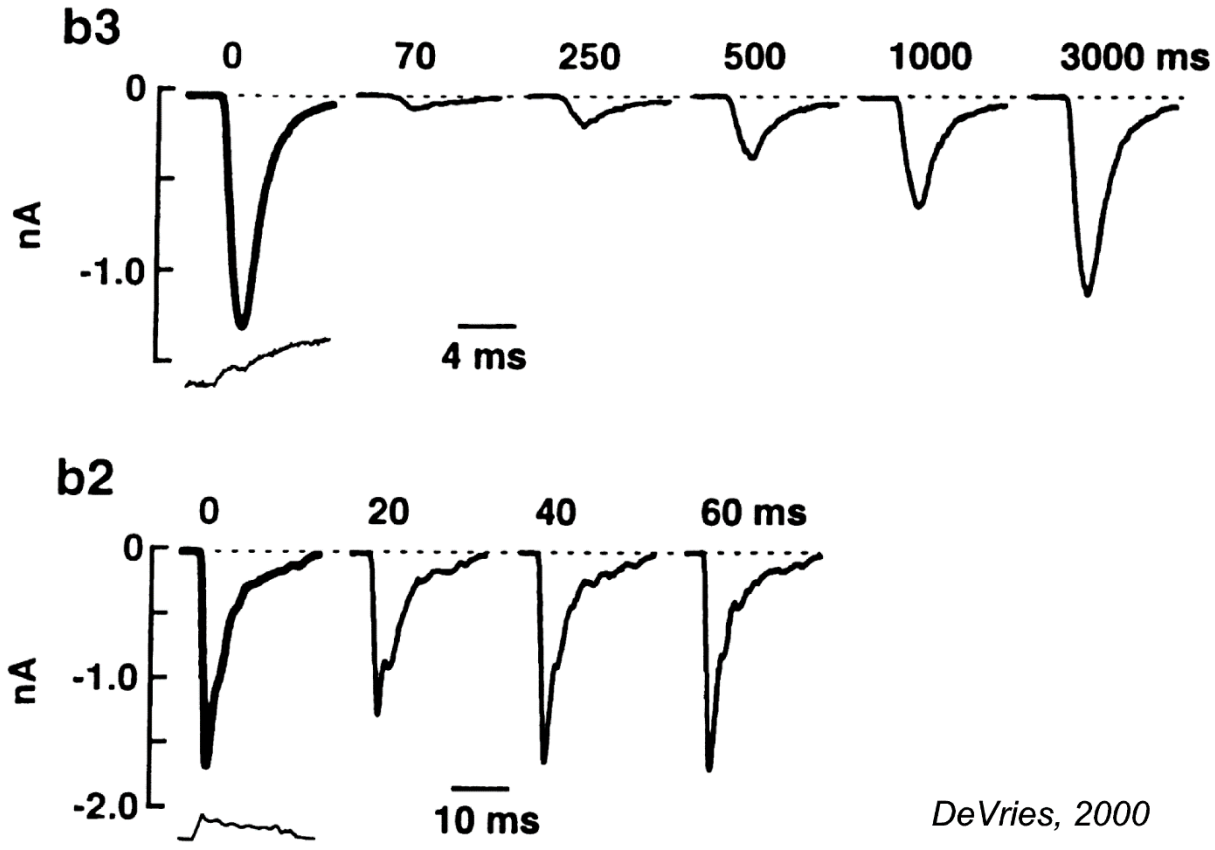

Figure 13. Different OFF bipolar cells re-sensitize at different rates after glutamate treatment. In whole cell patch recordings from ground squirrel retina, bipolar cells b3 and b2 are desensitized by an initial glutamate pulse ('0'). The time course of recovery is measured by responses to a second pulse after different delays. Type b3 (Fig. 16) bipolar cells utilize kainate-type glutamate receptors and require several seconds for complete recovery. Type b2 bipolar cells (Fig. 16) utilize AMPA-type glutamate receptors and recover 100 times faster. The illustration is from DeVries, 2000 (92, 93)..

Exhaustive correlations of ON or OFF bipolar cell physiology with axonal stratification patterns are now available for several species. Light responses or, as a surrogate for light responses, either dendritic glutamate responses, or responses to electrical stimulation of individual cones, can be measured in patch microelectrode recordings in retinal slice. Electrophysiological findings are correlated with axonal and dendritic morphology through microelectrode staining.

Salamander

In salamander retina Pang, Gao and Wu (2004) (112) separated bipolar-cell light-evoked responses into cationic currents originating from glutamatergic synapses with photoreceptors, and chloride currents originating with GABAergic or glycinergic synapses with amacrine cells. The polarity of light-evoked cationic currents (ΔI_C) correlated perfectly with axonal branching levels in the inner plexiform layer. Salamander bipolar cell types 1-5, with axonal stratification in the outer half of the inner plexiform layer (sublamina *a*), were OFF types, giving outward ΔI_C. Types 6-10, with axonal stratification in the inner half of the inner plexiform layer (sublamina *b*), were ON-types, giving inward ΔI_C (Fig. 15). The cationic synaptic currents were isolated from inhibitory chloride currents by clamping the cells at chloride reversal potential (V_m = −60 mV). Light evoked inhibitory chloride currents (ΔI_{Cl}) were examined by clamping the cells at cationic reversal potential (V_m = 0 mV). Both ON and OFF bipolar cells were inhibited by chloride currents, most likely generated by glycinergic and GABAergic synapses from amacrine cells onto bipolar cell axon terminals (Fig. 21, Fig. 22). One inhibitory

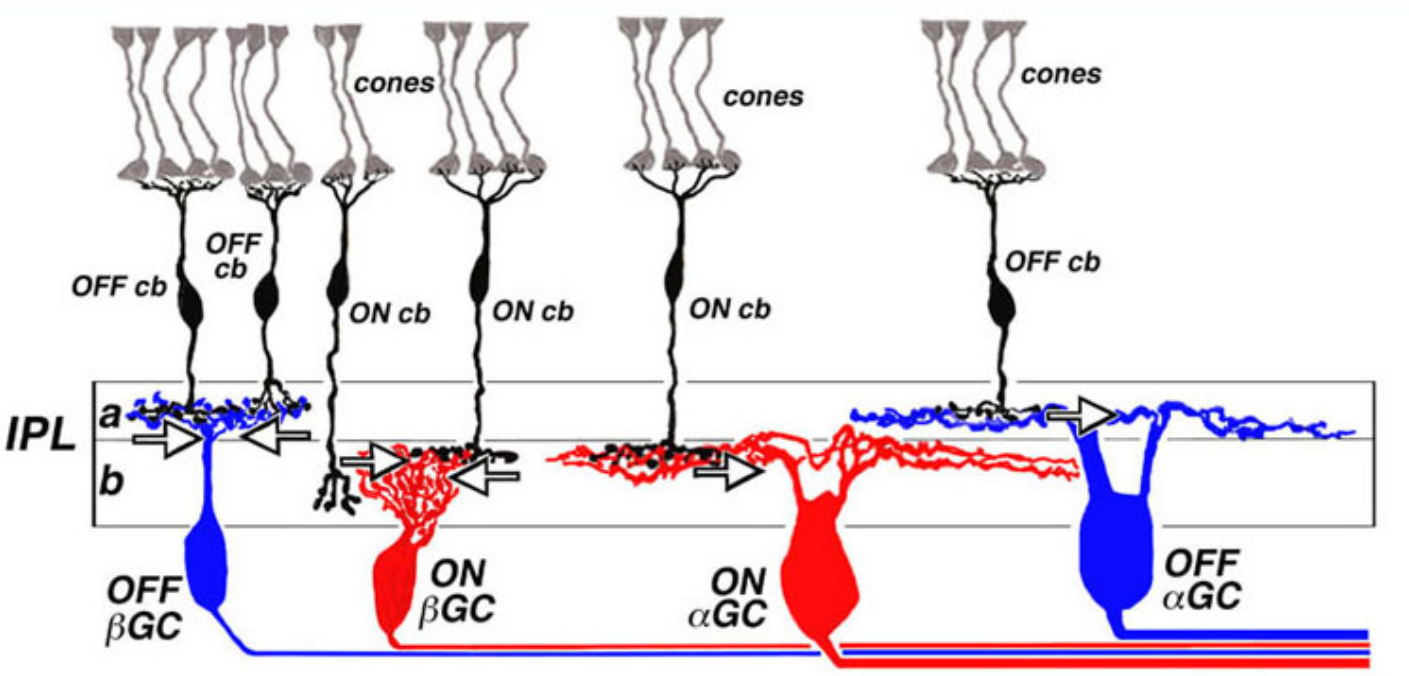

Figure 14. Layering of ON and OFF bipolar cell axons in the cat inner plexiform layer (IPL). OFF ganglion cell (*αGC* and *βGC*) dendrites and OFF cone bipolar cell axons (*OFF cb*) co-stratify in sublamina *a* of the IPL. ON bipolar axons (O*N cb*) and ON ganglion cell dendrites co-stratify in sublamina *b* of the IPL. These are the parallel ON and OFF cone pathways that originate with bipolar-cell dendritic contacts with cones. The illustration is modified from Nelson et al, 1978 (100)..

pattern was ON-sustained, while the other was ON/OFF. In addition to bipolar cells with highly stratified axon terminals (Fig. 15) others with broader stratification or even bistratification were encountered, giving a total of 22 morphological types (12). These latter types also followed the ON-OFF stratification rule, except for the types that were bistratified in both sublaminae, the a/b types. These could be either ON or OFF, but often a dual ON and OFF dendritic input could be dissected with pharmacological treatments (112).

Rod-dominated mammals

In rat retina, bipolar cell axon terminal arborization appears to obey perfectly the rule of ON and OFF layering (7). As judged by the level of axonal stratification, there are 9 bipolar types. The axons of cone bipolar cells 1-5 branch in the outer half of rat IPL (sublamina *a*). These cells responded with inward currents when stimulated with kainate, an agonist for AMPA/kainate receptors on the dendrites of OFF bipolar cells. Of a combined 15 recordings from types 1-5, only one cell responded to APB (DL AP-4), a glutamate agonist selective for ON center bipolar cells. Four cone bipolar cell types (types 6-9) with axons branching in the inner half of rat IPL (sublamina *b*) were identified. In net 12 of 14 of cells of these types responded with outward currents to APB, whereas only one responded to kainate (7). This is a better than 90% compliance with the ON and OFF stratification pattern for cone bipolar cell axon terminals in rat retina. Bipolar cell branching patterns in mouse retina appear similar to rat (113). A more limited set of recordings in cat and monkey retinas suggest also that there may be good adherence to ON and OFF stratification of bipolar terminals (109, 114).

Ground squirrel

Li and DeVries (15) have provided a significant technical advance in the mapping of form onto function for biplolar cells of the all-cone retina of ground squirrel. In these studies one patch electrode was used to electrically stimulate an individual cone within the dendritic arbor of a bipolar cell simultaneously patched and

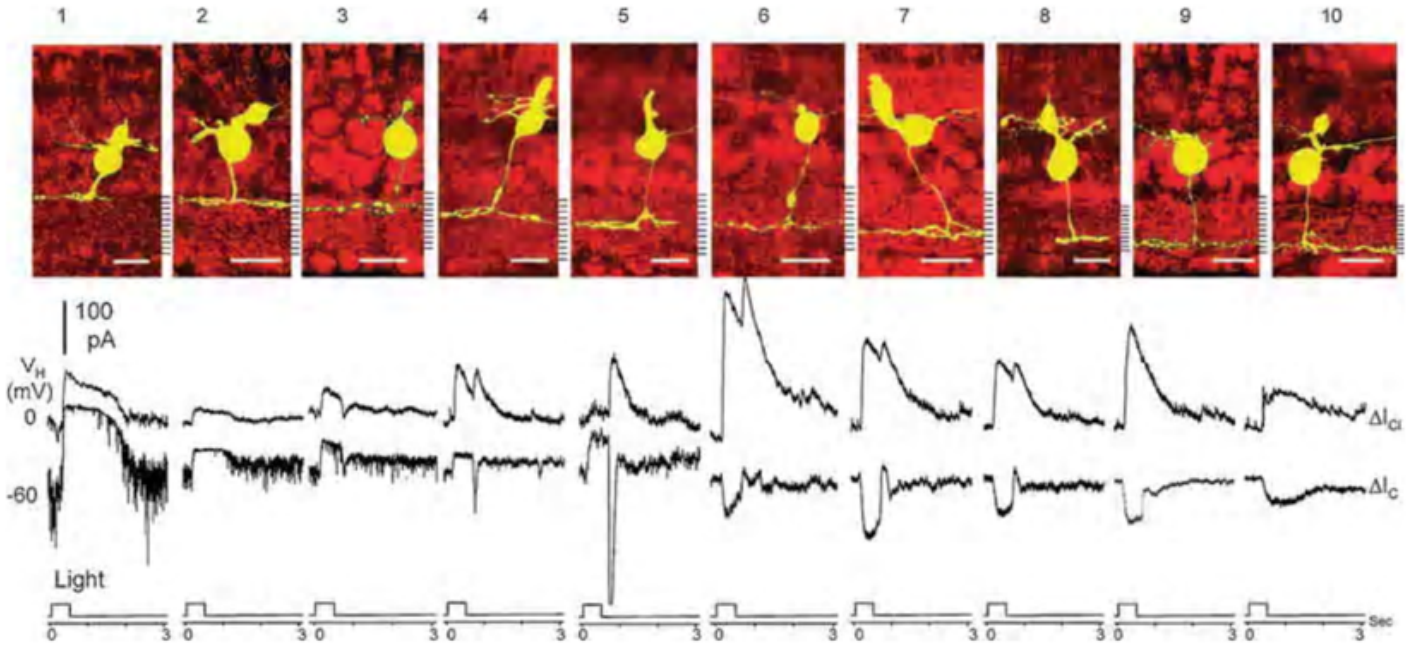

Figure 15. Functional stratification of bipolar-cell axon terminals in salamander retina. Types 1-5 are OFF bipolar cells with axonal branching in the outer half of the inner plexiform layer (IPL sublamina *a*). The light-evoked cationic currents (ΔI_C), obtained at a holding voltage (V_H) of -60 mV, are all outward, characteristic of dendritic AMPA receptors. Types 6-10 are all ON bipolar cells with axonal branching in the inner half of the inner plexiform layer (IPL sublamina *b*). The light-evoked cationic currents are all inward, characterisitic of dendritic mGluR6 receptors. Inhibitory chloride currents (ΔI_{Cl}) are seen at the cationic reversal potential ($V_H = 0$). These are either sustained ON, or transient ON/OFF. Inhibitory currents arise mainly from amacrine cells. The illustration is from Pang et al, 2004 (112).

stained by a second microelectrode. In this way both the cone contacts and the nature of these contacts onto bipolar cells are directly verified. Six cone bipolar types have been mapped by this technique, one ON type contacting only blue cones, an ON and an OFF type contacting both blue and green cones, and remaining types contacting only green cones (Fig. 16). No color opponent cone synaptic inputs using different glutamate receptors were detected in ground squirrel bipolar cells. The lamination patterns for ON and OFF types follows that proposed for rod-dominated mammalian retinas (100, 115).

Cyprinids

In anatomical studies using a technique called 'diolistic labeling', Connaughton et al (2004) (6) distinguished 17 bipolar-cell types in zebrafish based on axonal stratification patterns. In work still in progress in the Dowling laboratory, cone contact patterns have been added to axonal stratification patterns (116, 117), resulting in perhaps 20 or more bipolar types that can be anatomically distinguished. However, in the latter studies 90% of the examples are accounted for by as few as 9 of these types. There are 5 exclusively cone-contacting groups that are distinguished by the pattern of cones contacted and by axonal stratification. There are 4 types that contact rods in addition to various cone groupings (Mb types). The most selective cone-contacting type contacts only green-cones. It is very wide in dendritic and axonal field and is OFF-stratified. The most diffuse pattern of photoreceptor contacts is an OFF stratified type that contacts all photoreceptors, rods, red, blue, green, and UV cones. In mammals it appears that all the dendritic contacts emanating from a single bipolar cell express the same glutamate receptor (15). This appears not to be the case in fish or amphibian bipolar cells, where the same cell may express different glutamate receptors at different dendritic tips (72, 82, 88, 112), with each receptor type segregating according to the photoreceptor type contacted (82, 88).

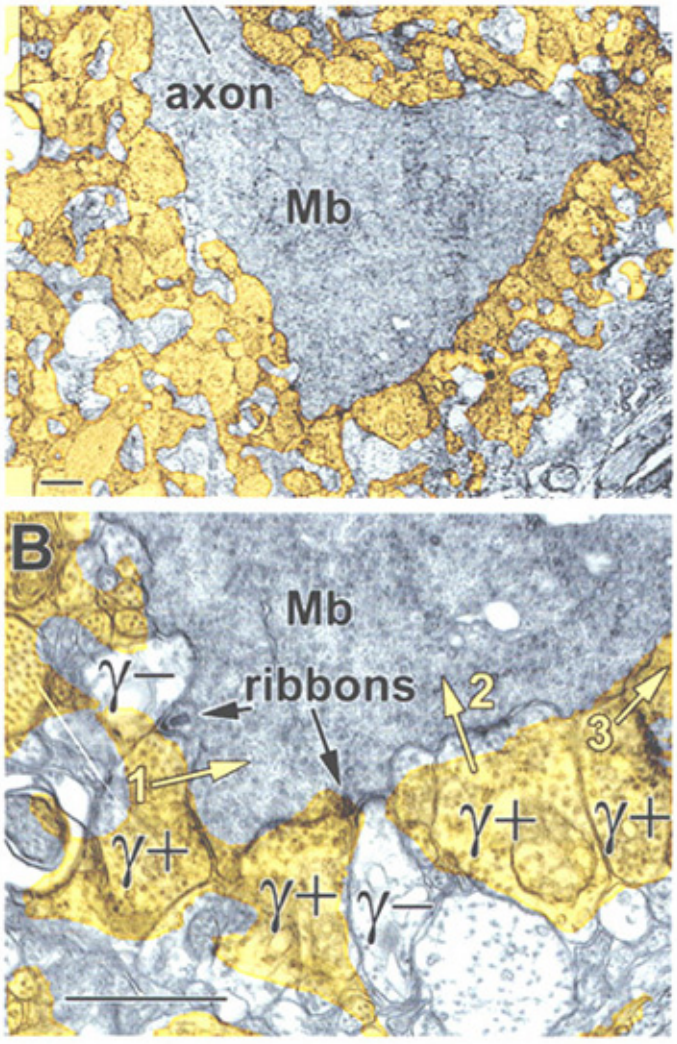

Figure 21. Immunostaining for the inhibitory neurotransmitter GABA (γ^+) in goldfish retina shows dense innervation of type Mb bipolar axon terminals. The yellow image for light-microsocpic immunostaining (yellow) is superimposed upon the electron micrograph image of an Mb (ON-type mixed rod/cone bipolar) axon terminal. The illustration is from Marc and Liu, 2000 (168).

Glutamate responses of zebrafish bipolar cells with axonal boutons in sublamina a (Group a) and sublamina b (Group b) are summarized in Fig. 17. Bipolar cells with 1 or 2 terminal boutons restricted either to sublamina a or to sublamina b obey the ON and OFF stratification rule. OFF cells branching in sublamina a express AMPA/KA type receptors. ON cells branching in sublamina b express either or both of two inhibitory glutamate mechanisms, ionotropic (I_{glu}, transporter-like chloride current) or metabotropic (APB receptor).

Carp retina (115, 118) also exhibits a bisublaminar organization of bipolar-cell terminals.

Bistratified axon terminals

Bisublaminar orderliness breaks down to some extent in species where multistratified bipolar cell axons are common. While multistratified cells exist in mammals like monkeys, cats, and squirrels (10, 15, 119, 120) (Fig. 2-GBB; Fig. 16 b3), these types are much more common in birds, reptiles, amphibians and fishes. Multistratified types selectively contact cones (19, 120) and so may be characteristic of cone-dominated species. If broad or multistratified bipolar terminals are restricted to either the ON or the OFF sublaminae (i.e. all branches and boutons within the same sublamina), the ON and OFF stratification rules apply. This is seen for type b3 bipolar cells in ground squirrel (Fig. 16). However, if the axonal stratification pattern crosses the ON-OFF boundary, the

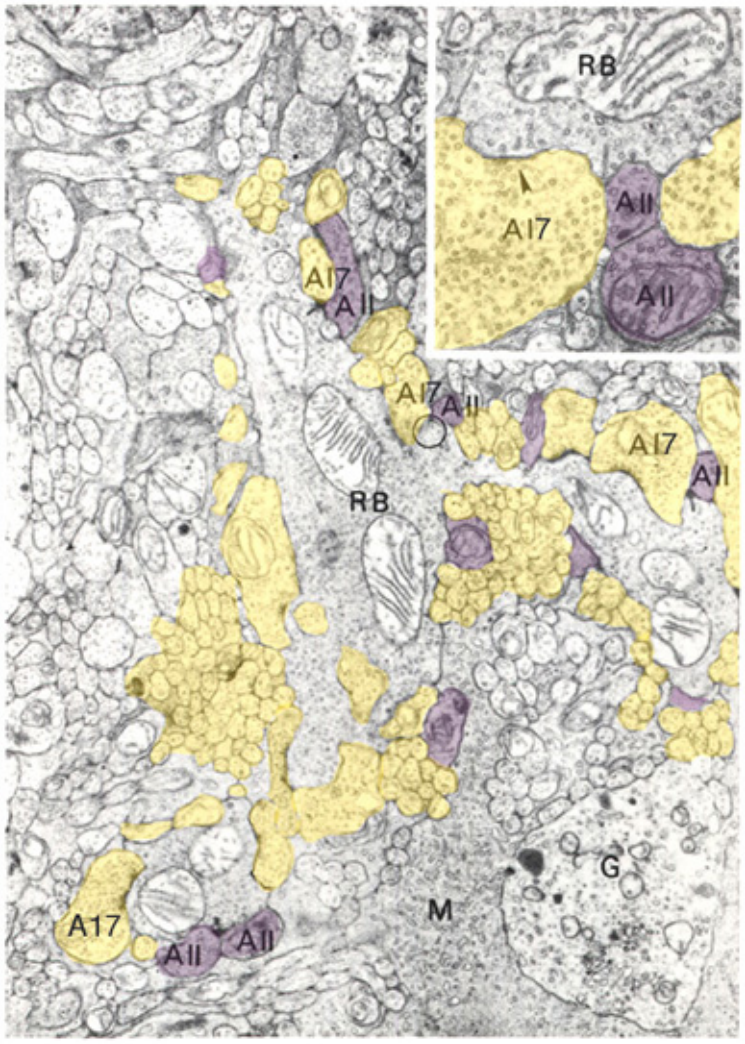

Figure 22. GABAergic and glycinergic inhibitory terminals surround a rod bipolar axon terminal (RB) in cat retina. The A17 amacrine cell (yellow) is GABAergic and transmits at $GABA_A$ receptors on the rod bipolar axon terminal. The AII amacrine cell is known to be glycinergic (purple). The electron micrograph is adapted from Kolb, 1979 (105).

cells may be either ON-type or OFF-type (11, 72, 103). In some cases such multistratified bipolar cells may even express both ON and OFF physiologies (11, 88, 112), with the OFF physiology mediated by AMPA receptors, and the ON physiology mediated by either mGluR6, or EAAT. In giant danio such cells are color opponent (88). In zebrafish multistratified bipolar cells with boutons in both sublaminae were found to be either ON or OFF types Fig. 17. Connaughton and Nelson concluded that multistratified ON types use only I_{glu}, the transporter-like chloride current (72), however in the related giant danio, Wong et al find a bistratified type that is both ON and OFF, expressing both I_{glu} and AMPA/kainate receptors (88). The pattern for other giant danio ON bipolar cells is similar to zebrafish where the I_{glu}, or excitatory amino acid transporter (EAAT), mechanism is found particularly in ON-type cone contacting bipolar cells, while the mixed Mb rod and cone contacting types utilize both EAAT and MGluR6 mechanisms (121). The glutamate transporter blockers TBOA was found effective in blocking EAAT transmission (121).

Stratification of rod bipolar cell axon terminals and rod pathways

Rod bipolar cells are unique. These cells are easily identified in both mammals and fish (122). In most mammals, judged by axonal stratification pattern and contacts with photoreceptors, there is only a single class of rod bipolar cell (20, 122). The axon descends deep into ON sublamina *b* of the IPL, where it arborizes in a bulbous

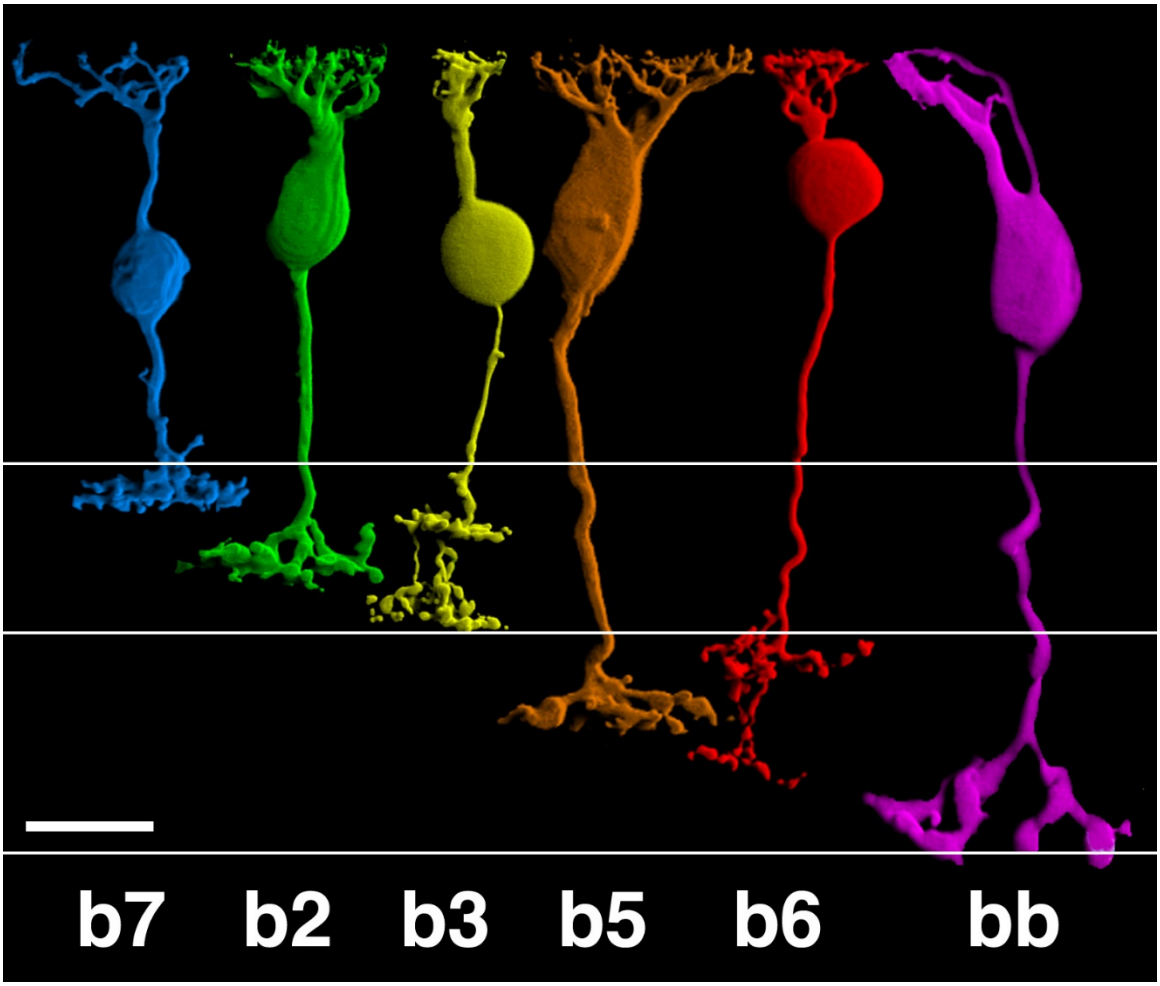

Figure 16. Axonal stratification of bipolar cells in ground squirrel retina. Bipolar cells are stained by dye-filled patch electrodes while recording responses to microelectrode stimulation of individual cones contacting the dendritic tips. 'bb' is an ON-type blue cone bipolar cell; 'b2' is and OFF-type bipolar cell (Fig.13) that contacts both blue and green cones. 'b5' is an ON bipolar cell contacting both blue and green cones. Both 'b3' (Fig.13) and 'b7' are OFF-type bipolar cells that contact only green cones. 'b6' is a heterogeneous grouping of ON cells contacting almost exclusively green cones. While the cone contacts vary, the ON and OFF stratification of axon terminals follow the typical vertebrate pattern. The scale bar is 10μm. The illustration is from Li and DeVries, 2006 (15).

terminal just adjacent to ganglion cells (Fig. 18, rb). The mammalian rod bipolar cell is an ON-type cell (123) utilizing metabotropic APB-sensitive, glutamate receptors (31, 32, 64, 124). In fish, the comparable cell type is the Mb bipolar cell (125). In fish retinas, rod-contacting bipolar cells also contact cones. Five such types are found in goldfish retina, including multiple ON types with axon terminals branching in sublamina *b*, and likely OFF types with axon terminals branching in sublamina *a* (14). Interestingly in mouse retina there also appear to be multiple ON type rod bipolar cells. While axon-terminal morphology differs only subtly, light-evoked signals in DBC_{R1} are completely rod dominated, whereas DBC_{R2}, similar to fish, receives substantial cone signal input in addition to rod input. The cone signals in DBC_{R2} types disappear in connexin 36 knockout mice (126, 127). Regardless of species, classic ON-center rod bipolar cells are all universally recognized by high immunoreactivity for protein kinase C (PKC) (64, 113, 126, 128-130).

Although the axon terminals of rod bipolar cells are directly adjacent to ganglion cells, they do not contact them directly. In the mammalian retina, the AII amacrine cell (105, 131, 132) is the first intermediary in transferring rod bipolar signals to ganglion cells. The AII cell achieves this through direct innervations of cone bipolar processes within the IPL, either by means of chemical synapses with OFF bipolar cells (large arrow in sublamina *a*, Fig. 18) or through gap junctions between AII dendrites and ON cone bipolar axons (large arrow with red

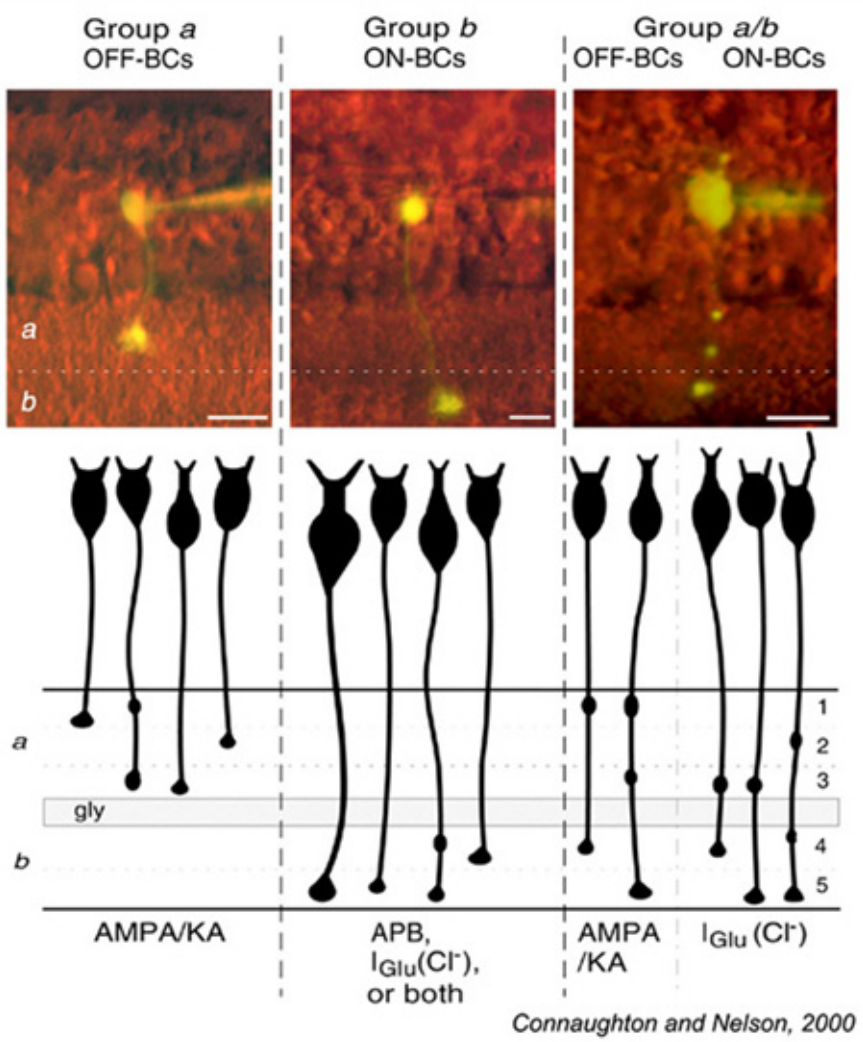

Figure 17. ON and OFF stratification of bipolar-cell axon terminals in zebrafish retina. There are three groupings: axonal boutons only in IPL sublamina *a* (Group *a*), axonal boutons only in sublamina *b* (Group *b*), axonal boutons in both sublaminae (Group *a/b*). ON and OFF properties and glutamate receptor types were determined from whole-cell currents evoked by puffs of glutamate, kainate, APB or NMDA directed at dendritic arbors. AMPA/KA shows cells responding to glutamate or kainate with inward currents. APB shows cells responding to glutamate, APB, or both with outward currents and reversal potentials at or beyond 0 mV. $I_{Glu}(Cl^{-})$ shows cells responding to glutamate with outward currents reversing at -60 mV, the I_{Glu} or EAAT mechanism. NMDA evoked no responses. There is an immunoreactive band for glycine (gly) that appears to separate IPL sublamina *a* from *b*. The scale bar is 10 μm. The illustration is from Connaughton and Nelson, 2000 (72)..

asterisk, Fig. 18). The cone bipolar axon terminals are the second intermediary in transferring rod bipolar signals to ganglion cells. The AII-amacrine-to-cone-bipolar gap junction is down-regulated by the humeral factor nitric oxide acting through an intracellular cGMP pathway (133) and also is susceptible to pharmacological blockade by meclofenamic acid (134).

Cone bipolar cells participate in transferring ON and OFF rod signals from distal retina to ganglion cells even without AII amacrine intermediation. This occurs through two pathways. In the first, signals flow through gap junctions between rods and cones (135-139), and by this pathway into cone bipolar cells. In the second, cone-contacting bipolar cells make direct dendritic contact with rods, as commonly occurs in non-mammals (14, 117, 140, 141). In mammals this type of cone bipolar pathway is usually restricted to OFF cone bipolar cell dendritic contacts with rods (139, 142, 143). This pathway bypasses the slower, albeit higher gain and more sensitive, metabotropic pathway of rod bipolar cells using the faster ionotropic pathways in the OFF cone bipolar cells

(143). In contrast to the typical mammalian pattern, mouse retina shows an analogy to fish retina in having ON cone bipolar cells that directly contact rods (144). Separate rod signaling pathways can be distinguished in humans, both behaviorally, and in evoked potential recordings (145). A sensitive scotopic pathway may represent the rod-bipolar-to-AII pathway, whereas a less sensitive and faster mesopic pathway may represent a rod-to-cone gap-junction pathway, or perhaps additionally, an OFF cone bipolar pathway with direct rod input.

4. Electrical properties, lateral inhibition, and synaptic release

Voltage-gated currents

Voltage-gated channels permeate the membranes of retinal bipolar cells and contribute to voltage responses. In general, these channels carry calcium (Ca^{2+}) and/or potassium (K^+) ionic currents. Intracellular recordings show bipolar cells produce graded potentials in response to a light stimulus, but not action potentials (1). This finding is supported by several studies in which voltage-gated Na^+ currents were not identified in bipolar neurons (146-148). However, some other studies do report voltage-gated Na^+ currents in some cone bipolar cells in rat (149-151) and in goldfish (152). In general such Na^+ currents may not produce action potentials, except sometimes under special conditions where K^+ channels are blocked. It seems rather that these currents may typically serve to amplify synaptic events and shape photoresponse waveforms.

The cb5b bipolar cell of ground squirrel retina is an exception. Spontaneous and light-evoked Na^+ spikes can be recorded from these bipolar cells using perforated patch recordings (Fig. 19) (5). The light-evoked bipolar spikes appear to trigger impulse generation in post-synaptic ganglion cells.

Na^+ spikes have not been seen in rod bipolar cells. However in fish retinas, Ca^{2+} spikes have been identified in the rod bipolar axon terminals (3, 153, 154). In zebrafish with bipolar cells transgenically labeled with the Ca^{2+} fluorescent indicator SyGCaMP2, 65% of bipolar terminals produced at least 1 Ca^{2+} spike every second (4). This suggests that Ca^+ spikes occur in the axon terminals of both rod and cone bipolar cells. As yet light-evoked Ca^{2+} spiking is only reported in cyprinid retinas.

All bipolar cells examined to date express inward Ca^{2+} currents in response to membrane depolarizations. The Ca^{2+} currents are either transient (T-type/low voltage activated) and/or sustained (L-type/high voltage activated). The expression of these different Ca^{2+} current types varies among vertebrate species. For example, in goldfish, L-type Ca^{2+} currents are present (155, 156); whereas, mouse bipolar cells express only a transient T-type current (156, 157). In salamander (158) and zebrafish (146), however, both T- and L-type Ca^{2+} channels are present, with the L-type localized to the axon terminal. Recordings of a zebrafish bipolar cell expressing both L-type and T-type Ca^{2+} currents appear in figure 20, I_{Ca}.

A number of potassium (K^+) currents have been identified in bipolar cells. Membrane depolarization typically elicits a combination of outward K^+ currents. In goldfish (159) and tiger salamander retina (25), a slowly activating, delayed rectifying (I_K) potassium current, modulated by dopamine (160), is activated. In contrast, axolotl bipolar neurons (161) express a rapidly activating, slowly inactivating I_A current in response to depolarizing membrane potentials. Bipolar cells in fish, such as white bass and zebrafish, express one or the other of these two types of K^+ currents, suggesting that these neurons can be differentiated into distinct populations based on the voltage-gated currents they express (146, 148). Membrane depolarizations also elicit a calcium-dependent K^+ current ($I_{K(Ca)}$) that contributes to the overall outward current amplitude observed (146, 148, 159). These outward currents tend to hyperpolarize the cell, restoring membrane potential after depolarization. On the other hand membrane hyperpolarizations elicit the slowly activating, inward rectifying (I_h) current (146-148, 159). This also tends to restore membrane potential. Examples of K^+ currents evoked by membrane depolarization (I_K, I_A, $I_{K(Ca)}$), or hyperpolarization (I_{sust}, I_h) appear in figure 20. These were recorded in zebrafish retinal bipolar cells.

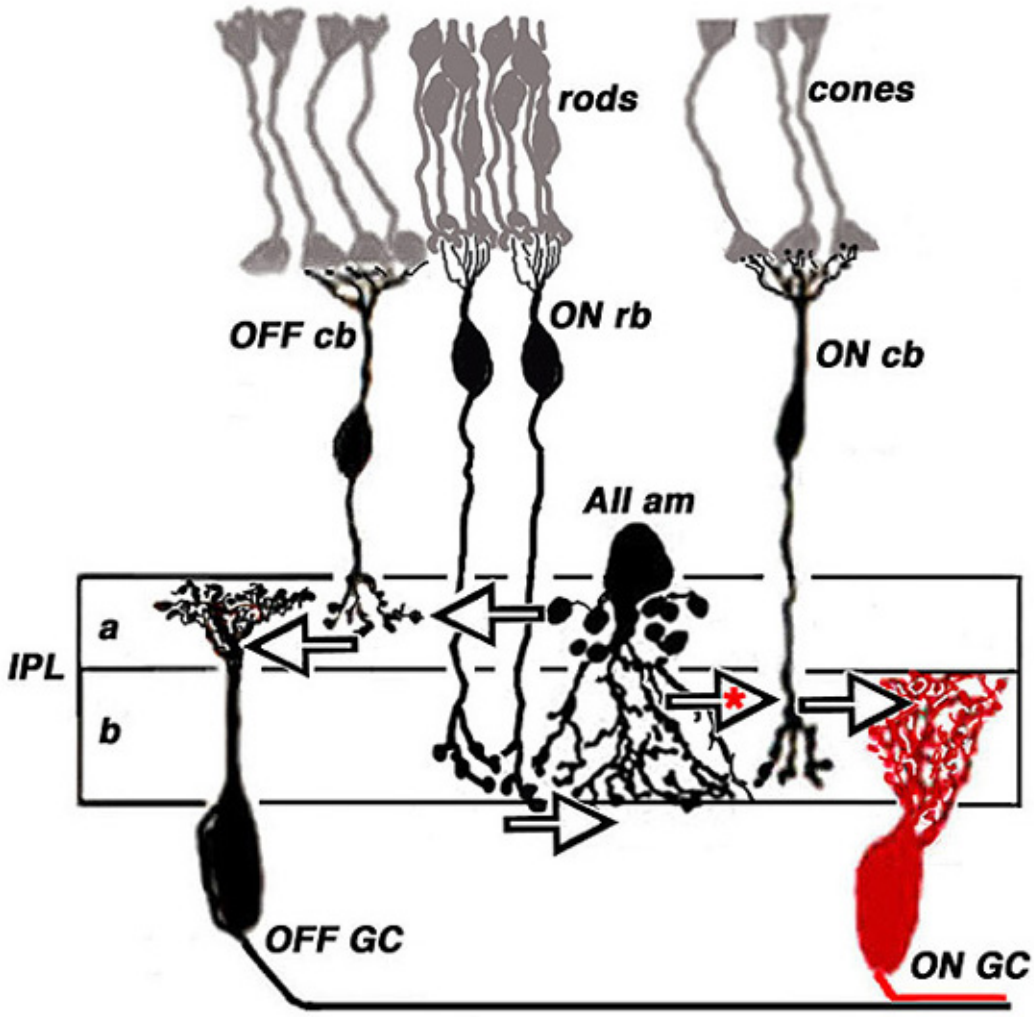

Figure 18. Rod bipolar cells in the mammalian retina are ON type (*ON rb*). Rod bipolar cell signals are split into ON and OFF components by the glycinergic AII amacrine cell (*AII am*, center arrows). Rod ON signals flow from rod bipolar cell to AII amacrine cell to ON cone bipolar cells at gap junctions (asterisk) in IPL sublamina *b*. Rod OFF signals are generated at inhibitory glycinergic synapses between AII amacrine cells and OFF cone bipolar cells within IPL sublamina *a*. The illustration is modified from Kolb and Famiglietti, 1974 (131)..

Inhibitory GABA-gated currents

As described above, light stimulation of the bipolar cell receptive field reveals characteristic center-surround antagonism (Fig. 1), where the response of the center is of opposite polarity to the response of the surround. It is believed that the center component of the bipolar cell light response arises from direct glutamatergic inputs from photoreceptors, while the surround response is generated indirectly by horizontal-cell suppression of glutamate release from cones (162). Horizontal-cell feedback to cones is further discussed in the Webvision chapter *S-potentials and horizontal cells*.

A further potential surround mechanism is through direct inhibitory GABAergic and/or glycinergic inputs from horizontal cells or amacrine cells. These neurotransmitters open chloride channels and generate signals of either hyperpolarizing or depolarizing polarity, depending on the sign of the chloride (Cl^-) gradient across the synaptic membranes (163). Chloride-mediated responses at light onset and offset have been observed in ON bipolar cells of tiger salamander (12, 25, 112). These components appear to originate with AMPA excitation of GABAergic and glycinergic inhibitory interneurons, rather than with photoreceptors directly (25, 164). The

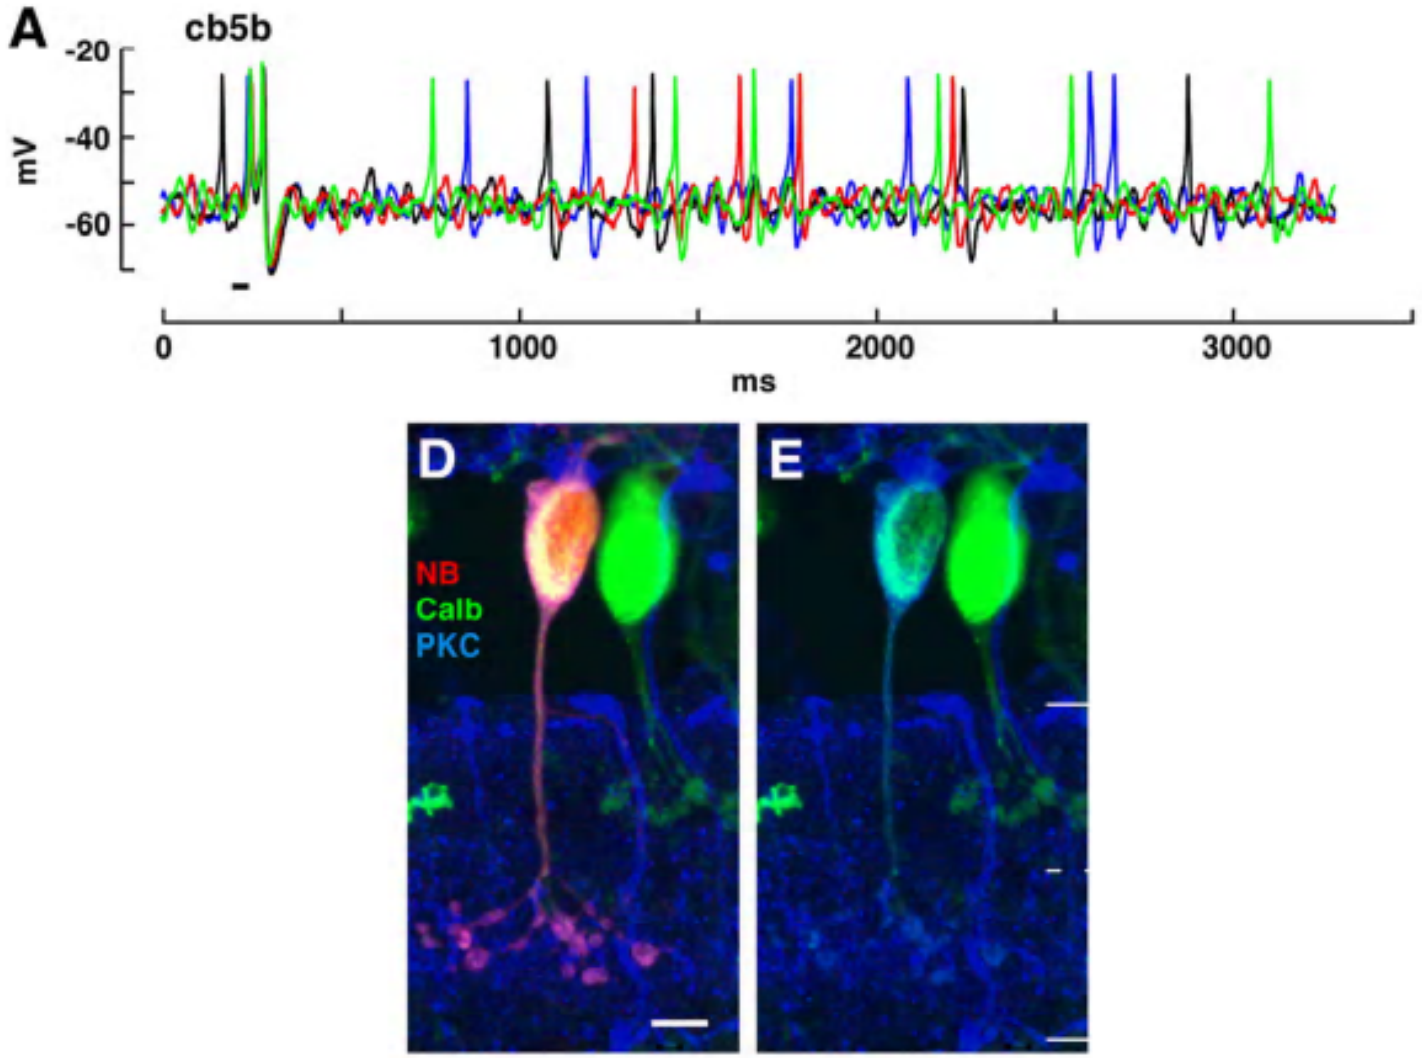

Figure 19. Spontaneous and light-evoked actions potentials in a ground squirrel bipolar cell. Four traces are superimposed in *A*. The short horizontal bar represents a 40 msec light flash that evokes a spike doublet at the beginning of each trace. The remaining spikes are spontaneous activity. In *D* the red label is the neurobiotin (NB) injected cb5b bipolar cell. In *E* this cell labels for protein kinase C (PKC), characteristic of ON bipolar cells, and calbindin (Calb). The green label in *D* and *E* is a calbindin reactive cb2 OFF bipolar cell, not recorded in this session. The scale bar is 5 µm. The illustration is modified from Saszik and DeVries, 2012 (5)...

waveforms of these ON or OFF inhibitions depend on whether the excitatory ON responses are rod or cone dominated. Rod dominated cells tend to have sustained ON inhibition without offset inhibitory transient, whereas cone dominated cells are transiently inhibited at both onset and offset of the stimulus (112). Immunocytochemical studies show that bipolar-cell dendrites and terminals are surrounded by GABAergic processes. In the OPL, these processes belong to horizontal cells; whereas, in the IPL, GABAergic amacrine cell processes surround bipolar terminals (165-170). Illustrations of the GABAergic inhibitory synaptic arrangements surrounding bipolar cell axon terminals appear in figure 21 for a cyprinid Mb (rod bipolar) terminal and in figure 22 for a cat rod bipolar cell axon terminal.

Bipolar cell processes are selectively sensitive to external GABA application (Fig. 23). GABA-evoked currents are typically greatest at the axon terminals (171-174), though smaller amplitude currents can be elicited from the soma and/or dendrites (Fig. 23). This suggests a major inhibitory feedback circuit from neighboring amacrine cells (171-175) occurs through direct GABAergic input onto bipolar-cell terminals. GABAergic inputs to bipolar dendrites may also occur indirectly, through a feedback synapse involving photoreceptors (176-179).

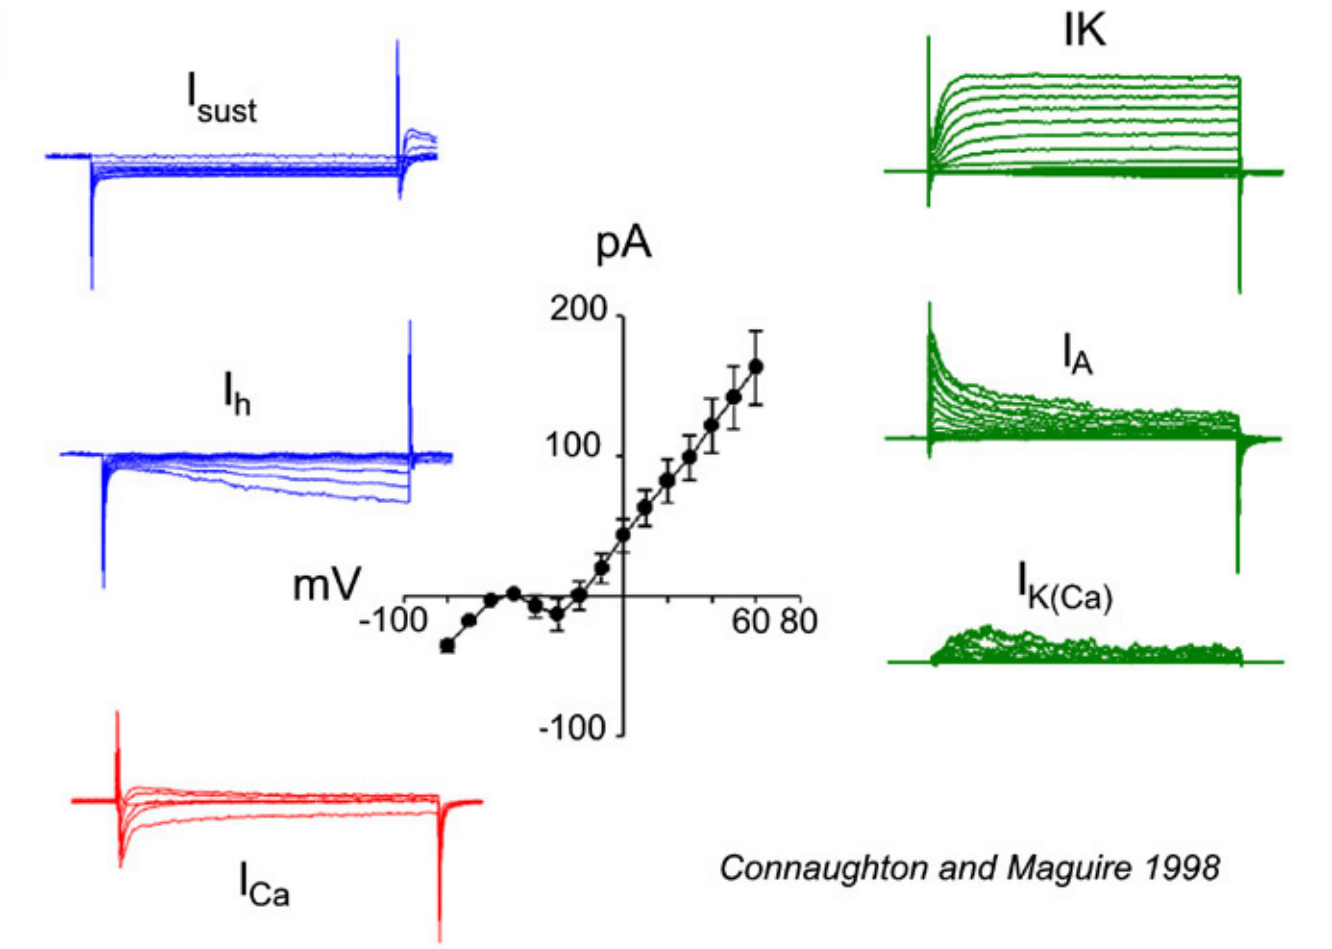

Figure 20. Voltage gated currents found in zebrafish bipolar cells. Inward currents (I_{sust} or I_h) are evoked by hyperpolarizing voltage (blue traces, left). Outward currents (IK, I_A and $I_{K(Ca)}$) are evoked by stepping membrane potential from -90 mV to a maximum of +60 mV (green traces, right). IK is the delayed rectifying K^+ current, I_A is the transient K^+ 'A' current, and $I_{K(Ca)}$ is the Ca^{2+} activated potassium current. I_A and I_{sust} tend to be found in the same cells, as do IK and I_h. I_{Ca} (below, red trace) is the depolarization-activated Ca^{2+} current. Both T (transient) and L (sustained) type Ca^{2+} currents are seen. In the center is the mean bipolar cell I-V plot, the prominent dip at -30 mV is caused by Ca^{2+} currents. The illustration is modified from Connaughton and Maguire, 1998 (146).

GABA application elicits a chloride (Cl^-) current. Depending on the Cl^- gradient either depolarization or hyperpolarization may result, though the most common result is hyperpolarization. GABA-elicited currents have both transient and sustained components. The transient response is mediated by $GABA_A$ receptors; while the sustained component results from the activation of $GABA_C$ receptors (173, 180-187). The sustained components of $GABA_C$ responses last many minutes and the hyperpolarizing action is readily seen in voltage probe studies of dissociated bipolar cells using oxonol, a slow distributive probe, as voltage reporter (171, 188). The different time courses of $GABA_A$ and $GABA_C$ currents and the different sensitivity to selective antagonists are illustrated for ferret bipolar cells in figure 24. The molecular properties of retinal $GABA_C$ receptors are explained in the Webvision chapter *GABAc Receptors in the Vertebrate Retina*. Interestingly, though most bipolar cells appear to express both $GABA_A$ and $GABA_C$ receptors, it is the $GABA_C$ receptor that underlies 70-80% of GABA-elicited responses. With light stimuli these receptors transfer more net charge to bipolar cell terminals than either $GABA_A$ or glycine receptors (189). Expression of both $GABA_A$ and $GABA_C$ receptors allows bipolar axon terminals to respond to a range of GABA concentrations and time courses within the synaptic cleft, as these different receptor types display collectively high sensitivity to long duration applications of low GABA doses ($GABA_C$), and short duration applications of high GABA doses ($GABA_A$) (181, 183).

$GABA_B$ is the 'metabotopic' GABA receptor. These receptors have been identified on the axon terminals of salamander and goldfish bipolar cells, where they reduce calcium influx (158, 190), modulating synaptic release of bipolar-cell glutamate.

Functional consequences of GABA inhibitory circuitry

GABA receptors affect the dynamics of retinal light responses (191-194). $GABA_A$ antagonists cause ganglion cell ON discharges to become more transient (193, 195), an effect seen in ON bipolar cells (195). Zhang et al suggest a serial synaptic pathway to explain this counterintuitive result. On this model, the native action of GABA, not GABA antagonists, is to make light responses more transient, through delayed inhibition. Amacrine cells synapsing on bipolar cells with $GABA_C$ synapses, however, are themselves inhibited by other amacrine cells utilizing $GABA_A$ synapses. Blockade of the $GABA_A$ input causes more robust inhibition of bipolar terminals by $GABA_C$ and further transience of light responses. In this model a counterintuitive action is explained by a polysnaptic pathway. $GABA_C$ currents measured in bipolar cells actually do increase in the presence of the $GABA_A$ antagonist bicuculline (189). GABA release from amacrine cells activates receptors on bipolar cell terminals, causing the suppression of a depolarization-elicited calcium current (158, 196) and associated synaptic release (197) presumably modulating or reducing neurotransmitter release from these cells (198). Measurement of the light evoked excitatory currents in amacrine cells postsynaptic to bipolar cells suggests that the kinetically slower $GABA_C$ inhibition limits the duration of excitatory post-synaptic events, whereas the faster glycine and $GABA_A$ inhibition limits the peak amplitude of postsynaptic excitatory events (191).

GABAergic synapses between A17 amacrine cells and rod bipolar cells (Fig. 22) activate $GABA_A$ receptors (199). While being wide in dendritic field, the action of A17 amacrine cells on rod-bipolar axon terminals is local (200, 201) and depends on calcium entry through local A17 AMPA channels excited by the rod-bipolar-cell ribbon synapse (201), not impulses propagating in the A17 dendrites (200). $GABA_C$ inhibition of rod bipolar terminals is long range and depends on impulse activity (200). These two inhibitory systems have been dissected in the Diamond laboratory. The short range reciprocal $GABA_A$ feedback is eliminated by ablating A17 amacrine cells with 5,7 dihydroxytryptamine (DHT), a toxic serotonin analogue that is selectively taken up by A17. The long range $GABA_C$ feedback is abolished by tetrodotoxin (TTX). This abolishes nerve spikes that allow signal propagation along amacrine cell dendrites other than A17. Interestingly, though wide in dendritic field, the regulatory actions of A17 appear to be independent local-circuit reciprocal interactions with rod bipolar cells (Fig. 25).

Inhibitory glycine-gated currents

Glycine applied to bipolar cells elicits a strychnine-sensitive, hyperpolarizing chloride current. As with GABA, different bipolar-cell regions are differentially sensitive to glycine. In mouse (156, 202) and carp (177) the axon terminal shows the greatest sensitivity; while in rat (147) and salamander (203) the dendrites are more sensitive. There is a tendency for glycinergic inhibitory circuitry to impinge selectively on OFF cone bipolar cells (177, 204); the outstanding example is AII amacrine innervation of the mammalian OFF cone bipolar cells (105, 205-207). In this case glycine acts as a neurotransmitter intermediary in the pathway to dark adapted ganglion-cell center responses (Fig. 18). In general the inhibitory pathway onto cone-bipolar-cell axon terminals uses glycine, whereas the rod bipolar axon terminal receives GABAergic inhibition (208). Glycine, however, is a component of inhibition on rod bipolar terminals. This pathway is innervated by both ON and OFF bipolar cells through a preferentially NMDA glutamate receptor mechanism impinging on amacrine cells (209). Dendritic impulse propagation plays a role in the transmission of glycinergic inhibition at this synapse. Noise analysis performed on glycine-elicited currents from dendrites and axon terminal suggests that each region may express a different subtype of glycine receptor (210). In fish retinas glycinergic inputs to bipolar-cell dendrites and axon terminals are believed to arise directly from populations of amacrine and glycinergic interplexiform cells (203).

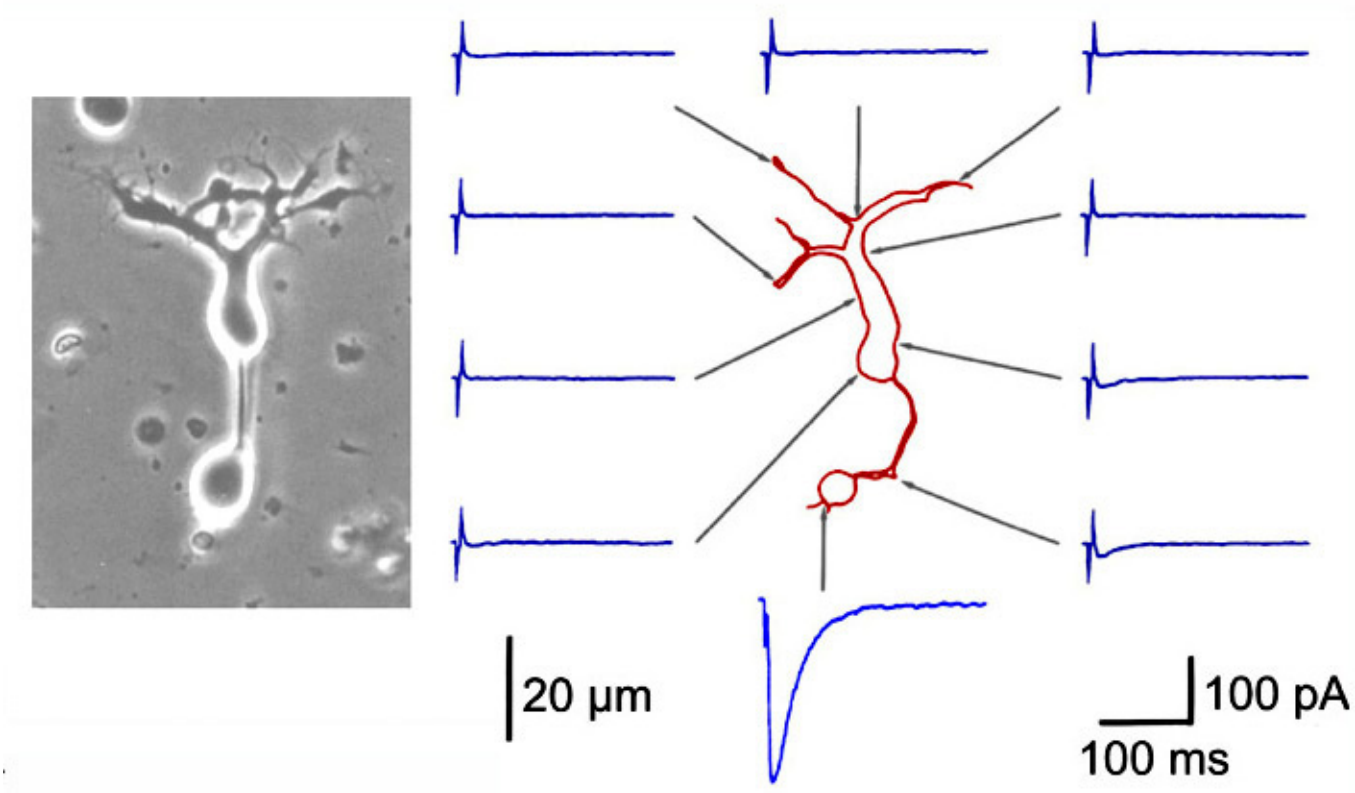

Figure 23. A rod bipolar cell is dissociated from goldfish retina (left). When the selected cellular regions are stimulated with micro puffs of GABA, the most sensitive region is the axon terminal (right). The figure is modified from Tachibana and Kaneko, 1987 (173).

Glycine-containing interplexiform cells have only been seen so far in fish retinas; glycine receptors can be found on processes postsynaptic to photoreceptors, including bipolar cell dendritic processes (211).

Glycine is believed to modulate the surround light responses of bipolar cells, though the reported effects of glycine are not consistent. Stone and Schutte (1991) (212), working in Xenopus, report that glycine application eliminated surround responses in both ON- and OFF-type bipolar cells. In contrast, surround responses in salamander are not blocked by glycine (213). While GABA application elicits responses in all bipolar cells examined, glycine elicits responses from only a subset of bipolar cells, such as OFF bipolar cells in carp (177) and the small-field bipolar cells in skate (214), suggesting glycine may have a selective role in retina. Glycinergic feedback connections between amacrine and bipolar cells decrease light-evoked glutamate release onto ganglion cell dendrites (198). Glycinergic feed-forward synapses transfer rod bipolar signals from AII amacrine cells to OFF cone bipolar terminals in mammalian retinas (105, 215). Thus, glycinergic synapses onto bipolar cells may be important in mediating the transfer of information among neurons in both the proximal and distal retina.

Glutamate release from vesicles in goldfish bipolar cell axon terminals

Due to their large size, the axon terminals of goldfish Mb1-type ON-bipolar cells are used as a model system in which to examine neurotransmitter release. The axon terminal can be directly recorded in patch clamp studies (216). Changes in internal calcium (217) and both exocytosis and endocytosis activity (217, 218) can be detected using fluorescent calcium probes and observing capacitance changes as vesicle membrane is added or removed from this presynaptic terminal. Images of releasing vesicles at Mb1 terminals are seen by evanescent fluorescence microscopy in figure 26.

Neurotransmitter release from bipolar terminals occurs at ribbon synapses (219, 220); conventional synapses are rare in bipolar axon terminals although they have been seen in some species (221, 222). Each ribbon is an

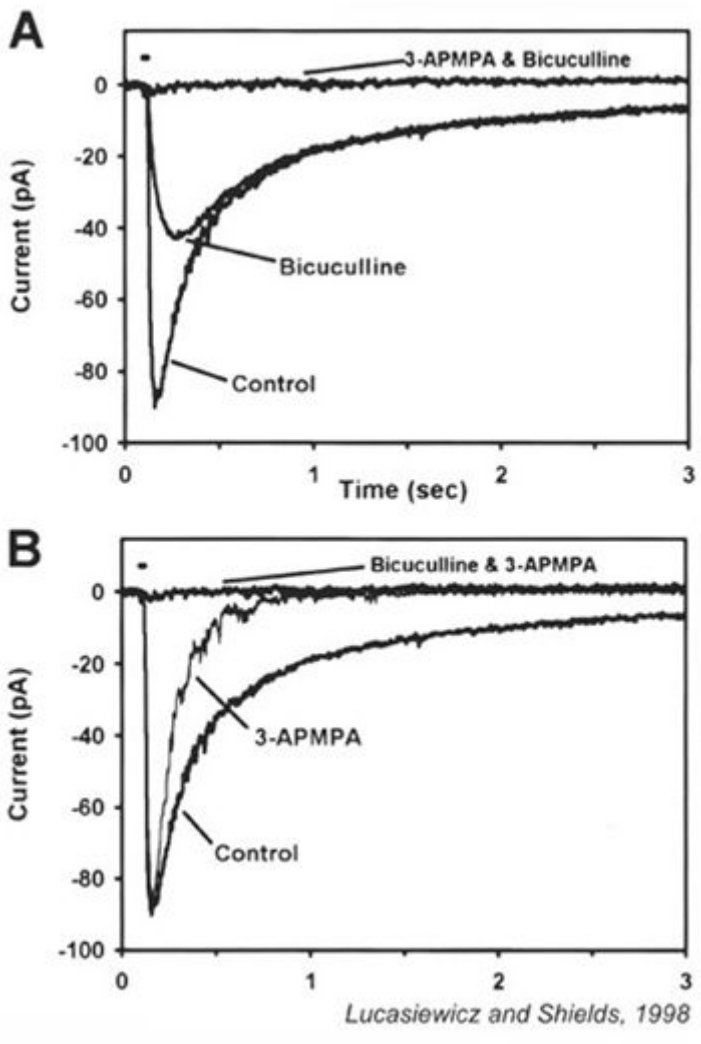

Figure 24. Mixtures of $GABA_A$ and $GABA_C$ receptors in ferret OFF bipolar cells are separately blocked by selective antagonists. *A*. The transient $GABA_A$ response component is blocked by bicuculline (200 μM), leaving a slowly desensitizing $GABA_C$ waveform. *B*. The $GABA_C$ response component is blocked by 3-APMPA (300 μM), leaving the rapidly desensitizing $GABA_A$ waveform. When both antagonists are mixed together, the GABA response is fully blocked. The illustration is from Lukasiewicz and Shields, 1998 (182).

electron dense structure oriented perpendicular to the plasma membrane. One ribbon may contain as many as ~110 tethered vesicles along the sides. Vesicles along the base of the ribbon, or "docked vesicles", are in contact with the presynaptic membrane (216). The arrangement of the ribbon synapse at the bipolar cell axon terminal and associated post-synaptic events are shown in figure 27. All vesicles associated with the ribbon constitute the readily releasable pool of vesicles. Since one axon terminal averages 55 active zones in the goldfish, each with an associated ribbon (218), there are ~6000 tethered or rapidly releasable vesicles per terminal (von Gersdorff et al., 1996). Combining these values with capacitance measurements indicates that maximal release per active zone occurs at a rate of ~500 vesicles/sec (216). Species with smaller rod or cone bipolar axon terminals (amphibians, reptiles and mammals) have smaller numbers of ribbons and smaller volumes to contain synaptic vesicles so the release rates may be different compared with the model goldfish system.

The ribbon synapse, in the absence of light, releases vesicles spontaneously. The single spontaneous excitatory postsynaptic synaptic currents (sEPSCs) can be studied by voltage clamp techniques in ganglion cells (221). It is thought that normal spontaneous release activates AMPA receptors located immediately below the active release zone (Fig. 27). Light stimulation of ON bipolar cells induces release of many vesicles along a single ribbon site and glutamate spillover activates both AMPA and NMDA receptors (Fig. 27). The patch recordings of sEPSCs,

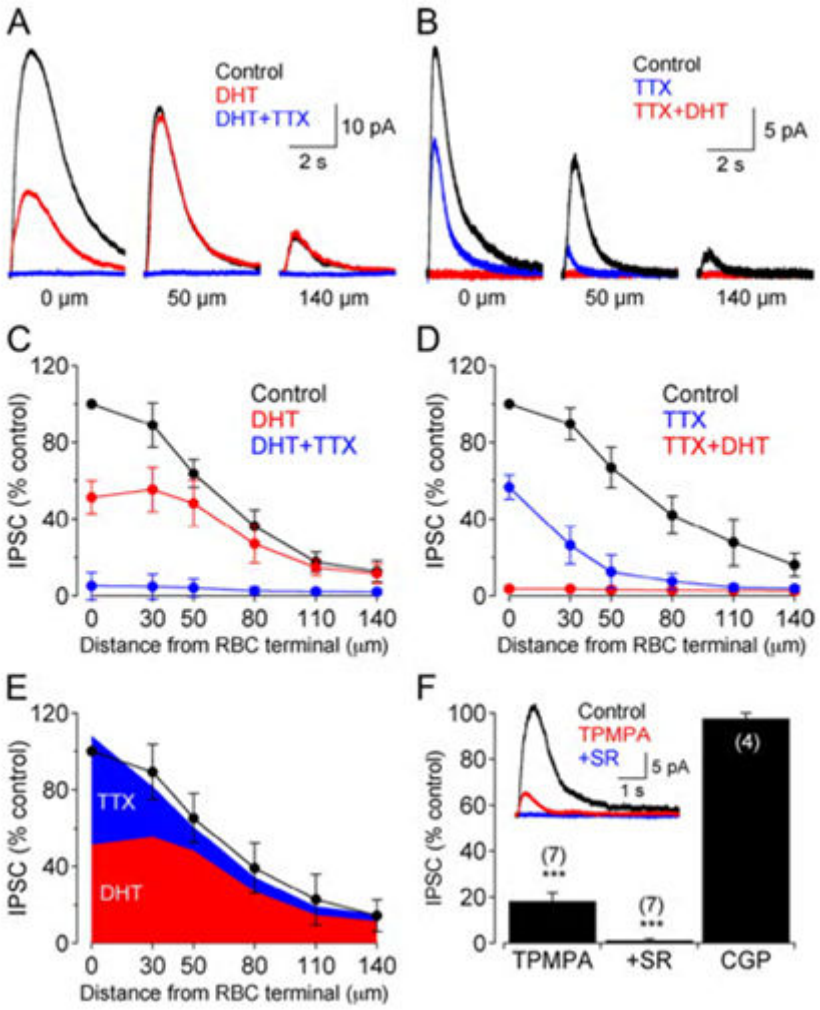

Figure 25. Long-range and short-range inhibitory circuits for rod-bipolar-cell axon terminals. Ablation of A17 amacrine cells in rat retina with 5,7 dihydroxytramine (DHT) eliminates local GABAergic inhibitory post synaptic currents (IPSC) in rod bipolar terminals. Tetrodotoxin (TTX), which blocks nerve spikes, eliminates long range IPSC's. *A-D*. The spatial profiles of GABA inhibitory responses are evaluated by puffing glutamate at different distances. This excites all GABAergic amacrine cells. DHT-ablated retinas lack local feedback from A17 amacrine cells. TTX treated retinas lack long range feedback. *E*. TTX and DHT sensitive inhibition add to produce total observed inhibition. This suggests a lack of interaction between the two systems. *F*. TPMPA, a $GABA_C$ antagonist blocks virtually all inhibition in DHT treated retinas, suggesting long range inhibition acts through $GABA_C$ receptors. The illustration is from Chavez, Grimes and Diamond, 2010 (200).

under conditions of hyperosmotic Ringer to enhance rates of spontaneous events, reveal large and small as well as fast and slow events (Fig. 27, control). The sEPSCs are mostly eliminated by NBQX, a highly selective antagonist for AMPA and kainate receptors (Fig. 27, NBQX). But small amplitude events still are seen (Fig. 27, NBQX) until the NMDA antagonist D-AP7 is added (Fig. 27, NBQX+DAP7). This indicates that both AMPA and NMDA receptors are active in post-synaptic ganglion cells (223). Further, a maintained inward current is also blocked by both these antagonists, suggesting bipolar-cell ribbon synapses transfer information across a broad temporal spectrum.

Vesicular release at the bipolar ribbon synapse occurs in a calcium-dependent manner (224-226), though there does not appear to be a selective requirement for calcium, as other divalent ions, such as strontium and barium, can stimulate exocytosis, though to a lesser degree (227). Calcium entry occurs through L-type channels in goldfish (155) and/or T-type channels in mouse (228). These channels are located on the axon terminal

membrane. Internal calcium concentrations of 10-20 μM stimulate exocytosis (155) of the readily releasable pool (216, 218, 229). Exocytosis occurs in two phases. Initially, membrane depolarization elicits an increase in capacitance (time constant ~1.5 ms) corresponding to the rapid release of docked vesicles. This is followed by a second capacitance increase with a slower time constant (~250-300ms), believed to represent the movement of tethered vesicles to the active zone and their subsequent release (218, 230). Estimates indicate that 20% or ~1100 vesicles (of the 6000 in the readily releasable pool) are released during rapid exocytosis (229, 230), with the remainder released during the slow component. The depleted pool is restocked with a time constant of about 8s (231). Both the fast and slow phases are calcium-dependent, though they display differential sensitivities to calcium buffers (230).

Following neurotransmitter release, the vesicular membrane is recovered rapidly (226) and continuously (217, 232). The continual cycling of vesicles through the processes of exocytosis and endocytosis, is compatible with tonic release of neurotransmitter (217). This is suspected as bipolar cells generate sustained responses to light, and at least in some cases, transmit sustained signals to postsynaptic neurons (1). Though neurotransmitter is released following continuous or paired-pulse stimulation of the terminals, release decreases with time (229, 230). This synaptic depression is believed to be due to depletion of the readily releasable pool and a decrease in exocytosis of this pool (229).

Vesicle release at the mammalian rod-bipolar-to-AII-amacrine synapse

The pharmacology and kinetics of the mammalian ribbon synapse between rod bipolar cells and AII amacrine cells has been studied by simultaneous patch recording of presynaptic and postsynaptic cells (199). This glutamatergic synapse uses exclusively AMPA receptors (233). Within the retinal inner plexiform layer there is a transformation from the largely sustained light response of bipolar cells to the largely transient responses of amacrine cells (1). The mechanism of this transformation is a major topic for retinal neural circuitry. Rod bipolar cells respond to maintained light stimuli with maintained depolarizations (123), whereas the AII amacrine response to light is a transient depolarization (123, 132). Singer and Diamond (2003) (199) argue that vesicle depletion, at least a higher stimulus levels, is a major contributor to the sustained-transient transformation (123, 132). The rod-bipolar-to-AII synapse is fast, rising to peak in about 1 ms following depolarization of the rod bipolar. It is also transient, responding to a depolarizing rectangular voltage step in the presynaptic rod bipolar with a saw-toothed waveform decaying to a lesser steady-state release level within 20 msec. Presynaptic calcium currents that lead to vesicle release are L-type and sustained and do not explain the decay (199). The sustained-to-transient transformation occurs even in the presence of inhibitory synaptic blockers that block reciprocal $GABA_A$ feedback. GABA feedback could be observed as a delayed transient outward current in the rod bipolar recording, but did not measurably alter synaptic release.

After the decaying phase of the response completes, a residual train of small synaptic events persists. The transient waveform slows, but is evident, even at stimulation threshold (199). Singer and Diamond (2003) conclude that presynaptic vesicle depletion within a 'releasable pool' accounts for the transient waveform of the synapse. Decline in the number of available vesicles reduces the number of vesicles released over time, even though for an individual vesicle this probability may remain constant. This is typical of synaptic transmission. One unique feature of this synapse however is synchronous release of vesicle pairs (234). Singer and Diamond (2006) (235) estimate the readily releasable pool in the rat rod-bipolar-cell terminal is in net about 70 vesicles, which amounts to about 7 vesicles per ribbon. The synapse appears able to replace vesicles at about 0.5 vesicles/ms, giving each ribbon a steady-state release rate of about 50/s. Release is easily depressed in paired pulse experiments and recovers with a time constant only of about 4 s, but sustained exocytosis appears to accelerate vesicle recovery. These properties may confer the ability for synaptically-based neural adaptation (235).

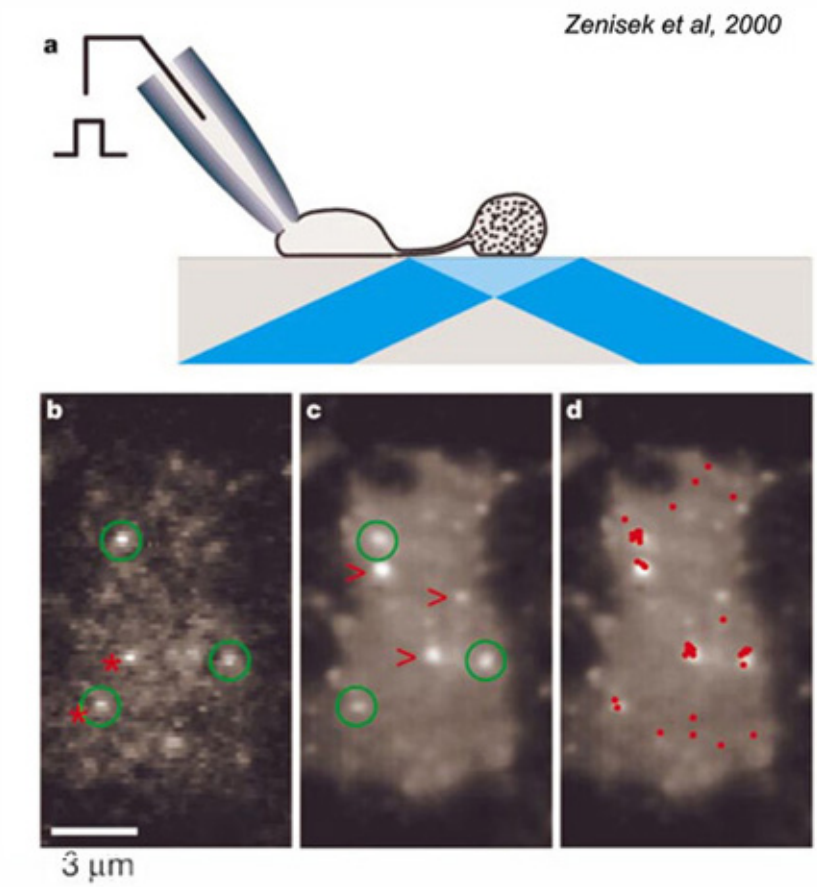

Figure 26. Vesicle release at Mb-1 bipolar terminals can be observed by evanescent fluorescence microscopy. *a*. Schematic showing simultaneous stimulation of release by patch recording, and dark-field evanescent fluorescence imaging of FM1-43 loaded fluorescent vesicles. *b*. Single frame showing vesicles near the membrane. The asterisked vesicles were released and disappeared in subsequent frames *c* and *d*. Averages of multiple images show preferred sites of vesicle docking and or release (circles and arrowheads in *c*, *d*. The actual sites of release during the averaged image are indicated as red dots. The illustration is from Zenesek et al, 2000 (218).

5. Behavioral and clinical implications of bipolar-cell abnormalities

ON bipolar cells appear uniquely vulnerable to insult. The mGluR6 receptor, for example, can be selectively removed (i.e., knocked out) without major effect on other neural pathways. This can be accomplished through a variety of techniques, such as use of selective pharmacological blocking agents (i.e., APB) or site directed mutagenisis techniques designed to eliminate the mGluR6 receptors themselves (Fig. 4). Further, naturally occurring mutations and disease processes related to mGluR6 selectively target ON bipolar cells. These include compromise of the TRPM1 channel (Fig. 7), and the associated glycoprotein nyctalopin (Fig. 9). Other disease processes also single out ON bipolar cells. Surprisingly humans or animal models with ON-bipolar deficit(s) perform visual tasks relatively normally. The major problem is loss of nocturnal vision, which appears dependent on the physiological integrity of a single ON bipolar-cell type, the mammalian rod bipolar cell.

Mice with ON bipolar knockout perform visual tasks

The electrophysiological consequences of site-directed mutagenisis directed at the ON pathway are seen in figure 4 for mGluR6 deficient mice. The electroretinographic b-wave component, which arises from the activity of ON bipolar cells, is abolished (31). These authors further demonstrate that light-evoked field potentials from the

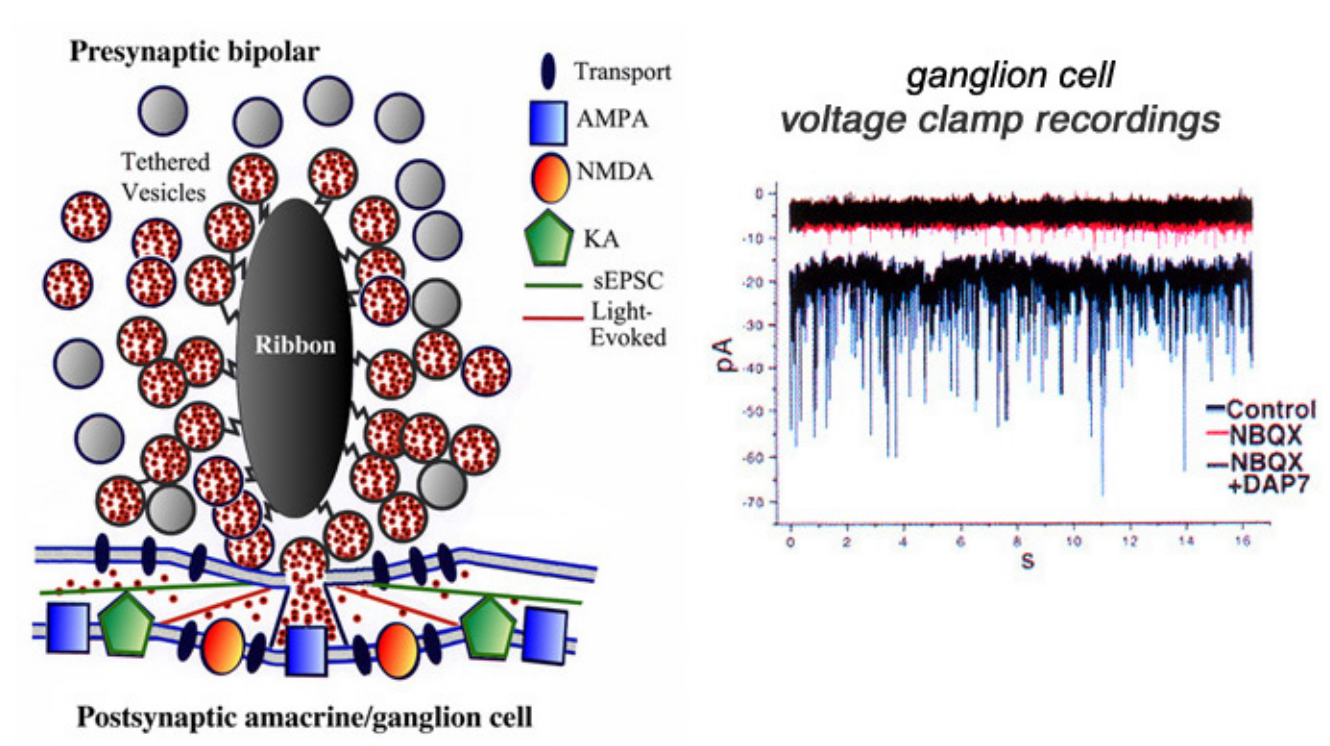

Figure 27. *Left*, cartoon of a ribbon synapse at a salamander ON bipolar synapse. Docked vesicles, release sites, transporters and postsynaptic receptors are indicated. *Right*, voltage clamp recordings (V_H= −70 mV) from a salamander ganglion cell postsynaptic to an ON bipolar cell show rapid inward events (EPSCs) as large as 50 pA, as well as baseline fluctuations, suggesting that both fast and slow events contribute to the responses. NBQX, a selective antagonist for AMPA and KA receptors, eliminates most large spontaneous events but the addition of D-AP7 (NMDA specific antagonist) is needed to eliminate the small amplitude events. The illustration is from Miller et al., 2001 (221).

superior colliculus, which in mouse is the main termination site for ganglion cell axons, lack ON responses, though OFF-type waves appear. In wild type mice, transient collicular waves are seen at both onset and cessation of light stimuli. The altered mGluR6 physiology would seem to imply a behavioral deficit.

Interestingly some tests do suggest deficits in behavior while others do not. In a shuttle box avoidance learning analysis, both mutant and wild type mice performed equally well (31). Since the original site-directed mutant line was created, a forward-genetic mGluR6-mutant line, nob4, has been found (236). Circadian clocks, characterized by wheel running activity in the dark phase, are normal in both mutants. In each mutant light stops this activity (237, 238). In the site-directed mutant this action is phase delayed (237); in nob4 this action is sensitized, a seemingly paradoxical result (238). In both mutants pupillary responses were observed only at high light levels (238, 239). In the site-directed mutant optokinetic responses were seen only at high contrasts (239), suggesting a general loss of sensitivity. These studies indicate that the OFF bipolar cells alone can mediate vision, even if somewhat impaired. Interestingly the ON and OFF layering of the inner plexiform layer persists in the site-directed mutant (240).

Melanoma-associated retinopathy (MAR)

Some patients with malignant melanomas lose night vision. They may further report hallucinations consisting of shimmering blobs of white light (241, 242). Visual processing in daylight appears otherwise normal. Color vision is not affected, nor is visual acuity dramatically worsened. Electroretinography reveals ON bipolar cell deficits for these patients. As with mGluR6 deficient mice, the b-wave is selectively absent in both rod and cone driven

responses (243) and the patients may have reduced contrast sensitivity (244). Although originally thought to be a side effect of chemotherapy (242), it became clear that the syndrome might arise in cancer patients prior to chemotherapy (241, 243). The IgG serum fraction of MAR patients induces reversible electroretinographic disturbances similar to MAR when injected into the eyes of monkeys (245). Electroretinographic a-waves and d-waves remain; the b-wave is lost from both rod and cone responses (Fig. 28). MAR appears to be caused by an autoimmune attack against retinal ON bipolar cells for both rod and cone vision. Antibodies induced by the melanoma cause the visual deficit. One of the epitopes appears to be the ON-bipolar-cell TRPM1 channel (246, 247), perhaps not surprisingly as the channel name derives from 'melanoma related'. MAR is one of several paraneoplastic retinopathies (PR) or cancer-associated retinopathies (CAR).

Congenital stationary night blindness (CSNB)

This visual dysfunction is an inherited retinal disease very similar in symptoms to MAR. In the Schubert-Bornschein, or complete, type (248), there is loss of nocturnal or rod vision (Fig. 29), but in daylight, cone-mediated color vision and visual acuity are relatively normal (249, 250), though the sensitivity of cone vision is somewhat reduced (250, 251). The disease is X-linked, affecting primarily males (250, 251).

Electroretinograms (Fig. 29) reveal a loss of b-waves for both the rod and cone systems. ON bipolar cell signals appear greatly depressed or absent, OFF cone bipolar signals, as represented by the electroretinographic d-wave, are spared (243), as is the rod a-wave (249). The presence of a rod a-wave but not b-wave provided the first suggestion that the retina could have genetic diseases of the post receptor, neural processing machinery (249).

Early on it became apparent that CSNB was a heterogeneous disease. Miyake et al (250) classified CSNB as 'complete' and 'incomplete'. 'Complete' or 'Shubert-Bornshein' type lacked all rod function and had no b-wave. 'Incomplete' or 'Riggs' type had reduced b-wave and rod function. Both 'complete' and 'incomplete' forms occurred nearly exclusively in males (50 of 55 examples) (250), and so both were X-linked, but multiple examples within a family tree were only of one type. Genetic analysis reveals that the complete form of CSNB involves defects in the glycoprotein nyctalopin (252). Animal models of this gene defect appear in the section *Metabotropic responses of ON bipolar cells*. Mutant proteins disrupt neurotransmission in ON bipolar cells. The genetic defect in incomplete CSNB has been localized to a gene uniquely expressed in retina and similar to the L-type calcium channel alpha subunit (253). Defects in this gene, CACNA1F, provide an example of a human retinal channelopathy.

There are also examples of human mutations in the *GRM6* gene, the gene that encodes mGluR6. This defect also results in CSNB, a type called 'arCSNB', 'ar' for 'autosomal recessive'. In this type an abnormal 15Hz flicker response near rod threshold distinguishes the electrical phenotype (254). The authors interpret this phase-reversed scotopic threshold response as the survival of an alternative rod pathway, perhaps an element of the 2 rod pathway model (145). More recently another autosomal recessive form of 'Complete CSNB' has been identified. This is a particularly common in females. The ON-bipolar-cell TRPM1 cation channel is the genetic defect (62). In this case the 15Hz rod flicker is similar to X-linked (*NYX* -/-) CSNB. Animal models of these defects are discussed above (see *Metabotropic responses of ON bipolar cells*).

6. Visual processing under mGluR6 blockade of the ON bipolar cells

Lateral geniculate and cortical neurons.

The responses of visual neurons in the central nervous system of primates have been investigated under conditions of ON-bipolar blockade using the metabotropic glutamate receptor agonist APB (DL AP-4). Recordings from the dorsal lateral geniculate nucleus (LGNd) indicate that light responses of ON-center geniculate neurons are completely blocked by APB (255, 256). ON-center geniculate cells are also blocked

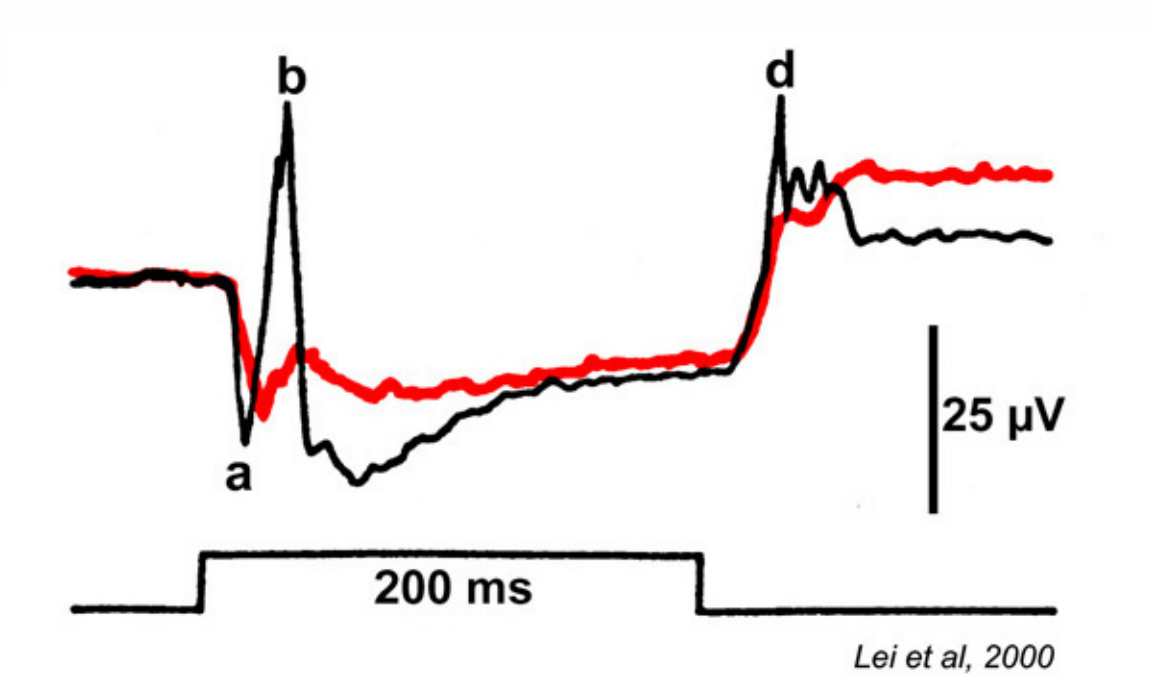

Figure 28. The ERG recordings are from a non-human primate model of melanoma-associated retinopathy (MAR), a disease sometimes associated with a primary cancer. The thin black trace represents a normal ERG with a, b and d waves. The red trace was recorded from an eye treated with an intravitrial injection of IgG from a patient experiencing MAR. There is a marked reduction in the b-wave. The illustration is from Lei et al, 2000 (245).

selectively in rabbit (257). Projection of retinal ganglion cells onto geniculate relay cells is selective for physiological types (258) so that ON and OFF pathways are preserved and can be selectively affected by retinal blockers.

Recordings of light responses of individual neurons in visual cortex suggest this is the site of final integration for ON and OFF bipolar-cell signals and their associated retinal neurons. Complex cortical cells continue to respond under APB blockade of ON bipolar cells, but leading edge responses to bright squares drifting through the receptive field are lost (255). The directional selectivity and orientation selectivity of these cortical cells appears unperturbed by the blockade (255). In a parallel study, monkeys under APB blockade were found to have much poorer perception of light increments than light decrements, but relatively unimpaired perception of simultaneous spatial contrast (259). Elimination of synaptic function for all ON bipolar types in mammals leaves a surprisingly functional visual system.

Dim light responses require ON bipolar cells

One common feature of rod-dominated mammalian retinas is the emergence of a single, ON-type bipolar cell for rods (64, 123, 124) dominated by the metabotropic, mGluR6, glutamate receptor and associated molecules. Pharmacological blockade of this pathway leads to physiological deficits in night vision. This is true behaviorally for both light increments and decrements (260), as well as for dim light responses in ON or OFF ganglion cells (205). Knockout of ON bipolar cell signals in mGluR6-deficient mice leads to loss of light sensitivity evident in the electroretinogram (31). As noted above ON bipolar cell diseases in humans are always accompanied by a loss of nocturnal vision. The secondary rod pathways that utilize either cone-system OFF bipolar cells or gap-junction pathways between rods and cones appear not to be involved in rod-mediated nocturnal vision, but rather it is rod-bipolar-cell metabotropic receptors that mediate dim light responses.

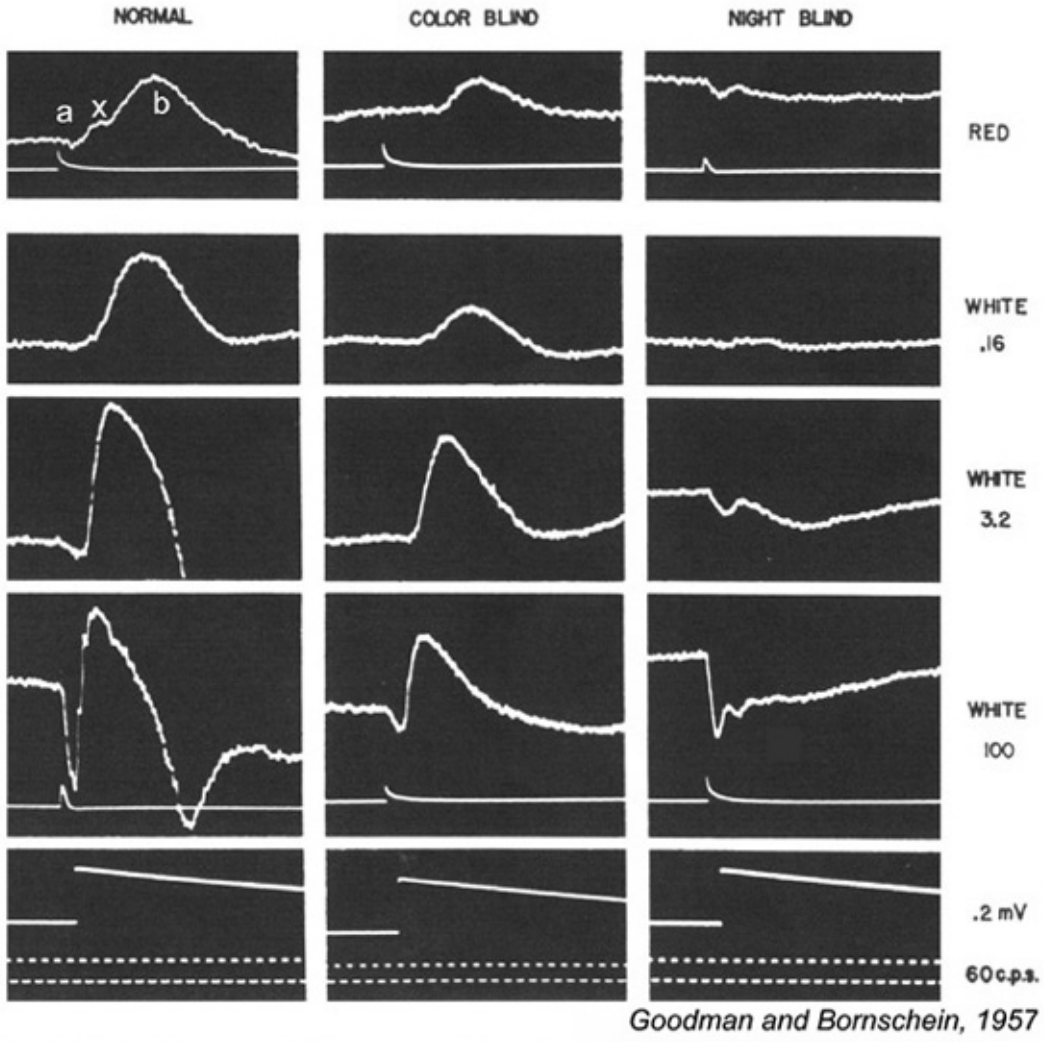

Figure 29. ERG responses from humans with a genetic retinal defect are compared to a normal subject. The color blind subject (middle column) lacks the x-wave, but has a normal b-wave and ON bipolar function. The night-blind subject (right) responds with an x-wave to red stimulation, but lacks a b-wave for any stimulation. An isolated a-wave appears with bright stimulation. The night blind subject is an early example of congenital stationary night blindness (CSNB).The illustration is from Goodman and Bornschien, 1957 (249).

7. Summary and conclusions

Bipolar cells are functionally crucial neurons that comprise the middle component of the vertical transduction pathway through the retina. ON- and OFF-type bipolar cells are presynaptic to similarly polarized ganglion cells in the retinal inner plexiform layer and can be distinguished by morphology, by light response, and by different types of dendritic glutamate receptor expression. These cells serve as models in which to examine different aspects of neurobiology, including embryological development, postsynaptic receptor systems, neurotransmitter release mechanisms, neural circuitry interactions, and visual system defects. ON and OFF bipolar cells initiate two functionally independent pathways, the ON and the OFF, each with center-surround organization, and each with a splitting into both transient and sustained signal types postsynaptic to bipolar cells. Each bipolar pathway is capable of independent image processing. The signals of ON and OFF bipolar cells are relayed separately to higher brain centers. ON bipolar cells appear selectively vulnerable to diseases, genetic defects, or pharmacological assault. Loss of ON bipolar cells results in a loss of nocturnal vision.

About the Authors

The biosketch for Ralph Nelson can be found in the About the Editors section of Webvision.

Victoria Connaughton, Ph.D. is an Associate Professor of Biology at American University in Washington DC. Born in Sellersville, Pennsylvania, Vikki earned a B. S. degree from Bucknell University and Ph. D in Marine Science from the University of Delaware, Lewes. She has been a postdoctoral fellow at the University of Texas, Houston in the Department of Neurobiology and Anatomy, and also at the National Institutes of Health where she continued studies of zebrafish retinal neuroanatomy and neurophysiology with co-author Ralph Nelson. Dr. Connaughton's current research interests encompass the disciplines of developmental biology (nervous system development) and neurobiology. Specifically, she is interested in examining the relation between visually-guided behaviors in larval teleosts and maturation of retinal neurons, circuits, and receptor mechanisms. She is also interested in examining how the development of neural connections can be altered due to mutations or drugs. She has performed experiments that address behavioral/ecological questions, as well as those that employ cell biology techniques to examine retinal circuitry in both developing and adult retinal tissue.

Retinal Neurogenesis

Early stages in the Development of Neurons and Pathways

Development of Cell Types and Synaptic Connections in the Retina

Josh Morgan and Rachel Wong

Created: May 1, 2005; Updated: May 29, 2007.

Introduction

Synaptic connections of the vertebrate retina are organized into distinct laminae (Fig. 1). In the outer retina, photoreceptors contact horizontal cells and bipolar cells within a single lamina, the outer plexiform layer (OPL). Within the inner retina, synapses between retinal ganglion cells and their presynaptic partners, the amacrine and bipolar interneurons, are localized to the inner plexiform layer (IPL). Connections between cells that are depolarized upon an increase in illumination (ON) occupy approximately the inner half of the IPL, whereas connectivity of cells hyperpolarized (OFF) by light is confined to the outer half of the IPL. What factors control the precision by which each cell type forms synaptic connections within the IPL and OPL are not completely understood. However, structural and functional studies have significantly improved our understanding of the mechanisms underlying retinal circuit development, aided in part by new technological advances.

Sequence of Circuit Assembly in the Vertebrate Retina

Ultrastructural studies (1-3) suggest that synaptogenesis between the major neuronal classes of the vertebrate retina occurs in three major phases (Fig. 2, illustrated for the mouse retina). Retinal ganglion cells and amacrine cells are the first cell classes to differentiate and form the earliest functional circuits in the IPL of the developing retina. Shortly after, horizontal cells and photoreceptors differentiate and contact each other in the outer retina, forming the OPL. The vertical networks in the inner and outer retina are later interconnected when bipolar cells are born and connections with ganglion cells are established. This sequential pattern of retinal circuit development is common across species, although the separation in time between inner and outer retinal circuit development varies, ranging from a few hours in animals such as the zebrafish to many days and weeks in mammals. The emergence of the IPL and OPL plexuses can be observed in the zebrafish embryo by *in vivo* time-lapse confocal imaging as visualized in Movie 1.

Structural Assembly

New Approaches

The morphology of the pre- and postsynaptic arbors of retinal neurons have been documented from Golgi staining many decades ago (4). These studies provided a wealth of information, not only aiding classification of distinct morphological cell types in the mature retina but also enabling visualization of the structure of their immature counterparts. More recently, fluorescent markers have been used to specifically label retinal cell classes and their subtypes. Cells can be targeted by intracellular dye filling methods using glass micropipettes (5, 6). This method leads to rapid labeling of the cell and its processes, within seconds to minutes. Intracellular dye filling has been used to visualize developing retinal neurons and remains a popular technique to determine their morphology at different ages.

Since its discovery, green fluorescent protein (GFP) has been used extensively as a live-cell marker. Its resistance to bleaching, compared with most fluorescent dyes, together with its lack of toxicity, make GFP ideal for studying how retinal neurons alter their structure in tissue explants or *in vivo*. GFP and its spectral variants can be expressed in retinal neurons either by transient transfection or in stable transgenic lines. To randomly label retinal neurons in explant cultures, a gene-gun can be used to deliver plasmids encoding GFP (7) (Fig. 3). Other color fluorescent proteins (FPs: yellow, cyan, red) can also be expressed this way. Electroporation can be used to

Download video

Alternatively, as cell type-specific promoters become increasingly available, labeling of retinal neurons in the developing and adult retina can be achieved by generating transgenic animals. For example, GFP expression is driven in cone photoreceptors in mice shortly after birth using the human L- and M-cone promoter (10) (Fig. 5). Also, a subset of bipolar cells expresses GFP in the gustducin-GFP mouse (11) (Fig. 5), and retinal ganglion cells are found to express fluorescent proteins under the Thy-1 promoter (12) (Fig. 5).

Zebrafish in which retinal neurons express fluorescent proteins have also been generated (Fig. 6). The major advantage for generating fluorescent proteins expressing transgenic lines is that structural development of the various retinal neuronal cell types can be followed in live tissue, or in the intact animal using time-lapse microscopy. The zebrafish, in particular, is highly suited for *in vivo* imaging because of its relatively rapid development and transparency during embryonic development. Details of how to image fluorescently labeled retinal neurons in zebrafish embryos is provided by Lohmann et al. (13).

Development of Pre- and Postsynaptic Processes

There are at least two features of the structure of retinal neurons that impact their connectivity and therefore the circuits that they form. The first relates to the lateral branching patterns of their axons and dendrites. The lateral organization of the pre- and postsynaptic arbors of retinal neurons determines the spatial coverage of the cell, and possibly the density of input and output that they form. The second, as mentioned earlier, is that the pre- and postsynaptic arbors of retinal neurons are highly restricted to laminae in the inner and outer retina. This laminar organization in structure reflects the connectivity between specific subsets of cells. Thus, one way to gain a better understanding of how retinal circuits form appropriately is to determine the mechanisms that regulate the lateral and vertical organization of the axonal and dendritic arbors of retinal neurons.

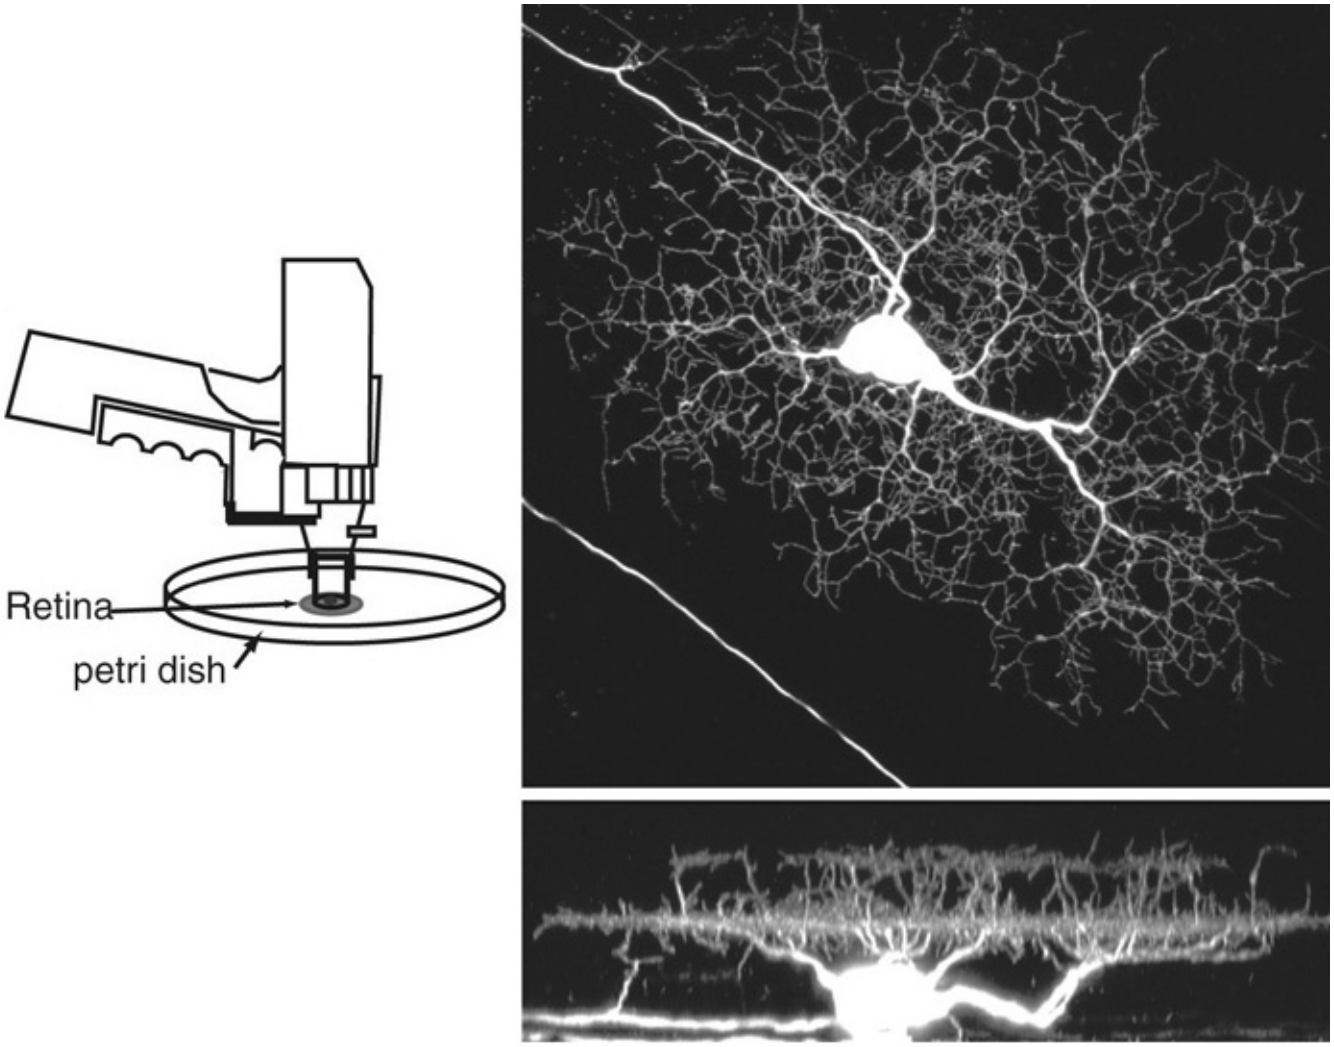

Figure 3. Biolistic delivery of plasmid encoding fluorescent protein by a gene-gun (diagram to the left) results in exquisite labeling of retinal ganglion cells in live, developing retina. Shown here is a YFP-expressing embryonic chick retinal ganglion cell.

Retinal Ganglion Cells

There are many types of retinal ganglion cells, each with characteristic branching patterns, arbor size, and amount of overlap with neighbors of the same subtype. Both intrinsic and environmental cues appear to shape the branching patterns of retinal neurons, at least for ganglion cells (reviewed in Sernagor et al. (14)). When retinal ganglion cells are isolated in culture without contact with other cells, they elaborate a dendritic arbor that is complex in branching and resembles cells *in vivo*. Stereotypic organization of the branching patterns of the various cell types (for example, alpha cells and beta cells in the cat retina) also argue that cell intrinsic mechanisms help define their branching patterns.

However, the shape and size of the ganglion cell dendritic arbor changes when the density of neighboring ganglion cells is altered during development (Fig. 7). Laser ablation or axon section results in a local lesion depleted of retinal ganglion cells (15). This manipulation results in cells at the edge of the lesion projecting their dendrites into the ganglion cell-free region. Experimental manipulation of eye size that causes an increase in the spacing between cells is paralleled by an increase in their arbor size (16). However, for certain subtypes of ganglion cells in the mouse retina, a reduction in ganglion cell density does not affect the size and patterning of their dendritic arbors (17). These differences raise the possibility that the balance between cell-intrinsic and cell-

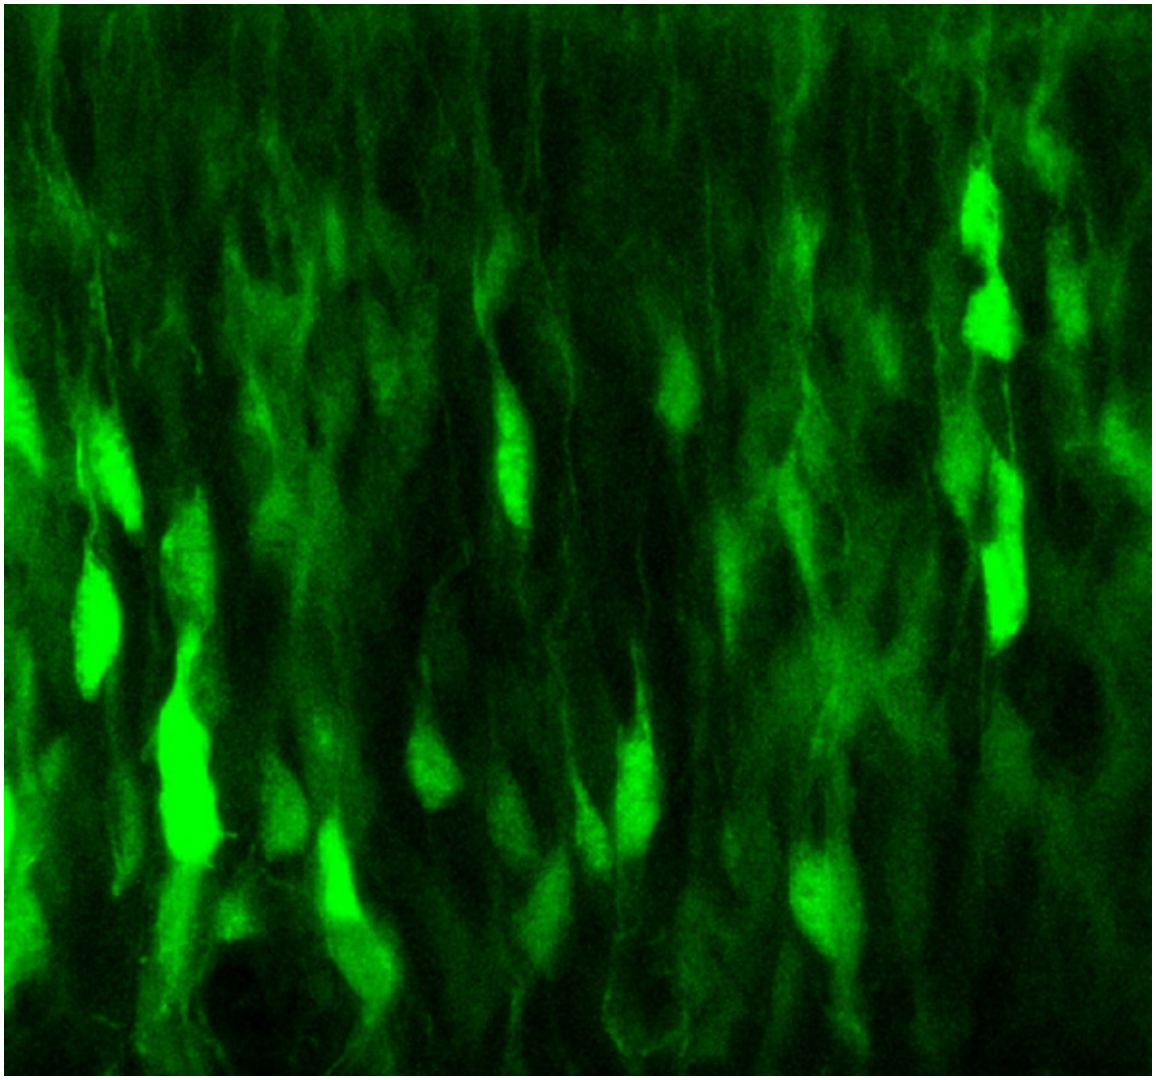

Figure 4. Retinal cells are labeled by GFP expression *in vivo* using electroporation methods. Shown here is a cross-section of a neonatal mouse retina (provided by Mike Dyer).

extrinsic cues in shaping the lateral organization of ganglion cell dendritic arbors may vary from one cellular subtype to another, or perhaps even across species.

If cell–cell interactions influence the branching and territorial size of ganglion cell dendritic arbors, what might be the signals? One way to address this is to better understand the dynamic behavior of ganglion cell dendrites during the period when their branching patterns and territories are established. Time-lapse imaging experiments of developing chick and mouse retinal ganglion cells reveal that dendritic branches are both added and eliminated over time, before the adult branching patterns are attained. Dynamic alterations to the dendritic territory upon branch addition and loss can be appreciated in Movie 2.

What cellular mechanisms might neurotransmission evoke to regulate dendritic branching in retinal ganglion cells? Live-imaging studies of embryonic chick retinas reveal that ganglion cell dendritic stability is calcium dependent. In low extracellular calcium, the dendrites of retinal ganglion cells retract (Fig. 8). Dendritic retraction can be locally controlled by calcium-induced calcium release (CICR) from intracellular stores (18). Spontaneous CICR is observed in small dendritic segments during calcium imaging of immature retinal ganglion cells. The pathways that CICR activates to stabilize the dendritic cytoskeleton remains to be determined. One possibility is that transmission from presynaptic terminals causes local CICR that then stabilize

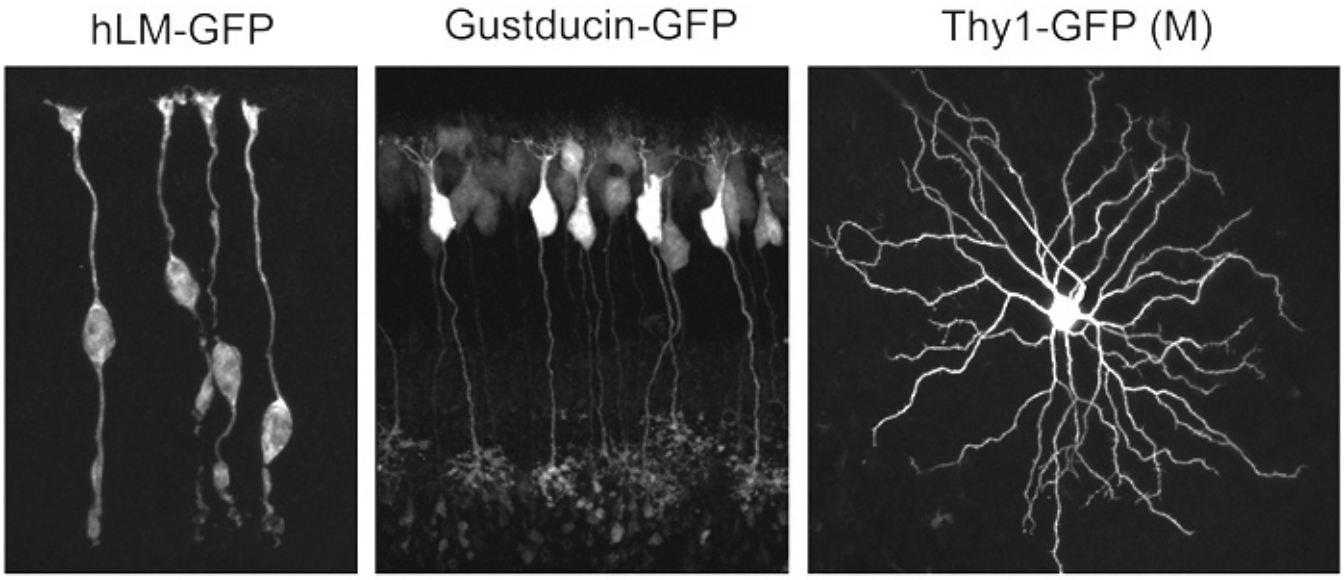

Figure 5. Examples of GFP-expressing retinal neurons in stable transgenic lines. Cone expression is driven by the human L- and M-opsin promoter (image provided by Rachel Huckfeldt); a subset of bipolar cells express GFP under the gustducin promoter, and a ganglion cell in the Thy-1-GFP M-line.

the contacted dendritic segments (18). Future time-lapse imaging experiments are needed to directly address whether nascent synapses stabilize dendrites of retinal ganglion cells upon contact, as has been demonstrated in zebrafish tectal neurons (19).

What factors shape dendritic stratification of retinal ganglion cells during development? In mammals, retinal ganglion cells initially project dendrites throughout the depth of the IPL (Fig. 9). Stratification occurs progressively and becomes precise by maturity (Fig. 9). Some insight into what mechanisms underlie ganglion cell dendritic stratification was gained by early studies where intraocular injections of 2-amino-4-phosphonobutyrate (APB, a mGluR6 receptor agonist) prevented the emergence of stratified alpha and beta ganglion cell dendritic arbors in cat (20, 21) and ferret (22) retina. Thus, neurotransmission may be involved in sculpting the final arrangement of ganglion cell dendrites. This is supported by pharmacological studies in turtles and chick, whereby blockade of cholinergic or glutamatergic transmission, respectively, resulted in ganglion cells with relatively smaller and less branched arbors (7, 23).

Amacrine Cells

How immature amacrine cells elaborate their processes after neuronal differentiation has been described by Golgi (24) and electron microscope (25, 26) studies a few decades ago. From observations of retinas fixed at different ages, it is thought that cells in the differentiating inner nuclear layer that are multipolar in shape are immature amacrine cells. Such cells extend neurites in many different directions before reaching the border of the INL and IPL. Thereafter, amacrine cells elaborate processes within the IPL to form their arbors (Fig. 10).

Time-lapse studies of amacrine cells labeled by expression of fluorescent protein in stable transgenic zebrafish lines have provided some insight into the lamination of amacrine cell neurites (27). In a transgenic line in which subpopulations of ON and OFF amacrine cells express GFP, it is possible to visualize the emergence of a plexus of processes from these amacrine cells (see Movie 1). Initially, it appears that GFP-positive amacrine cell processes contributing to the nascent IPL are diffusely arranged, because no sublamination is observed. However, over time, two distinct bands of bright fluorescence resolve, corresponding in depth to sublamina **a** (OFF) and sublamina **b** (ON) of the IPL. To determine how individual amacrine cells target their appropriate sublamina during development, it will be necessary to visualize and follow the development of individual

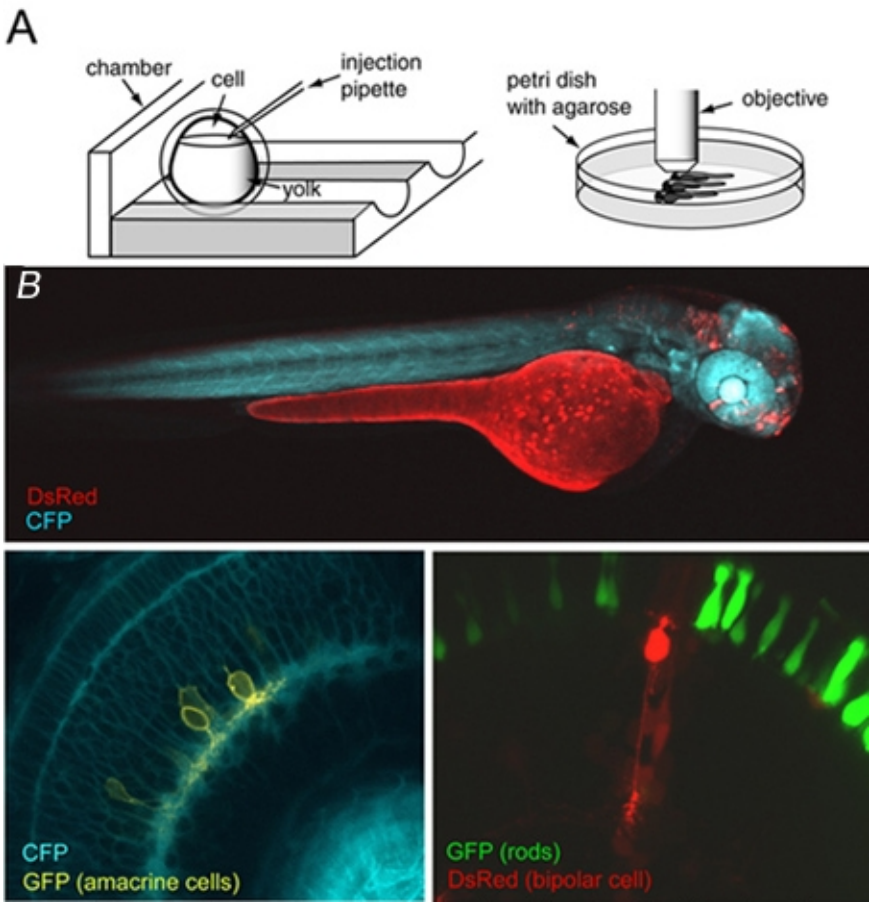

Figure 6. (A) Transient expression of fluorescent proteins is attained in zebrafish embryos by injection of plasmid into the fertilized egg at the one-cell stage. (58).

amacrine cells over time *in vivo*. This is because it is impossible to differentiate between closely apposed, but segregated, arbors in the IPL from arbors that are intermingled in depth.

It is evident that even after amacrine cell neurites have attained their correct sublamination, their arbors still undergo significant reoroganization in the lateral dimension before achieving their mature form. Starburst amacrine cells in the mammalian retina show a distinctive radial morphology early in development, but their detailed branching pattern alters with maturation. Similar to retinal ganglion cells, the morphological changes primarily involve the loss of small protrusions and the emergence of bouton-like structures at the distal branches (28) that, in the mature cell, are sites of presynaptic transmitter release (see chapters on amacrines and neuroactive substances).

What factors influence the development of amacrine cell neurites? First, it is evident that retinal ganglion cells, although a major postsynaptic target of amacrine cells, are not required for lamination of amacrine cell arbors. Optic nerve section in rodents that leads to ganglion cell death does not alter the stratification of starburst amacrine cells (reviewed in Chalupa and Gunhan (29). In mutant animals in which ganglion cells do not differentiate (Math5 knockout mice (30, 31) and the zebrafish lakritz mutant), amacrine cell lamination also occurs (Fig. 11). Because bipolar cells differentiate only after amacrine cell lamination has taken place, it is unlikely that these neurons influence the initial stratification of amacrine cells. It is possible that interactions

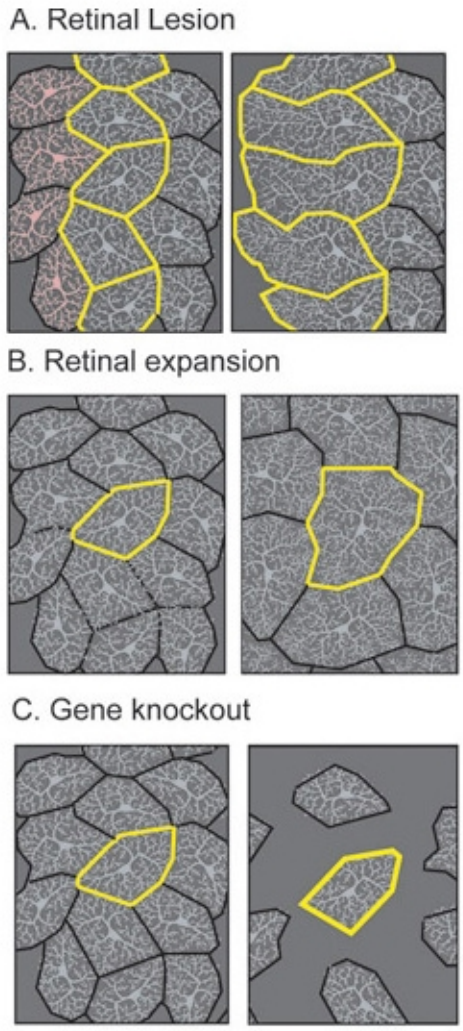

Figure 7. Schematized organization of dendritic territories of retinal ganglion cells under various conditions of manipulation. (A) Pink cells are lesioned by a laser (15). between amacrine cells that are specific to each subtype result in the formation of their separate laminae. Alternatively, lamination cues may arise from Muller glial cells or their precursors. Such cues may be diffusible, creating a gradient of permissive or repulsive factors with retinal depth, or are contact mediated. Because amacrine cells express neurotransmitters even before their cell bodies reach the INL/IPL border, it also remains plausible that communication between these cells via secretion of transmitters influences their arborization. Mutant animals in which specific forms of neurotransmission are absent would help address this possibility.

Bipolar Cells

Axo- and dendrogenesis of bipolar cells are not well understood because of the lack of markers for these cells early in development. However, Golgi studies of the chick retina suggest that the axonal and dendritic arbors of developing bipolar cells elaborate from vertical processes terminating in the inner and outer limiting membranes (32) (Fig. 12). The use of cell-specific markers to identify bipolar cells would further test this model of bipolar cell development.

Stratification of the axonal arbors of bipolar cells may be influenced by interactions with amacrine cells. AII amacrine cells, which are the postsynaptic targets of rod bipolar cells, have a bistratified arbor, each with

stereotypic morphology. The outer arbor (OFF sublamina) comprises lobular appendages, whereas the inner arbor (ON) is finely branched (see chapter on AII amacrine cells). AII amacrine cells express Disabled1, an adaptor protein involved in the reelin pathway (33). In the reeler mouse in which reelin is absent, the distribution of lobular and non-lobular appendages of the AII amacrine cells is imprecise. Likewise, some rod

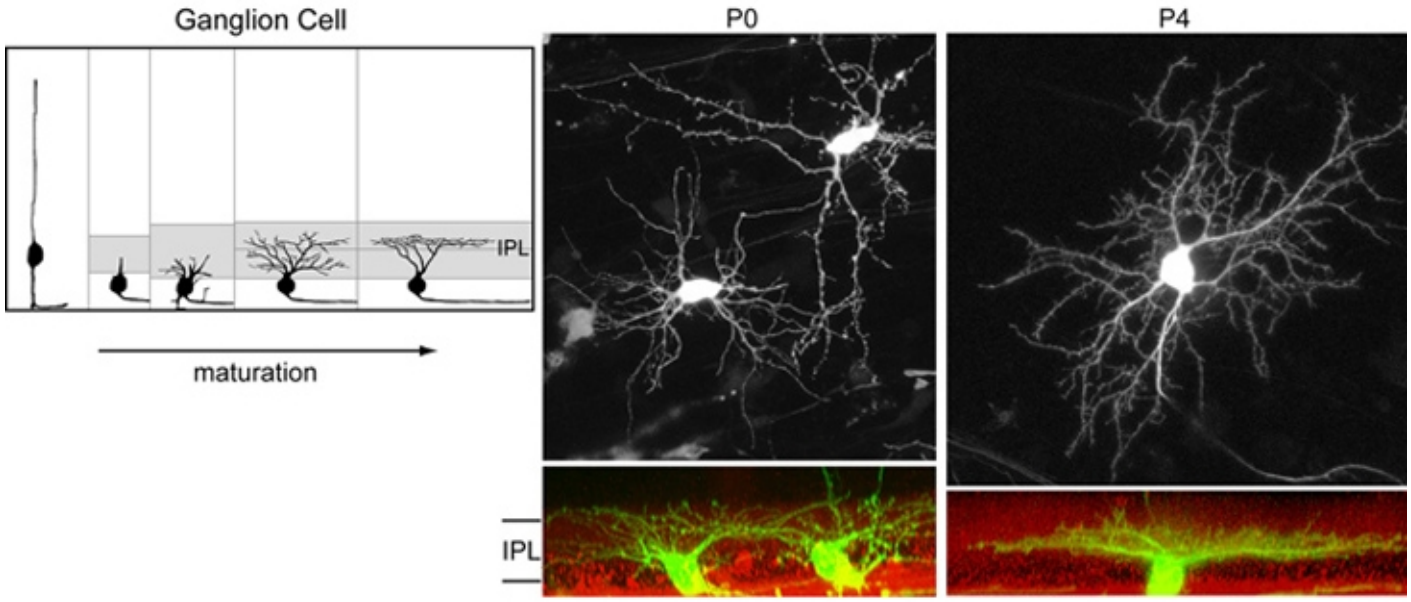

Figure 9. (left) Proposed sequence of dendritic development of mammalian retinal ganglion cells. (right) Labeling of mouse retinal ganglion cells at birth (P0) and at P4 demonstrates that initially, the arbors of these ganglion cells are unstratified. The depth of the IPL is judged by reflected light microscopy (red regions). The distribution of dendrites (green) with depth is best observed in the orthogonal rotations of confocal optical stacks encompassing the arbors, shown below the whole-mount images of the cells.

bipolar cells are found to have axonal stratification defects (Fig. 13). Also in the lakritz mutant, bipolar axonal terminals are similarly perturbed in their organization in local regions of disrupted amacrine cell lamination (Fig. 13). ON and OFF bipolar cell lamination persists in the absence of ganglion cells (30, 31, 34). Together, these observations raise the possibility that amacrine cells, rather than ganglion cells, provide lamination cues for bipolar axon terminals.

Horizontal Cells

Early Golgi studies and immunolabeling for GAD67 (35), one of the two synthetic enzymes for GABA, suggest that horizontal cell processes undergo dramatic progression from a radial to lateral organization during development (Fig. 14). Horizontal cells achieve this lateral organization in the absence of cone photoreceptors (36). However, abnormal lamination patterns in horizontal cells are observed in the Rb mouse during development in regions where rods are absent (37).

In the mature retina, horizontal cells do not contact cones uniformly within their dendritic fields. The number of dendritic terminals (Fig. 15A, examples of terminals) that contact cones decreases as a function of distance from the cell body (Fig. 15B). Interestingly, in developing horizontal cells, the number of terminals does not vary greatly with distance from the cell body. Because the overlap of dendritic fields of neighboring horizontal cells is relatively unchanged after birth in the mouse, horizontal cells appear to lose peripheral terminals but gain central terminals with maturation (Fig. 15B). The terminal branching pattern of horizontal cell dendrites is altered in the coneless mouse (36) (Fig. 15C). This suggests that contact with cones is either important in the initial organization, or in the maintenance, of these structures.

Photoreceptors

Structural changes in the morphology and axonal targeting of photoreceptors have been assessed using immunolabeling methods (schematized in Fig. 16A). In a variety of species, these studies reveal that the terminals of a large number of rods (80% of the population) and some cones project beyond the forming OPL,

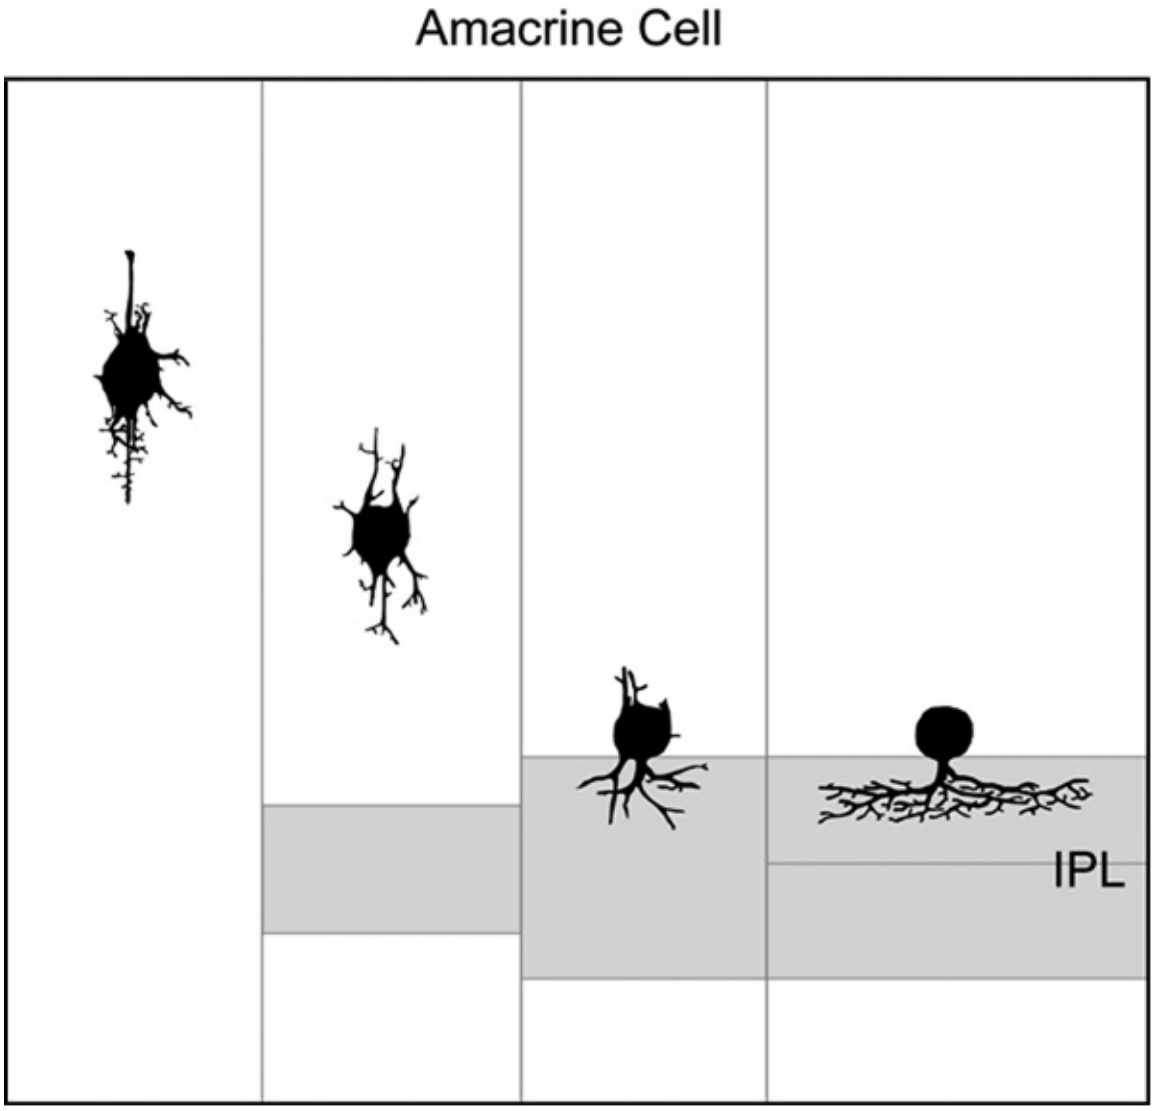

Figure 10. Proposed sequence of amacrine cell neurite development from serial EM studies (25).

reaching the IPL (38) (reviewed by Reese (39)) (Fig. 16). With maturation, all photoreceptor terminals become restricted to the OPL. The transient projection of photoreceptor terminals to the IPL is not perturbed when retinal ganglion cells are ablated. However, pharmacological deletion of amacrine cells, for example with VAChT-saporin, results in these photoreceptor terminals ending at various depths of the IPL, and even extending into the GCL. This implicates the amacrine cells as targets of the immature photoreceptor terminals (40) (Fig. 16).

Functional Assembly

New Approaches

Physiological properties of developing retinal neurons have often been assessed at the single-cell level using patch clamp, intracellular and extracellular recording methods. Simultaneous recording from large populations of developing retinal neurons became possible upon the development of multielectrode arrays (41) and advances in optical imaging methods (reviewed in Morgan et al. (42)). Both approaches have been used to assess activity patterns of retinal networks during development.

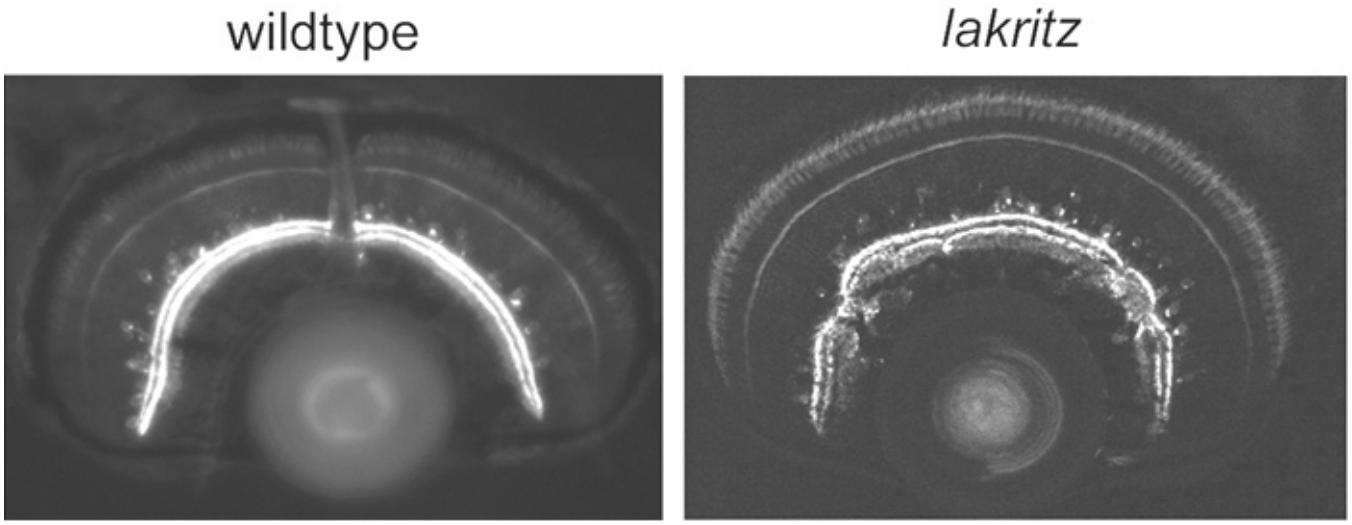

Figure 11. Sublamination of amacrine cell neurites is still apparent in the absence of retinal ganglion cells, as evident in the lakritz zebrafish retina (reprinted from Kay et al. (27).

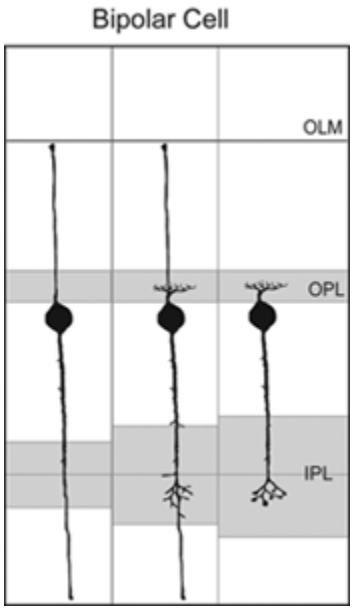

Figure 12. Proposed sequence of development of bipolar cell axons and dendrites from Golgi studies.

Multielectrode recording planar electrode arrays with 60 or more extracellular electrodes permit simultaneous recordings from tens of ganglion cells (Fig. 17) (see Movie 3). However, because they are extracellular recordings, it is not straightforward to determine which cells within the sampled area are associated with spike trains detected at each electrode site. These arrays are commercially available from several sources. Shown is an example of an array from multichannel systems used for recording spikes from the developing retina (43, 44).

Calcium Imaging

Calcium imaging approaches have been used to assess retinal neuronal activity at the single-cell level and to simultaneously monitor intracellular calcium levels in populations of cells (see chapter on retinal development by Marla Feller). The use of calcium indicator dyes is widely documented (see Lohmann et al. (45) for a detailed description of the methodology). Both membrane-permeant forms of indicators as well as genetically encoded

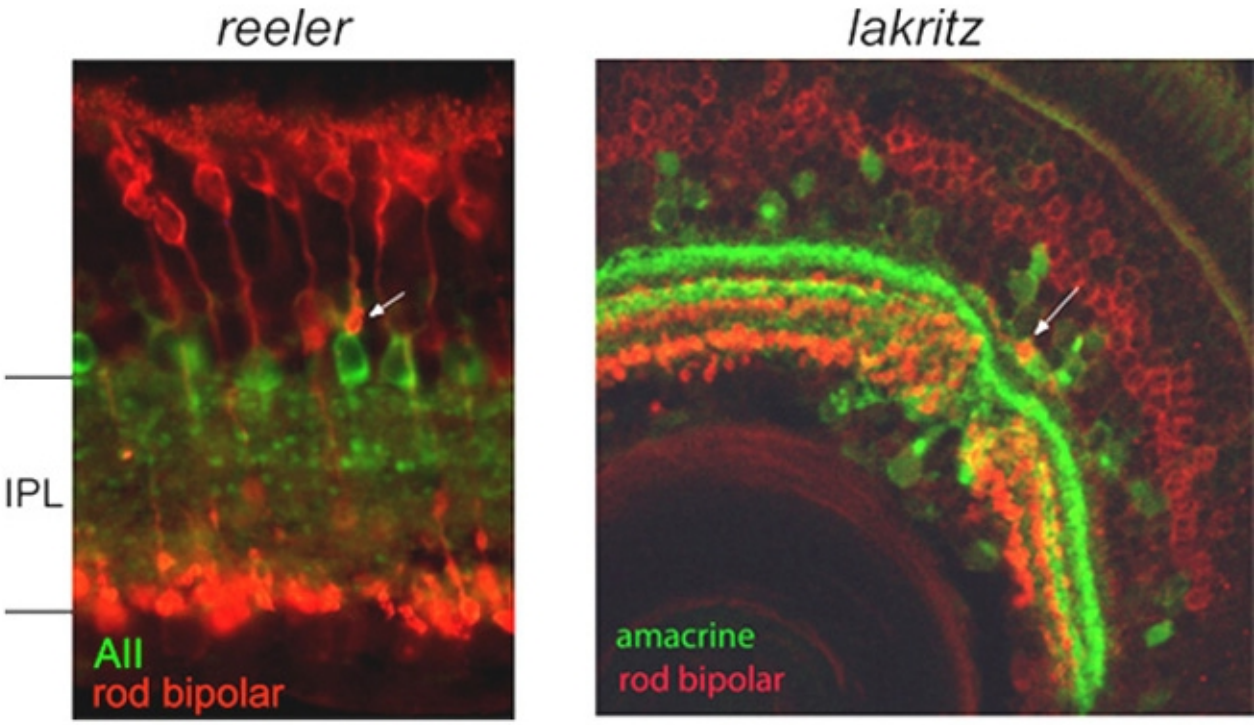

Figure 13. Bipolar cell axonal stratification is affected in the reeler mouse (left) and lakritz (right) zebrafish mutant at regions where amacrine stratification is disrupted (e.g., arrow). Image of cross-section of reeler retina provided by Dennis Rice, and lakritz retinal section reprinted from Kay et al. (27).

indicators are available and have been used successfully. Shown in Movie 4 is an example of spontaneous activity in an embryonic chick retina, showing elevations in intracellular calcium levels as there is increase in fluorescence intensity. The calcium levels elevate across the array in a wave formation. Ballistic delivery of calcium indicators can be used to actually visualize the processes of individual cells (18).

Development of Synaptic Connectivity

Functional drive onto retinal ganglion cells is first observed shortly after conventional synapses are present in the IPL, as assessed by electron microscopy. During this period of development, spontaneous excitatory postsynaptic currents (EPSCs) are detected in retinal ganglion cells and amacrine cells. These excitatory currents are mediated by acetylcholine, GABA, or glycine (14), transmitters used by amacrine cells. As in other parts of the CNS, GABA is depolarizing to retinal ganglion cells before the appearance of glutamatergic drive. Spontaneous glutamatergic drive is first observed in the mouse retina around P7, when bipolar terminals are clearly present in the IPL (46). Whether photoreceptors transiently projecting to the IPL provide glutamatergic drive to inner retinal neurons is not known, although it is suggested by the presence of synaptophysin-positive terminals (39).

Fig. 18 summarizes the time-line of key events associated with circuit development in the developing mouse retina.

Spontaneous Activity

Prior to vision, the inner retina generates a pattern of activity that is unique to the developing retina. Neighboring retinal ganglion cells exhibit rhythmic bursting activity that is correlated by propagating waves (reviewed in Wong (47)) (see Marla Feller's chapter). These waves are visualized by calcium imaging and are also

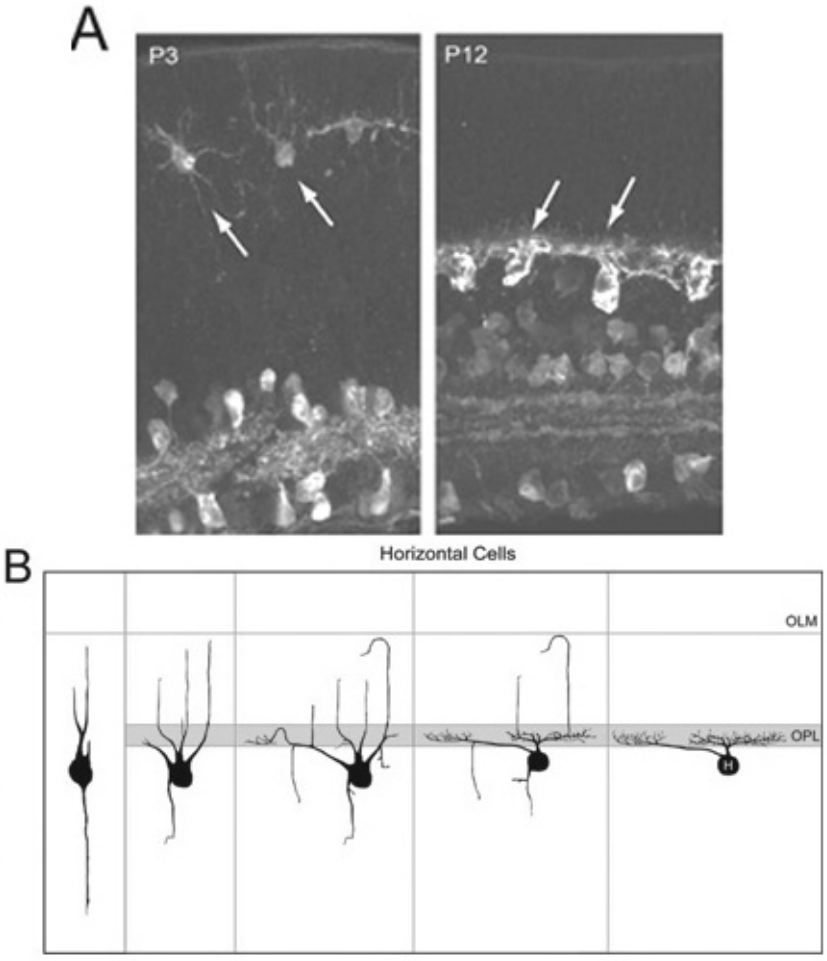

Figure 14. Horizontal cells (arrows) undergo dramatic remodeling of their processes during development, as visualized by immunolabeling for calbindin in the neonatal mouse (A) retina, and illustrated in the schematic diagram (B). OLM = outer limiting membrane; OPL = outer plexiform layer.

detected using multielectrode arrays (see Movie 3). Retinal waves disappear shortly after eye-opening (Fig. 19). The properties and significance of these retinal waves are discussed in the chapter by Marla Feller. Although there is increasing evidence for a role of waves in the refinement of connectivity between the retina (48) and its central targets, their role in shaping intra-retinal circuits, although possible, remains to be determined.

Light Responses

Emergence of ON *versus* OFF Responses

Immunolabeling studies show that VGlut1, a vesicular glutamate transporter, first appears in the axonal terminals of OFF bipolar cells, before being present in ON bipolar cells (49). This would suggest that the OFF pathway may become functional somewhat earlier than the ON pathway. However, immature amacrine cells in the developing rabbit retina show a predominantly ON response to light (50). Thus, to further ascertain whether ON and OFF transmission matures at different rates, it is necessary to record spontaneous glutamatergic currents and visual responses from identified ON and OFF retinal ganglion cells during development.

At the stage when ferret retinal ganglion cells are still diffusely unstratified, they are found to respond to both increments and decrements in light intensity (51). In mouse, multielectrode recordings show that a higher proportion of units sampled have ON-OFF responses during development, compared with the adult (52). Thus,

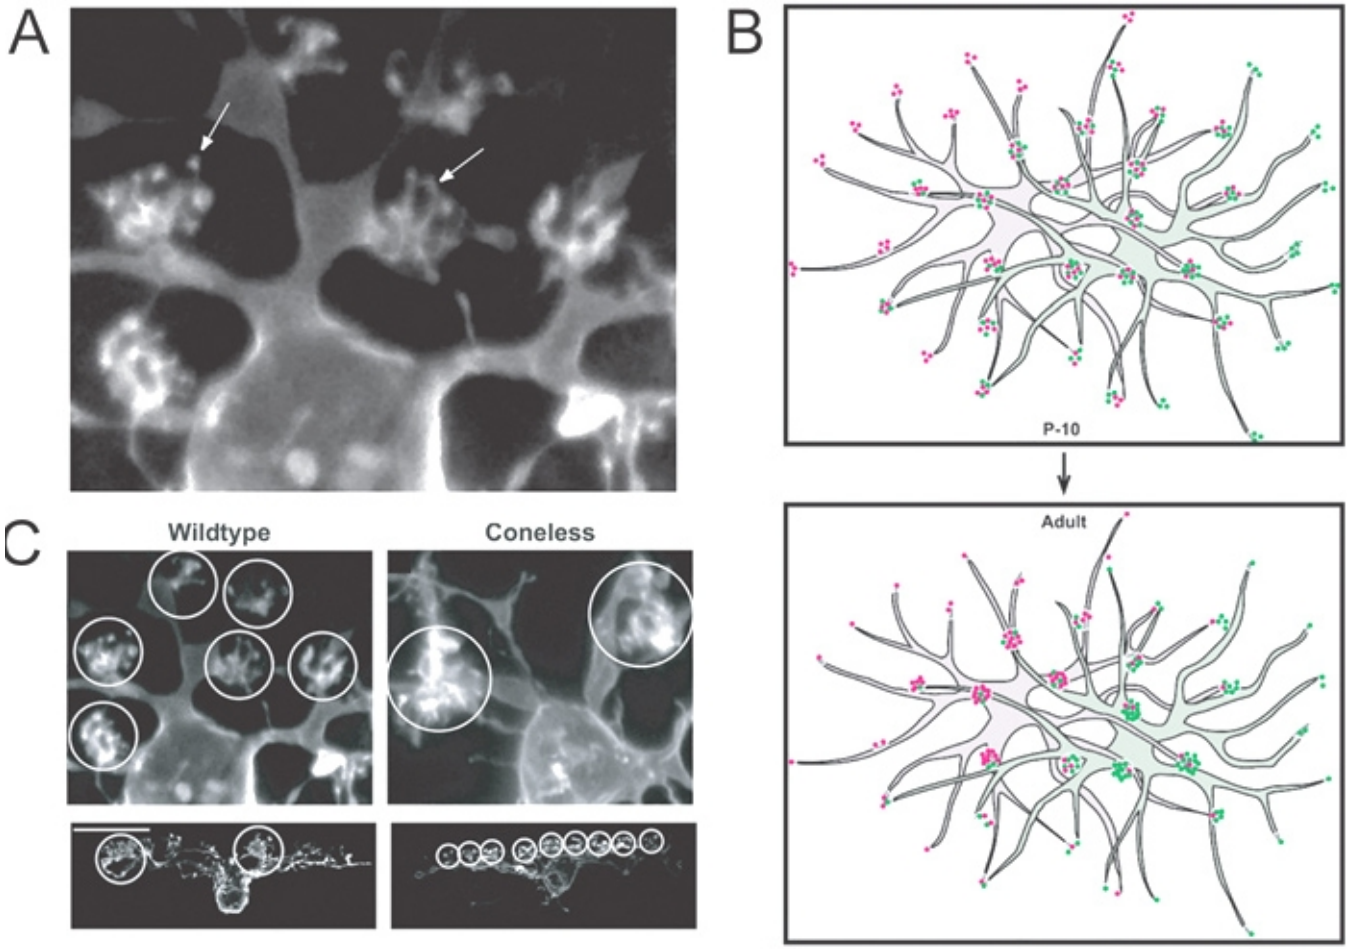

Figure 15. Development of horizontal cell terminals. (A) DiI labeling of a mouse horizontal cell, showing terminals that contact cone photoreceptors. (B) Developmental rearrangements in the organization of terminals across the arbor. (C) Dendritic terminals of horizontal cells are abnormal in the coneless mouse. Images provided by Ben Reese.

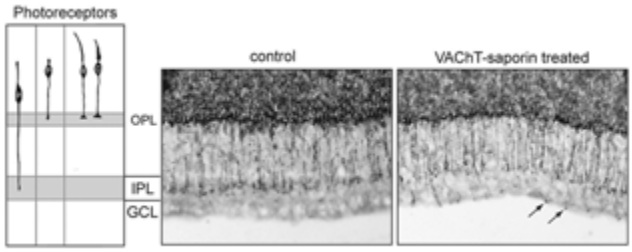

Figure 16. Structural development of photoreceptor axonal terminals. In ferret, the axonal terminals of recoverin-positive photoreceptors reach the IPL. Treatment with VAChT-saporin that kills cholinergic amacrine cells results in overprojection of these terminals into the GCL. OPL = outer plexiform layer. Images provided by Ben Reese (unpublished data).

it appears that significant refinement of ON and OFF bipolar axonal projections to the retinal ganglion cells occurs during maturation of the mammalian retina. One set of projections becomes dominant, and the other is eliminated. In addition to preventing dendritic stratification of retinal ganglion cells, intraocular injections of APB also results in a higher incidence of ON-OFF cells in the cat retina (20). Because APB suppresses spontaneous activity of both ON and OFF ganglion cell subtypes during development, how chronic treatment with this glutamate analog might affect the maturation of ON and OFF connectivity is not yet known.

Emergence of Receptive Fields

In vivo recordings from cat retina show that center-surround organization of receptive fields is apparent as soon as light responses are detected (53). Unlike the mature retina, however, receptive field center sizes appear larger than dendritic field size during development (53). In contrast to ganglion cells, the surrounds of rabbit bipolar cells appear after receptive field centers are clearly present (54).

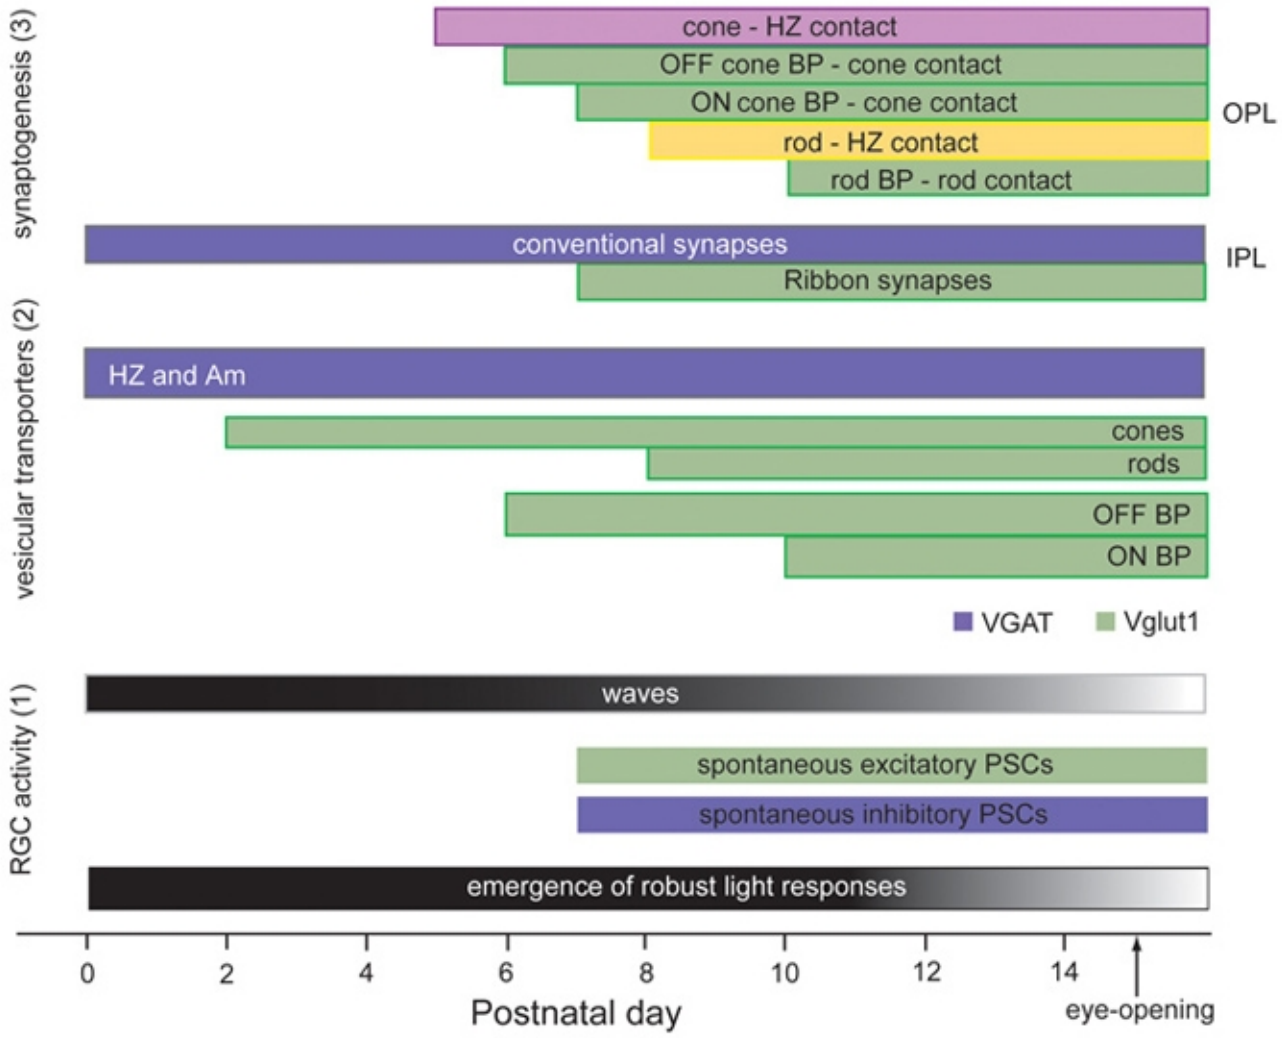

Figure 18. Summary of key physiological events during circuit assembly and maturation in the mouse retina. References for: ROC activity (46, 47);vesicular transporters (46, 49); synaptogenesis (1-3).

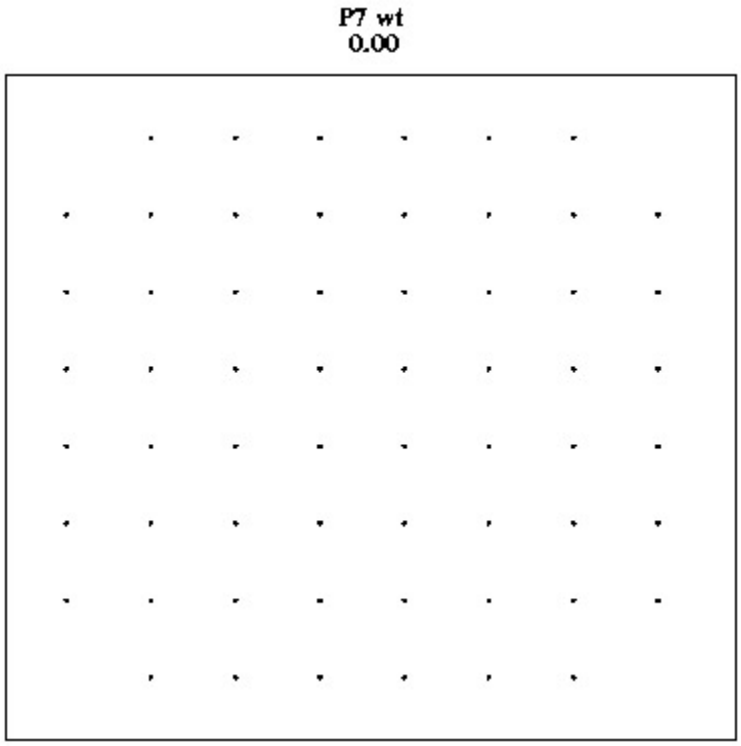
Specialized receptive field properties, such as direction-selectivity, can be detected before eye-opening in the rabbit retina (55). Recordings from the developing turtle retina, however, suggest that ganglion cells initially have "anisotropic" receptive fields, with more "isotropic" fields emerging only with maturation (56) (Fig. 20).

Influence of Light in Shaping Receptive Field Properties

Multielectrode recordings in the mouse retina suggest that light stimulation is necessary to facilitate the age-related loss of ON-OFF ganglion cells with maturation (52). Dark-reared mice, until about 3 weeks after birth, have an increase in the fraction of bistratified, ON-OFF ganglion cells in the retina (Fig. 21). This observation would suggest that interactions between bipolar cells and the retinal ganglion cells, or amacrine cells, act to fine-tune the extent of convergence of the vertical pathways onto an individual ganglion cell. This study also underscores the ability of retinal circuits to undergo reorganization, physiologically and structurally, after eye-opening.

Experiments in the turtle retina also implicate light stimulation in prolonging the period of spontaneous wave activity. This in turn affects receptive field maturation (57). Dark-rearing causes an expansion of receptive field size; however, this expansion is prevented when cholinergic-driven spontaneous activity is blocked.



Movie 3. A movie of multielectrode array recording from a week-old mouse retina. Each dot represents the location of an electrode site. The size of the dot is proportional to the firing rate. A wave of activity can be seen to propagate cross the array. Time in seconds.

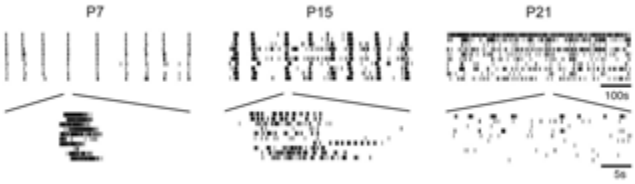

Figure 19. Examples of spontaneous activity patterns in the neonatal mouse retina recorded in the dark using a multielectrode array (Fig. 17). At each age, spike rates are shown for 10 representative cells at two different time scales. Correlated bursting activity is evident at postnatal day (P7) and gradually disappears with maturation. For details, see Demas et al. (43).

Summary

Much remains to be determined as to how retinal circuits are assembled precisely. Because the retina comprises a large diversity of cell components and numerous circuits, determining the cellular and molecular mechanisms regulating its wiring is a challenging task. Nevertheless, as retinal subcircuits with defined visual properties become identified (such as the direction-selective circuit), elucidating the developmental mechanisms regulating their assembly should become more tractable. Combined electrophysiological and anatomical techniques are necessary, and with rapid advancement in both approaches, it is likely that significant progress will be made in the near future.

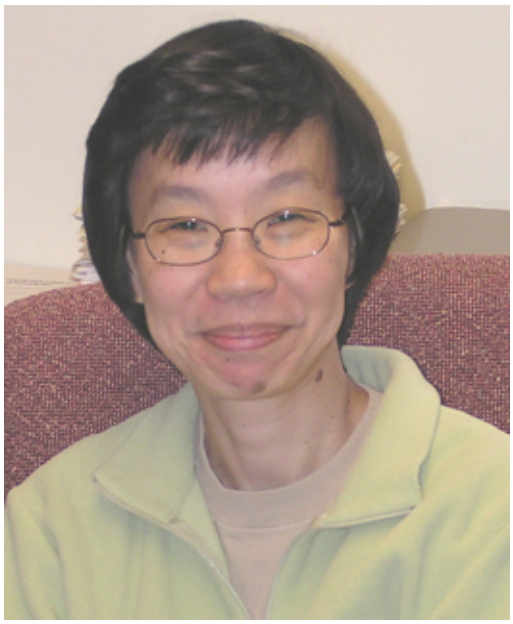
About the Authors

Josh Morgan received his B.A at New College of the University of South Florida with an area of concentration in neurobiology. He is currently a graduate student in Rachel Wong's lab in the Anatomy and Neurobiology Department of Washington University in St. Louis. He expects to spend his life imaging neural circuit development and has focused his graduate work on studying the development of bipolar cells, retinal ganglion cells, and the connections between the two.



Rachel Wong obtained her PhD from the Australian National University, Canberra, Australia, in Visual Neuroscience under the mentorship of Abbie Hughes. She then worked in the laboratory of Carla Shatz at Stanford University, focusing on early activity patterns of the retina together with Markus Meister and Denis Baylor. Subsequently, Rachel moved back to Australia to join the Vision group in the Vision, Touch and Hearing Research Centre, University of Queensland. From 1994-2010, she joined the Department of Anatomy and Neurobiology at Washington University School of Medicine, St. Louis. Now she is Professor of Neurobiology in the Department of Biological Structure, University of Washington, Seattle. Research interests concern how

neural circuits are developed in the vertebrate visual system using mice and chick retinas and now examining by in vivo analyses, the development of synaptic layers in the zebrafish retina.

Formation of Early Retinal Circuits in the Inner-Plexiform Layer

Kevin Ford, PhD[1] and Marla Feller, PhD[1]

Created: May 1, 2005; Updated: January 16, 2012.

1. Introduction

The mammalian retina has long been a model system for study of development of neural circuits in the CNS because the adult network is well organized into cell-type specific layers, and the anatomy, physiology and function of many of the retinal cell types is well characterized. A major focus of research in the retina is directed toward understanding how functional circuits arise during development.

The development of the retina requires several steps. The first step is to create the right proportion of the 7 cell types that comprise the retina. This process occurs primarily through genesis of the correct number of each cell type. Only ganglion cells have their final number regulated by cell death, which reduces the number of ganglion cells by as much as 50% in some species. The second step is for cells to migrate into the correct location. The third step is for neurons to form synaptic connections with other retinal neurons. Finally, for some of these groups of synaptically coupled cells, synaptic refinement is necessary to generate the circuits that comprise the adult retina.

The process of neuronal migration in the retina has been the focus of developmental biologists since the time of Cajal, who used Golgi staining techniques (Fig. 1). Progenitor cells in the neurepithelium lining the surface of the neural tube later become the ventricular zone of the optic vesicles, optic cup and early retina. Postmitotic cells leave the ventricular zone to migrate to one of three cell layers in the retina remaining attached radially from one side of the retina to the other. The neural cells lie at different levels in the retina and, when in correct position, lose their anchoring radial connections. Then polarity of the differentiating cells occurs and dendrites and axons grow out appropriately. The ganglion cells are the first to emerge as recognizable neurons with axons passing to the optic nerve and central brain structures (Fig. 1a and b). Then amacrine cells (Fig. 1c), Müller cells, bipolar cells (Fig. 1d), and horizontal cells form in the correct layer and finally photoreceptors remain to line the top layers (Fig. 1e and f).

Before the neural circuits that underlie visual processing emerge, the retina assembles and disassembles a series of intermediate circuits. These transient connections between cells produce the propagating spontaneous activity that is termed retinal waves (1-3). As the retina develops, so do the circuits that underlie retinal waves. The earliest spontaneous retinal waves are propagated via electrical coupling between cells. Then, around birth in mice, waves are produced by a transient network consisting of cholinergic connections between amacrine cells. Finally, just before visual processing begins, they are driven by early glutamatergic signaling.

In this chapter we will discuss how these transient circuits of the inner plexiform layer (IPL) assemble to produce specific patterns of neural activity, and how they transition from one circuit into the next. Finally, we will discuss the role of spontaneous activity in shaping the development of the visual system within both the retina and the brain.

2. Neurotransmitters and Early Retinal Development

Early in development, neurotransmitters can function in the absence of traditional synapses (4). Ultrastructurally identified conventional synapses within the IPL are first formed a few days after birth in mice (5). However, even before that there is evidence of neurotransmitters. Below we discuss the role of early neurotransmitters and their receptors prior to the formation of circuits that mediate vision.

Acetylcholine

Acetylcholine (ACh) signaling plays a key role in the development of the retina. Prior to synapse formation, paracrine action of ACh is essential for regulating early developmental events, such as the regulation of the cell cycle (6) and the growth of neurites (7). In addition, cholinergic synapses are among the earliest to mature and thereby constitute the earliest functional circuits in the retina.

ACh in the retina is produced solely by one cell type, the starburst amacrine cell (SAC), a type of amacrine cell named for its radially symmetric processes (8). In the mature retina, released ACh acts on both muscarinic and nicotinic receptors to modulate the response properties of many different types of ganglion cells (9-13), but it does not affect the SACs themselves (14). However, during development, cholinergic signaling does occur between SACs (14). During the first week after birth in mice, ACh released from SACs activates nicotinic acetylcholine receptors (nAChRs) on neighboring SACs and thus gives rise to a cholinergic network. A key developmental function of this cholinergic network is the generation of retinal waves. This network appears at birth in mice and mediates the initiation and propagation of waves.

Aside from the effect ACh has on ganglion and amacrine cells via nicotinic acetylcholine receptors, it also acts on the muscarinic acetylcholine receptors (mAChRs) of many cells in the neuroblastic layer (15, 16) (Fig. 2). Figure 2 shows the effect of acetylcholine on progenitor cells in rabbit retina. A one-day old rabbit retina is loaded with Fura-2. Images show responses to bath application of 200μM nicotine (Nic, left), which activates nicotinic acetylcholine receptors, or 100μM carbachol (CCh, right), which activates muscarinic acetylcholine receptors. Red indicates cells that had increases in intracellular calcium whereas blue indicates cells without increases in intracellular calcium.

The mAChRs are G-protein coupled receptors that lead to an increase in intracellular calcium via release of calcium from internal stores, as opposed to influx through ligand- or voltage-activated channels. Interestingly, the ACh released during retinal waves drives correlated mAChR-dependent calcium transients in undifferentiated cells of the ventricular zone (Fig. 2) (15). Hence, it is possible that ACh released by retinal waves induces signaling that is important for early phases of neurogenesis and for cell migration (17).

GABA

GABA is expressed in more cells during development than during adulthood, thus suggesting that it plays a transient role in circuit formation (18). During the first few postnatal days in rabbit, GABA displays a high transient expression in the ganglion cell layer. Moreover, the IPL of P0 ferret exhibits markers for enzymes involved in the synthesis of GABA (19).

During development, GABA initially serves to depolarize neurons. When activated, ionotropic GABA receptors, $GABA_A$ and $GABA_C$, flux chloride (Fig. 3A). Since the chloride concentration within developing retinal neurons is high due to low expression of the potassium-chloride co-transporter, KCC2, receptor activation leads to an efflux of negatively charged chloride ions through the open channels and thus causes depolarization of the cell (Fig. 3A, B left). KCC2 expression gradually increases during the first two weeks after birth in mice (20). Thus there is a 'switch' from excitation to inhibition as the reversal potential for chloride drops below the threshold for firing action potentials (Fig. 3 A, B right).

In turtle retina, the timing of the GABA switch correlates with a decrease in propagating spontaneous activity (21), suggesting that GABA depolarization plays a role in this propagation. In mammalian retina, GABA plays a minor role in correlated spontaneous activity during its excitatory period (1, 22, 23). However, after the GABA switch, GABA's inhibitory action takes on a prominent role in shaping spontaneous activity. Blocking $GABA_A$ receptors greatly increases the frequency of spontaneous retinal waves (22, 24).

What underlies the switch of GABA's action from depolarizing to hyperpolarizing? Several environmental factors, including neural activity (25), have been implicated in the timing of this switch in the retina. A recent study used acutely isolated retinas from knockout mice and pharmacological manipulations in retinal explants demonstrates that the timing of the GABA switch in retinal ganglion cells is unaffected by blocking specific neurotransmitter receptors or global activity (26) (Fig. 4). Purified retinal ganglion cells remain depolarized by muscimol for at least two weeks in culture (Fig 4, right), indicating that the GABA switch is not cell-autonomous. Purified ganglion cells co-cultured with other retinal neurons also remain depolarized by

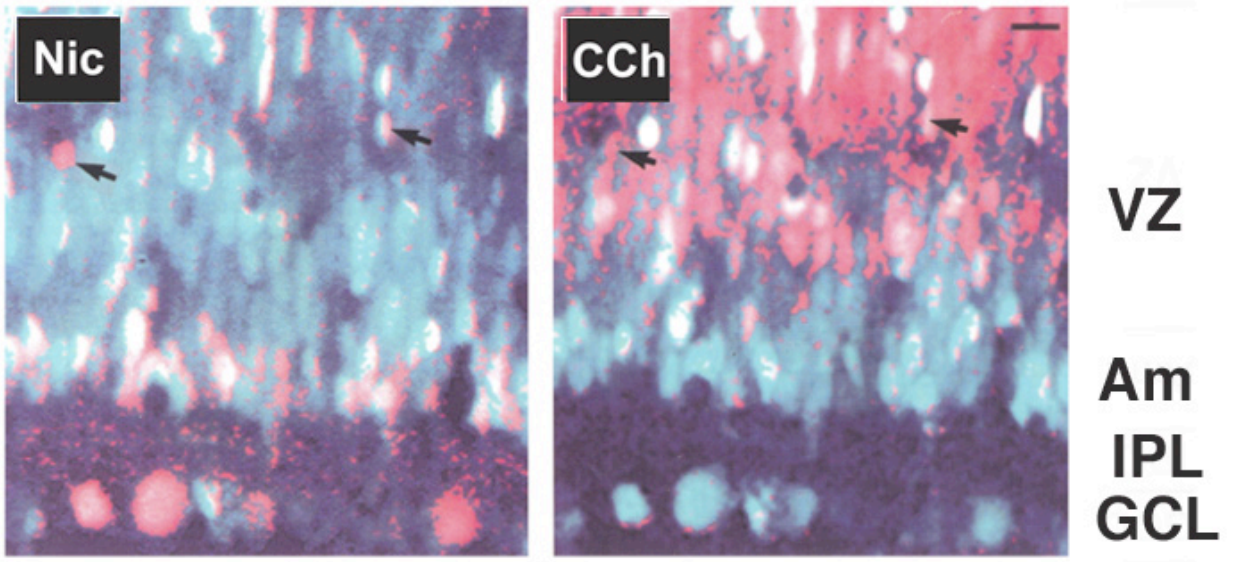

Figure 2. Acetylcholine acts on nicotinic receptors in ganglion and amacrine cells and on muscarinic receptors on progenitor cells. Adapted from Wong, 1995. VZ ventricular zone; Am, amacrine cell layer, IPL, inner plexiform layer; GCL, ganglion cell layer.

Figure 2. Acetylcholine acts on muscarinic receptors in progenitor cells and nicotinic receptors in ganglion and amacrine cells. Adapted from Wong et al, 1995 (16).

muscimol (Fig. 4, middle). However, culturing purified ganglion cells with dissociated cells from the superior colliculus (Fig. 4, right), or treating purified ganglion cells with media conditioned by superior colliculus cultures (Fig. 4C, red), results in a switch to inhibition by muscimol after two weeks in culture, indicating that a diffusible signal independent of local circuit activity regulates the maturation of GABAergic transmission.

Glutamate

Glutamatergic signaling is the last to develop within the IPL. Glutamate is released primarily from bipolar cells and a small subset of amacrine cells (27, 28). In mice, the axons of bipolar cells first express VGLUT1, the enzyme responsible for packaging glutamate into vesicles, around one week after birth (29). Although, ribbon synapses between bipolar cells axons and the dendrites of amacrine and ganglion cells do not form until 11 days after birth (5), glutamatergic currents can be measured before this (24, 29).

State-of-the-art transgenic and imaging techniques have characterized the distribution of glutamatergic synapses onto ganglion cells and between particular subtypes of bipolar and ganglion cells (30, 31). Before the functional maturation of bipolar cell ribbon synapses and long before the structural maturation of the ganglion cell dendritic arbor, adult-like patterns of glutamatergic synapses can be seen. However, between some subtypes of bipolar and ganglion cells, there appears to be an activity dependent remodeling of these synapses (30).

3. Spontaneously active synaptic circuits in the inner plexiform layer

Retinal Waves

Prior to photoreceptor maturation and eye opening, retinal ganglion cells periodically fire bursts of action potentials on the order of once per minute. This spontaneous rhythmic activity was first measured in fetal rat pups and was found to be highly correlated among neighboring ganglion cells (32).

Extracellular recordings using a multielectrode array (2) (Movie 1) and imaging of calcium transients (Movie 2) associated with bursts of action potentials (1, 33) have revealed that these spontaneous bursts propagate from one cell to the next in a wavelike manner. These retinal waves are an extremely robust phenomenon, observed in a large variety of vertebrate species, including chick, turtle, mouse, rabbit, rat, ferret and cat (34).

Retinal waves persist for an extended period throughout development as shown in Figure 5. However, as the retina matures, the circuitry underlying these retinal waves changes. Thus the wave generating circuits progress through three distinct stages, reflecting the nature of the connections and the cells that are involved (Fig. 5).

Embryonic waves

The earliest waves recorded in mammals are thought to be propagated via gap junctions. Retinal waves before embryonic day 23 in rabbit persist in the presence of antagonists to ionotropic GABA, glycine, ACh, and glutamate receptors, but are completely blocked by 18β-GA, a blocker of gap junction coupling (22). Similarly, mice prior to birth exhibit waves that are insensitive to chemical transmission antagonists (35). How waves are initiated and propagated during this early stage of development is still not clear. During the first week after birth in ferret and mouse, neurobiotin coupling between ganglion cells of the same subtype and amacrine cells has

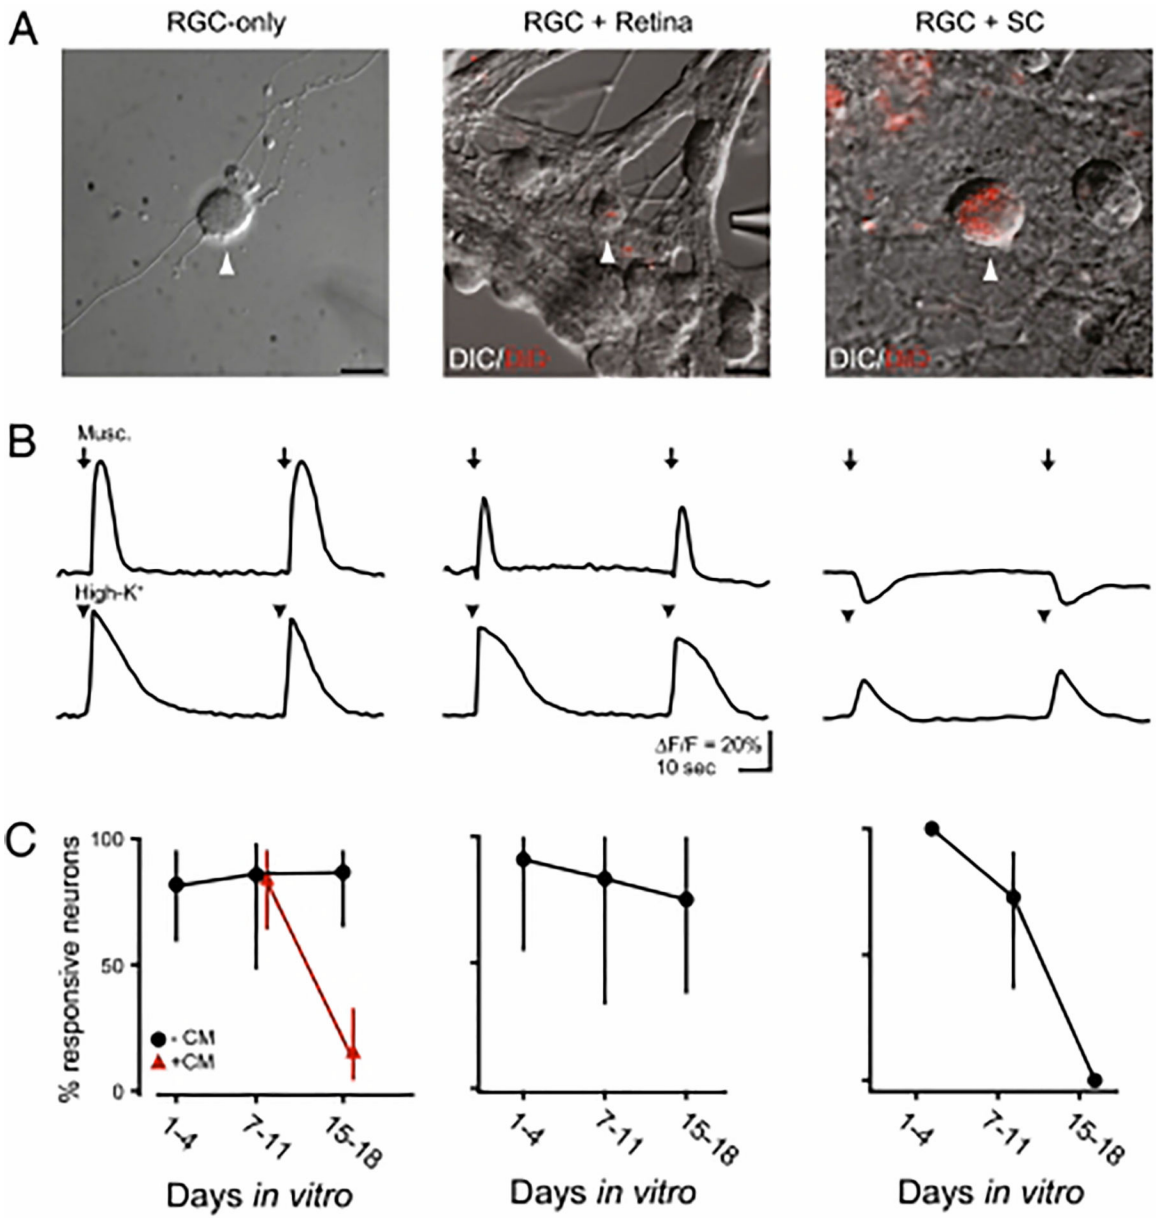

Figure 4. The GABA switch in retinal ganglion cells is due to a diffusible factor. From Barkis et al., 2010 (26).

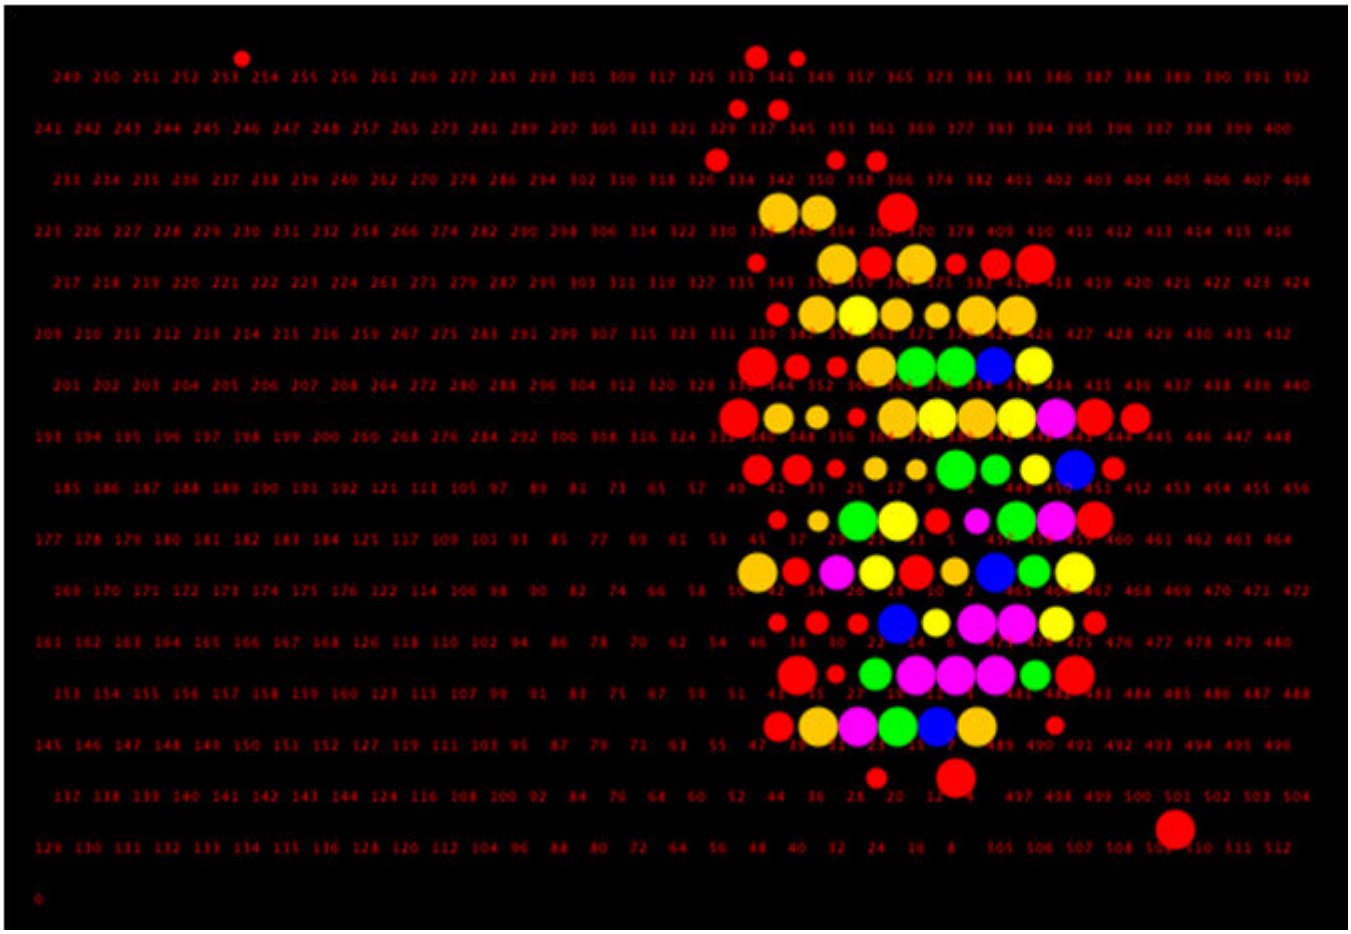
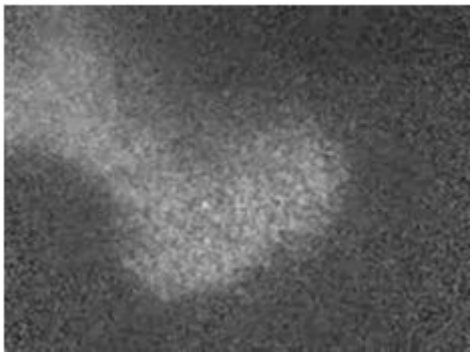
been seen (3, 36). However, ganglion cell coupling is initially weak and becomes stronger with age, while the correlations generated by waves become weaker with age (37). In addition, tracer coupling is found primarily between retinal ganglion cells of the same subtype and many other ganglion cells are not gap junction coupled. Thus, the issue of wave propagation in this early network still remains to be explored.

Neurotransmitters play a modulatory role during early stage waves. At the earliest ages studied in chick retina (E8-E11), wave frequency decreases in the presence of an ACh antagonist and increases with an ACh agonist but waves are not blocked. These waves are unaffected by $GABA_A$ and glutamate receptor antagonists (38). Similarly, embryonic waves in mouse are reduced in ACh receptor antagonists (35). In addition, in rabbit, early waves are blocked by the activation of $GABA_B$ receptors and are increased in frequency by the inhibition of these receptors (22).



Movie 1. Multi-electrode array recording of cholinergic waves. 512 electrode array recording from the mouse at 37°. Each dot represents multiunit activity recorded on an electrode at that site. The size of the dot is proportional to the amplitude of the signal, and the color is proportional to the frequency of the signal. Movie is at 5× normal speed. From Stafford et al, 2009 (43).



Movie 2. Calcium imaging of cholinergic waves. P3 mouse retina loaded with Oregon Green-Bapta-1AM. Playback 10x, size 800x600 μm (unpublished).

Cholinergic waves

Several experimental results show that chemical synaptic transmission is a prerequisite for cholinergic wave propagation. First, simultaneous whole cell voltage clamp recordings from ganglion cells demonstrate that increases in $[Ca^{2+}]_i$ correlated across cells are driven by compound synaptic inputs (1). Second, the compound postsynaptic currents measured from ganglion cells are blocked by bath application of Cd^{2+}, a blocker of

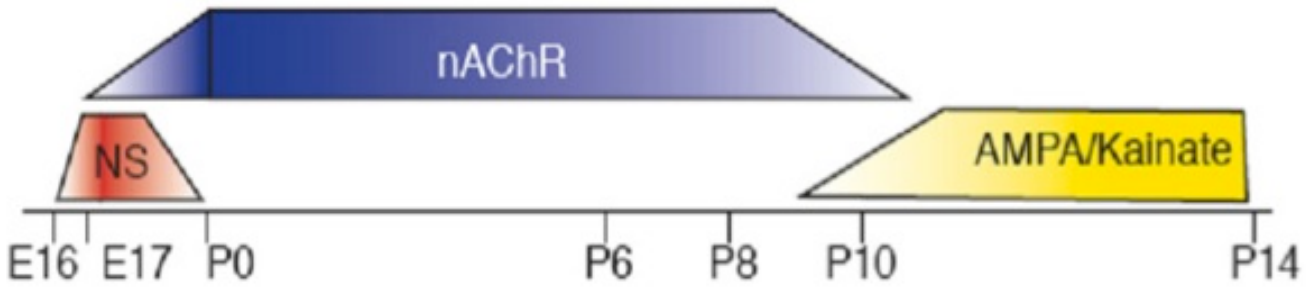


Figure 5. Retinal waves occur in three stages. Before birth in mice, waves are mediated by non-synaptic (NS) circuits. From around birth until 10 days after birth, waves are mediated by acetylcholine acting on nicotinic acetylcholine receptors (nAChRs). From 10 days after birth until the end of the second week, waves are mediated by ionotropic glutamate receptors. Modified from Bansal et al. 2000 (35).

calcium channels that are associated with transmitter release (1). Third, the periodic Ca^{2+} increases, action potentials, and compound postsynaptic currents associated with waves can all be blocked by a variety of nAChRs antagonists (1, 39). Finally, genetic deletion of the beta2 subunit of the nAChR receptor (35) or deletion of the enzyme responsible for synthesis of ACh (40) results in the disruption of normal waves during the first week after birth.

The spatiotemporal properties of cholinergic retinal waves have been well-characterized by fluorescence imaging of calcium indicators, which are reliable markers of cell depolarizations. Figure 6 schematizes these waves (41). Waves initiate in small clusters of coactive neurons and then propagate over spatially restricted areas of the retina. Initiation sites and wave boundaries are distributed randomly across a given retina, indicating that the global patterns of waves are not determined by fixed structures such as pacemaker cells or by repeated activation of the same clusters of neurons. Instead, the propagation boundaries of waves are determined in part by wave-induced refractory regions that last for 40-50 seconds. These observations have led to the hypothesis that every region of the retina is equally likely to initiate or propagate a wave, and therefore the global spatial patterns of waves are determined by the local history of retinal activity (Feller et al., 1997).

Recent studies in rabbit (Zheng et al., 2004; Zheng et al., 2006) and mouse (Ford et al. 2012) retina have revealed the cellular properties of starburst amacrine cells (SACs), the cell type that gives rise to cholinergic waves (Fig. 7) (42). Identifying SACs in mouse retinas was facilitated by the use of a line of mice in which GFP is expressed in SACs (mGluR2-GFP, Fig 7A). Using calcium imaging, spontaneous depolarizations of individual SACs were observed in the absence of synaptic excitation (Fig 7A), indicating that SACs themselves may be the source of initiation for waves. Paired recording between SACs revealed reciprocal cholinergic transmission (Fig 7C), indicating that waves are propagated via these slow, excitatory connections between neighboring SACs. Finally, wave boundaries are thought to arise from a slow after-hyperpolarization in the SACs that recovers over the course of tens of seconds following the depolarization during waves (Fig 7B).

Cholinergic waves may play a role in terminating early stage gap-junction mediated waves. Knock-out animals that lack nAChR receptor subunits still exhibit wave like activity under certain recording conditions, such as elevated temperature [alpha3(-/-) (35), beta2(-/-)(43, 44)]. This activity is likely mediated by gap junctions (44). Moreover, a study using a genetic model that eliminates ChAT in a large portion of the retina found normal cholinergic waves in the spared region, but compensatory waves in the region lacking ChAT (40). These studies suggest a sequential maturation of the retinal circuitry that relies on checkpoints to make transitions from one stage (gap-junction mediated waves) to the next (cholinergic transmission mediated waves). This sort of

checkpoint model of neuronal development (45) is further supported by the disassembly of the cholinergic network to make way for glutamatergic signaling (46).

Glutamatergic waves

The synaptic circuitry that drives retinal waves changes postnatally. Though retinal waves early in development require cholinergic neurotransmission, studies in older ferret, rabbit, and mouse indicate that waves become insensitive to cholinergic antagonists and can be blocked by glutamate receptor antagonists (35, 47, 48). This switch in the requisite transmitter occurs at the age that bipolar cells make their initial synaptic connections with ganglion cells and conventional synapses between amacrine and ganglion cells become morphologically mature and numerous. This timing suggests that perhaps waves are mediated by neurotransmitters only when the synapses are first forming.

Glutamatergic waves have distinct spatial and temporal features. Unlike cholinergic waves that drive correlations in all neighboring ganglion cells regardless of subtype, glutamatergic waves occur more frequently in OFF cells than in ON cells (49) (Fig. 8). Waves occur in rapid clusters separated by periods of silence lasting about one minute (24). Within clusters, there is a distinct pattern of firing where ON and OFF cells alternate in firing bursts of action potentials (50) (Fig. 8). These spatial and temporal features are significantly shaped by inhibitory circuits. Blocking ionotropic GABA receptors increases wave frequency (51). Blocking glycine receptors does the same but also eliminates the asynchronous firing between ON and OFF cells.

Similar to the transition from gap-junction to cholinergic waves, the onset of glutamatergic waves may play an active role in the disassembly of the cholinergic circuits (46). Mice lacking the vesicular glutamate transporter VGLUT1 lack glutamate release from bipolar cells. However, these mice still have retinal waves during the time that littermate control animals have glutamatergic waves. Interestingly, these waves in the VGLUT1 knockout mice are unaffected by glutamate receptor antagonists but are blocked by nAChR antagonists (24). Thus, glutamate signaling from bipolar cells seems necessary for dismantling the cholinergic network.

There is some evidence that the transitions between the different circuits that mediate waves are linked. Prior to birth waves are thought to propagate via gap-junctions between ganglion cells (Fig. 9A, left). From postnatal day 1-10 waves are propagated via SAC release of acetylcholine onto other SACs (Fig 9A, Middle, black box). Acetylcholine also depolarizes ganglion cells. During this period of development, the gap-junction signaling between ganglion cells is reduced (Fig 9A, Middle, red box). From P10-P15 bipolar cells release glutamate to propagate waves in a mechanism that is thought to involve spillover of glutamate to excite neighboring bipolar cells (Fig. 9A right, black box). Cholinergic signaling between SACs is reduced (Fig. 9A right, red box).

Genetic disruption of cholinergic or glutamatergic waves result in an extended action of the previous wave generating circuit (Fig. 9B). In wild type mice gap-junction mediated waves (gray) are followed by cholinergic waves (blue) starting at P0, then glutamatergic waves (green) at P10. In mice lacking the Beta2 subunit of the nicotinic acetylcholine receptor, gap-junction mediated waves persist until ~P8. In mice lacking vesicular glutamate transporter VGLUT1, cholinergic waves persist through the second postnatal week.

Gap junctions and waves

Gap junctions are thought to play a role in the generation of embryonic waves, as described above. At later ages in mammals, however, gap junctions also play a minor role in the propagation of retinal waves. Gap junction antagonists reduce or partially block retinal waves after birth in mice (36) and at later stages in rabbit (22) when waves depend critically on chemical transmission. However, these antagonists also have several non-specific effects so these results are inconclusive. A different approach is to study mice in which specific connexins are genetically deleted (Fig. 10). Knockouts of connexins 36 and 45, the two major gap junction forming connexins in the IPL, have normal wave propagation (Fig. 10 A) but the firing between waves at later stages is increased (Fig 10B). Glutamatergic waves and the firing between waves is eliminated by the application of bipolar cell

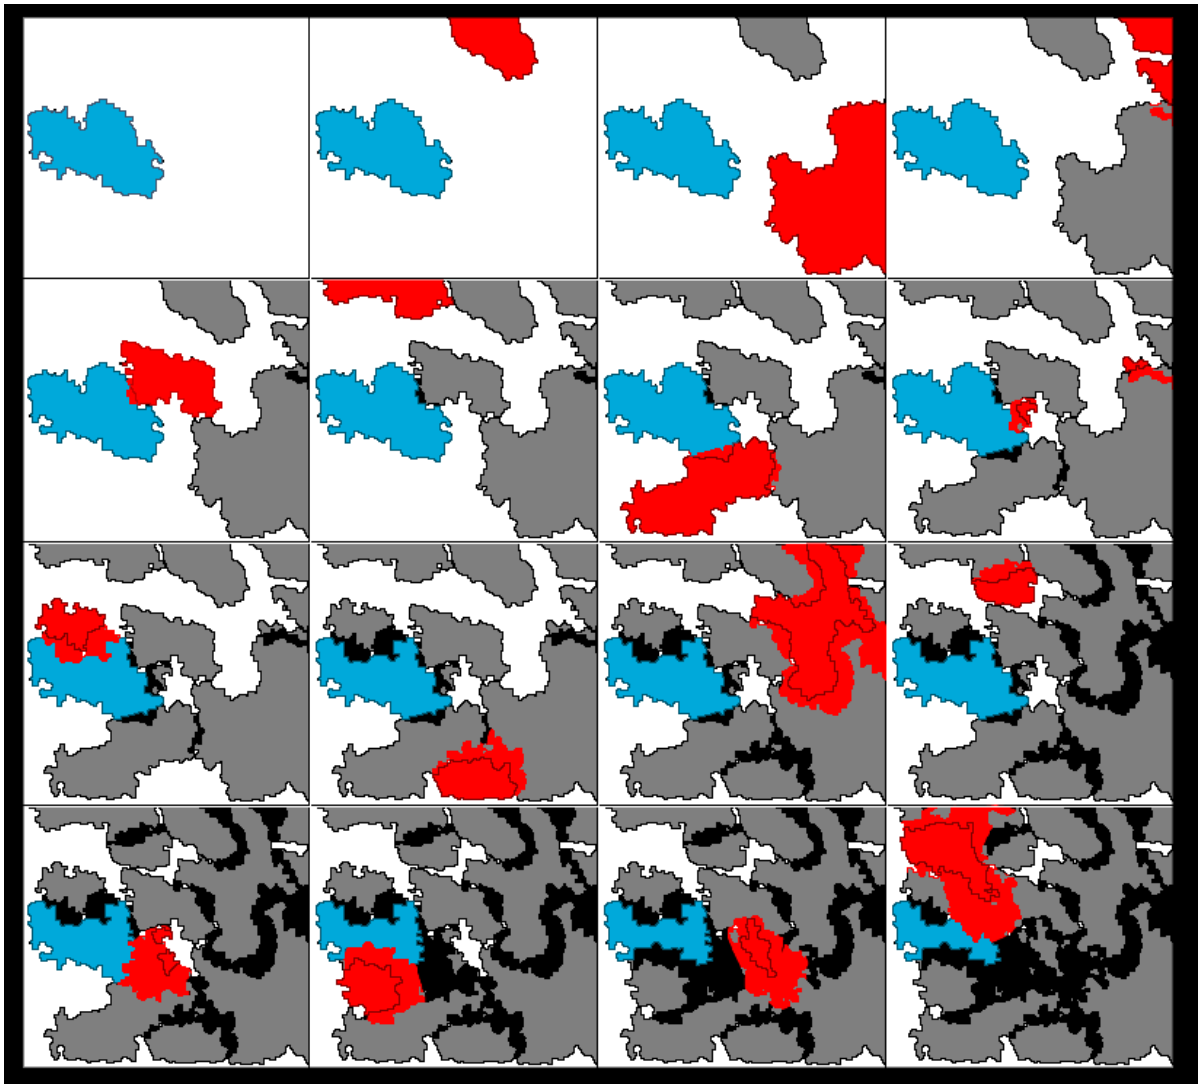

Figure 6. Cholinergic retinal waves tile the retina. Pictured is a sequence of retinal waves that were measured using calcium imaging in a P2 ferret retina loaded with the calcium dye fura-2AM (read from left to right, top row first). This analysis is used to show that a mosaic of waves is created by sequential waves to tile the entire retina. The blue figure in the first frame represents the total spatial extent of a single wave, which is termed a domain. The red domain in each frame corresponds to a new wave arising in the same region of retina monitored with fura-2 imaging. Gray shapes represent the regions of retina that previously supported a wave. Black corresponds to overlapping regions in which more than one wave occurs. This first domain remains blue through all of the subsequent frames to demonstrate that subsequent waves initiated within 10s of seconds of that first wave do not significantly invade its territory. The fact that almost the entire region is gray after 90 seconds indicates that the entire retina is tiled but that domain boundaries change constantly over time. The entire sequence corresponds to 90 seconds of recording. The total field of view is 1.2 x 1.4 mm. From Feller et al, 1997 (41).

synapse antagonists DNQX and AP5, indicating that bipolar input is important for the generation of waves as in wild type retinas (52).

In contrast, in the chick retina, gap junctions were found to be involved in wave generation at all ages. Octanol, a significant inhibitor of waves in E8 chick retina, restricts tracer coupling between ganglion cells and other cell types but not between ganglion cells themselves, indicating that the circuitry mediating these waves involves cells other than ganglion cells (38).

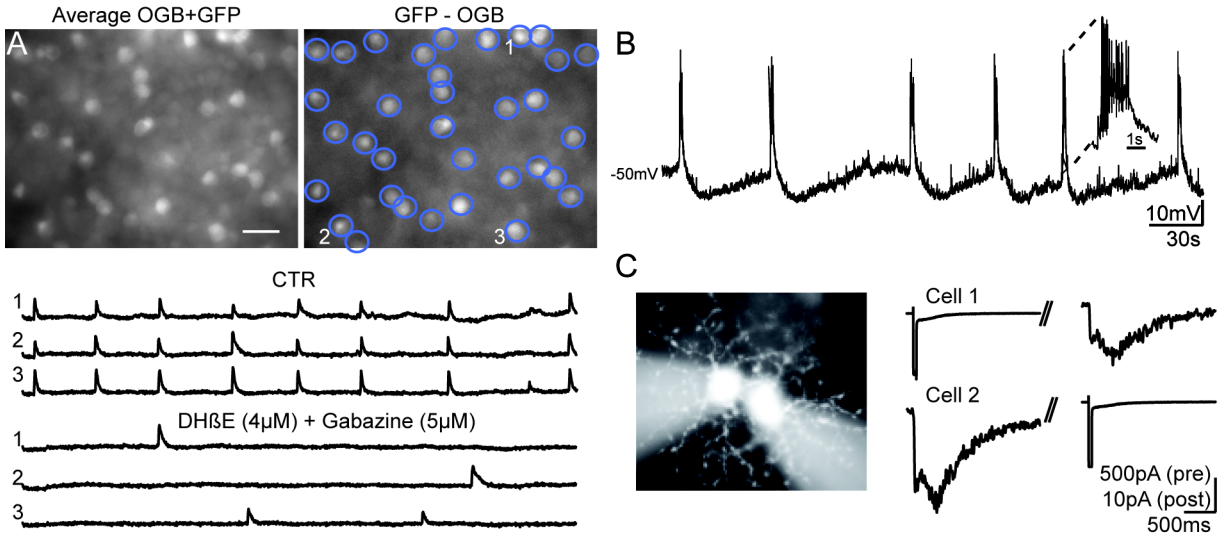

Figure 7. Cellular features of starburst amacrine cells underlie the spatiotemporal properties of retinal waves. (A) Fluorescence image of an mGluR2-GFP retina loaded with OGB. Right, Fluorescence image of GFP cells. Regions of interest are shown around each SAC. Scale bar, 20 µm. B, Time course of DF/F averaged over the somas of three cells (labeled in A) in the absence (CTR, top) and in the presence of nAChR antagonist DHβE (4µM) and GABA-A receptor antagonist gabazine (5µM) (bottom). (B) Current-clamp recording from a SAC showing wave evoked depolarizations followed by sAHPs. (C) Voltage-clamp recordings from pairs of neighboring SACs show both fast slow cholinergic postsynaptic currents. From Ford, Felix and Feller, 2012 (42)

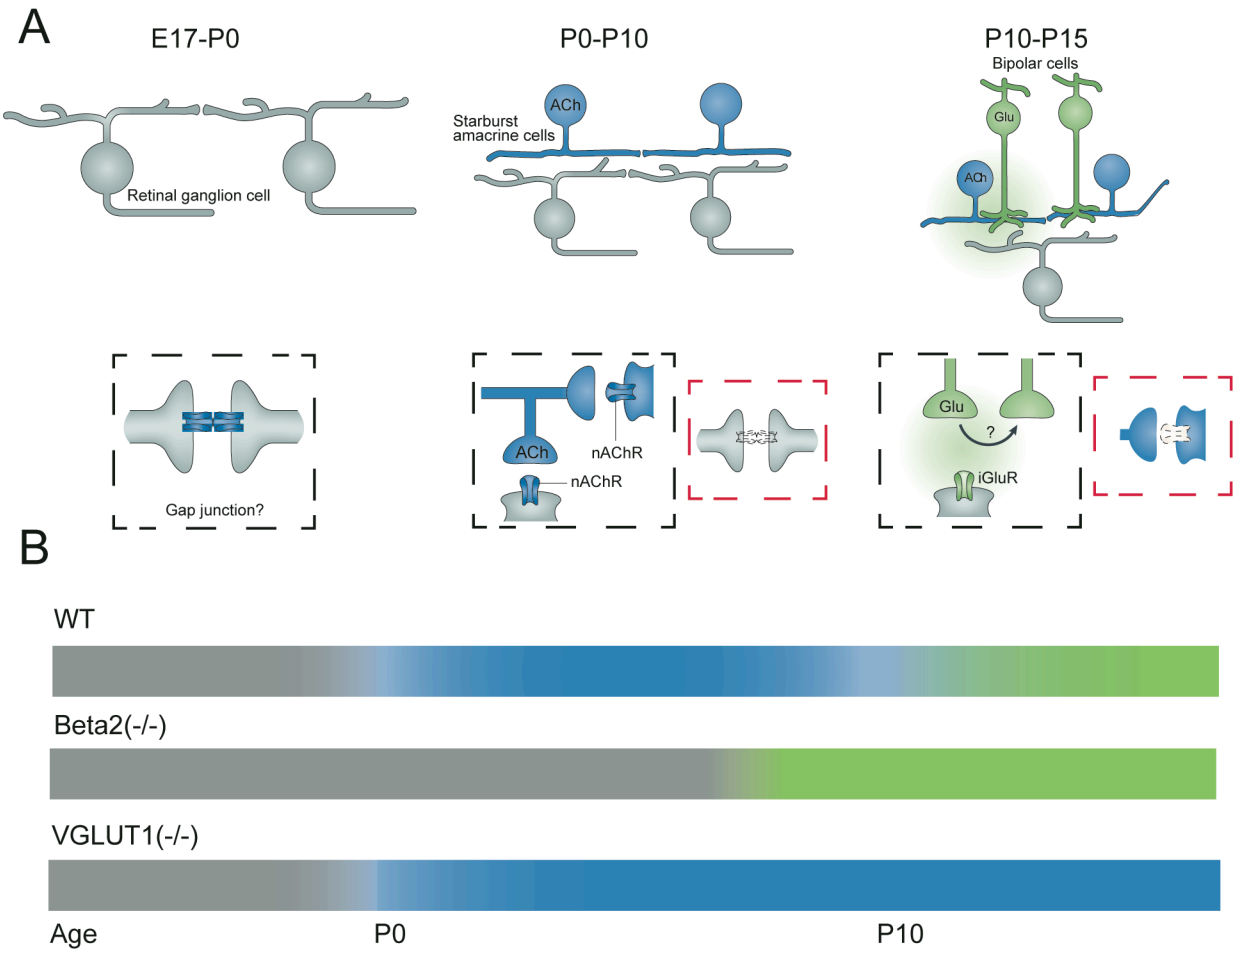

Figure 9. *A*. Transitions between waves stages are homeostatically regulated. Different circuits mediated waves at different ages. *B.* In wild type mice gap-junction mediated waves (gray) are followed by cholinergic waves (blue) starting at P0, then glutamatergic waves (green) at P10. In mice lacking the Beta2 subunit of the nicotinic acetylcholine receptor, gap-junction mediated waves persist until ~P8. In mice lacking vesicular glutamate transporter VGLUT1, cholinergic waves persist through the second postnatal week. From Ford and Feller, 2011 (72).

4. Role of activity in formation of visual circuitry

Spontaneous activity in the developing retina occurs while functional circuits are forming within the retina and projections from the retina are undergoing refinement at their target regions in the brain. What role do retinal waves play in sculpting the circuits that mediate vision?

ON/OFF circuitry within the retina

Two sub-circuits that have been well characterized in the adult retina are the ON and OFF pathways. The classes of bipolar cells that transmit responses to the onset of light (ON responses) are distinct from those that transmit responses to the cessation of light (OFF responses). These ON and OFF circuits have ganglion cell dendrites, amacrine cell processes and bipolar cell inputs that are physically segregated from each other into what are called the ON and OFF layers of the IPL. The formation of these ON or OFF circuits involves the dendritic maturation of ganglion cell types.

The dendrites of most retinal ganglion cells arborize diffusely within the IPL before restricting their dendrites to distinct lamina (35, 53-57) (Fig. 11). Some studies have suggested that this segregation of ganglion cell dendrites into ON and OFF layers involves bipolar cell activity. First, this segregation is prevented by applying APB to

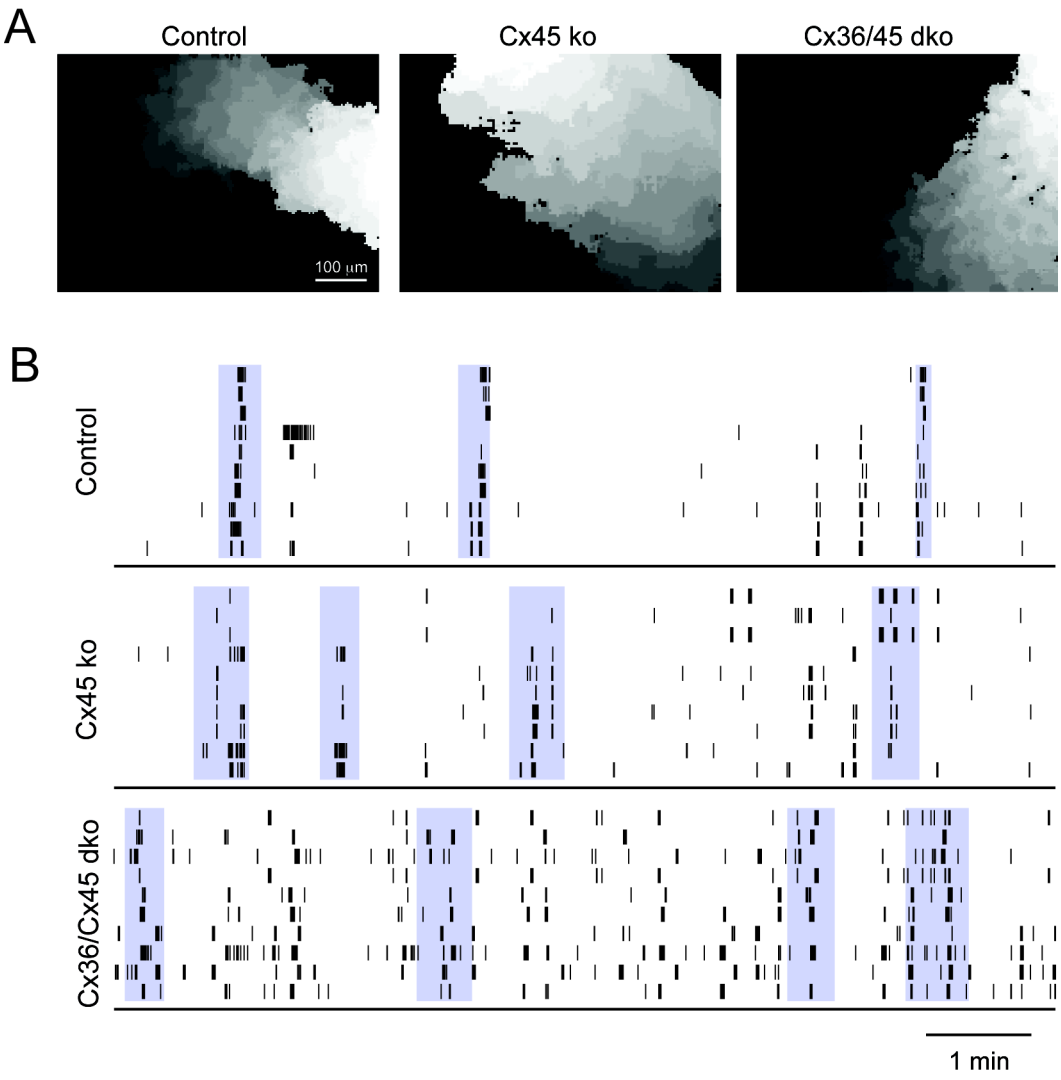

Figure 10. Spatiotemporal properties of retinal waves are similar in control, Cx45, and Cx36/45 double knockout mice. A, Examples of waves recorded in different genotypes. Each grayscale value represents an active area in one frame, with darker shades corresponding to later points in time during the wave. B, Raster plot of ganglion cell action potentials taken from multi-electrode array recordings from different genotypes. Correlated firing during wave events are shown in blue. From Blankenship et al. 2011 (52).

hyperpolarize ON bipolar cells during the period of glutamatergic retinal waves (Fig. 12) (58, 59). Second, mice that lack the MHCI receptor CD3zeta, and thus display altered glutamatergic retinal waves, have ganglion cells with reduced dendritic motility and more diffuse dendrites within the IPL (60) (Fig. 11). However, not all manipulations of spontaneous retinal activity during development alter dendritic stratification. Preventing synaptic release of glutamate from ON bipolar cells by expressing tetanus toxin does not prevent the stratification of ganglion cell dendrites, but it does reduce synapse formation onto the ON bipolar cells (30).

Is there a role for cholinergic waves in this ganglion cell stratification process? Several studies suggest that there is. First, blocking nAChRs during the period of cholinergic waves reduces the motility of filipodia on the dendrites of ganglion cells (61), demonstrating that cholinergic waves can drive structural changes in dendrites. Second, studies in turtle demonstrate that blocking cholinergic waves with nAChR antagonists reduces receptive field sizes (62). Finally, mice lacking the beta2 subunit of the nAChR exhibit a delay in, but not an absence of, the fine stratification of ganglion cell dendrites (35). These findings indicate that cholinergic waves do influence the outgrowth of ganglion cell dendrites but they are not the primary factor that dictates their final organization.

Refinement of retinal projections

Retinal axons undergo a period of refinement before vision begins. At birth in mice, axons from both eyes reside in overlapping regions of the dorsal lateral geniculate nucleus of the thalamus. By about two weeks after birth, the axon terminals from the ganglion cells of each eye separate into non-overlapping regions. Similarly, within the superior colliculus, retinal axons at birth extend over the entire area of the colliculus. However, over the course of about one week, these axons retract to their appropriate retinotopic regions and extensively arborize within a small target zone. These processes of eye-specific segregation and retinotopic map refinement occur during the period of retinal waves. Thus, the hypothesis has emerged that waves might provide cues within their activity pattern to instruct these developmental processes.

The refinement of retinal projections to the brain is thought to be driven by the precise initiation, propagation and termination properties of cholinergic waves (63). The periodic initiation of waves induces depolarizations and calcium transients that may be tuned to drive axon guidance (64, 65) and plasticity mechanisms (66, 67). Propagation speed sets the time scale over which neighboring cells are correlated, and thus may be critical for retinotopic map refinement (68). The spatial extent of wave propagation has been shown to be important for establishing eye-specific segregation of retinal inputs within the thalamus (69).

Retinal waves determine the final size of termination zones of retinal projections to the superior colliculus (SC, Figure 13A). Focal labeling of retinal ganglion cells using DiI labels in retina (Retina) gives small target zones in superior colliculus (WT, Fig. 13A, left). In knockout mice lacking normal cholinergic waves (β2-nAChR KO, Fig. 13A middle), termination zones are less compact. Rescue of the β2-nAChR gene in a subset of retinal cells (Fig. 13 β2 tg) produce small waves, which are sufficient to rescue normal retinotopic map refinement.

Retinal waves also play a role in eye-specific segregation of retinal ganglion cell projections to the lateral geniculate nucleus of the thalamus (Fig. 13b). In wild type mice, there is little overlap between ipsi- and contra-lateral projections. Mice lacking cholinergic waves (β2 KO) and mice with small waves (β2 tg) have significantly overlapping projections from either eye.

Retinal waves also play a role in eye-specific segregation of retinal ganglion cell projections to the lateral geniculate nucleus of the thalamus (Fig. 13b). In wild type mice, there is little overlap between ipsi- and contra-lateral projections. Mice lacking cholinergic waves (β2 KO) and mice with small waves (β2 tg) have significantly overlapping projections from either eye.

5. Conclusion

The neural circuits within the inner plexiform layer are highly organized, making them an ideal system for the study of circuit formation. Understanding how this organized structure and intricate connectivity arise during development is an important endeavor. It is clear that on the path to forming the circuits that mediate vision, the retina creates a series of intermediate circuits that generate spontaneous activity. These transitory circuits are then dismantled as the retina matures. During their brief existence, these transient networks play an important role in shaping the circuits both within the retina and from the retina to the brain.

A wealth of new tools will lead the way to a greater understanding of how these neural circuits develop. Several recent studies have identified lines of mice with GFP or Cre recombinase expression that is restricted to specific classes and even to subsets of retinal neurons. The ability to identify and alter the activity of specific components of a neural circuit will allow future experimentalists to observe how these circuits form and to ask what role spontaneous activity plays in their formation.

About the Authors

Dr. Kevin Ford received his B.S. in Biology from UC San Diego in 2005. He did his graduate work with Marla Feller first at UC San Diego and then UC Berkeley, receiving his Ph.D. in Molecular and Cell Biology from UC Berkeley in 2011. During his graduate career, he researched the cellular mechanisms underlying retinal waves in the developing mouse retina. He is still in Marla's laboratory at Berkeley.

Dr. Marla Feller received her B.A. and Ph.D. in Physics from University of California at Berkeley in 1985 and 1992 respectively. She was a postdoctoral researcher with at Bell Laboratories with Dr. David Tank (1992-1994) and then at UC Berkeley with Dr. Carla Shatz (1994-1998). She headed a laboratory at the National Institutes of Neurological Disorders (1998-2000), was at UC San Diego (2000-2007) and is now at UC Berkley Neuroscience as an Associate Professor of Neurobiology. She has done research in the elucidating the circuits that mediate retinal waves and also in what role retinal waves play in the establishment of retinal projections to the brain. Currently Marla is investigating the mechanisms underlying the generation of this highly patterned activity and exploring the role it plays in the development and shaping of ganglion cell responses, particularly those generated by a cholinergic amacrine cell network.
